No courier is looked for yet. A courier sent to a restaurant that then turns the order down has wasted a trip, so the delivery is created when the kitchen accepts, in the same transaction:

```
/// The kitchen takes an order: it says how long it needs, and the order's
/// delivery starts looking for a courier in the same transaction.
public OrderDto accept(String actor, String restaurantId, String id, int prepMinutes)
        throws IOException {
    if (prepMinutes < 1 || prepMinutes > 180) {
        throw new ResponseStatusException(400, "Say how many minutes it needs");
    }
    attempt(() -> accepted(actor, restaurantId, id, prepMinutes));
    tell(find(id));
    // Once committed, as an offer is always made: a courier asked from
    // inside the transaction could be shown an order that then rolled back.
    deliveries.search(id);
    return view(actor, false, id);
}

@Transactional
private Void accepted(String actor, String restaurantId, String id, int prepMinutes)
        throws IOException {
    CustomerOrder order = kitchens(restaurantId, id);
    if (orders.accept(id, OrderStateMachine.sources(OrderState.ACCEPTED),
            OrderState.ACCEPTED, prepMinutes, Instant.now()) != 1) {
        throw new ResponseStatusException(409, "That order is "
                + describe(order.getState()));
    }
    events.record(id, OrderState.ACCEPTED, actor);
    deliveries.dispatch(find(id), restaurants.findById(restaurantId));
    return null;
}
```

```
/// Creates the delivery for an order the kitchen has just accepted, with the
/// order's id, from the restaurant to the order's door. Runs inside the
/// transaction that accepts the order, so the two commit together; [#tick]
/// finds the delivery a courier from then on, while the kitchen cooks.
///
/// The courier is paid the delivery fee and the tip, so that is the fare a
/// courier is offered.
public void dispatch(CustomerOrder order, Restaurant restaurant) throws IOException {
```

```
    long now = System.currentTimeMillis();
    Delivery delivery = new Delivery();
    delivery.setId(order.getId());
    delivery.setState(DeliveryState.REQUESTED);
    delivery.setCustomer(order.getCustomer());
    delivery.setCourier("");
    delivery.setPickupLat(restaurant.getLat());
    delivery.setPickupLng(restaurant.getLng());
    delivery.setPickupAddress(address(restaurant.getName() + ", " + restaurant.getAddress()));
    delivery.setDropoffLat(order.getDropoffLat());

    delivery.setPaymentStatus(order.getPaymentStatus());
    delivery.setNote(order.getNote());
    delivery.setRequestedAt(Instant.ofEpochMilli(now));
    delivery.setUpdatedAt(Instant.ofEpochMilli(now));
    delivery.setSearchUntil(Instant.ofEpochMilli(now + searchMillis));
    deliveries.insert(delivery);
    event(order.getId(), DeliveryState.REQUESTED, "");
}
```

The delivery shares the order's id, so either side can find the other without a join table. From then on the couriers are asked while the kitchen cooks, and the order follows its delivery: the courier collecting the food moves the order to `PICKED_UP`, and only from `READY`, so nobody leaves with an order the kitchen has not finished; the delivery completing moves the order to `DELIVERED`. A delivery that finds no courier ends the order with `NO_COURIERS` and lets the hold go.

Every move of either state is a conditional update that names the states it may come from, so two answers at the same moment can't both win — a customer cancelling while the kitchen accepts, or two couriers taking one offer. It's the pattern Section 51.6.1, "Two answers at the same moment" explains:

```
private boolean tryMove(String id, DeliveryState to, String actor, String ownerField,
        String newCourier, Long newOfferExpiresAt) throws IOException {
    DeliveryState[] sources = DeliveryStateMachine.sources(to);
    if (sources.length == 0) {
        return false;
```

```
    }
    Instant now = Instant.now();
    int moved;
    if (newOfferExpiresAt != null) {
        moved = deliveries.offer(id, sources, to, now, newCourier,
                Instant.ofEpochMilli(newOfferExpiresAt.longValue()));
    } else if (CUSTOMER.equals(ownerField)) {
        moved = deliveries.moveAsCustomer(id, sources, to, now, actor);
    } else if (!COURIER.equals(ownerField)) {
        moved = deliveries.moveByServer(id, sources, to, now);
    } else if (newCourier != null) {
        moved = deliveries.giveBack(id, sources, to, now, actor, newCourier);
    } else if (DeliveryState.ACCEPTED == to) {
        // An offer that has lapsed cannot be taken, even in the moment
        // before the sweep takes it back.
        moved = deliveries.takeOffer(id, sources, to, now, actor);
    } else {
        moved = deliveries.moveAsCourier(id, sources, to, now, actor);
    }
    if (moved != 1) {
        return false;
    }
    event(id, to, actor);
    return true;
}
```

53.4. Hold now, charge on arrival

A rider pays at the end of a ride, for a fare known by then. A customer pays for food before anyone cooks it, but shouldn't be charged for an order that never arrives. The card is therefore authorized for the total when the order is placed and captured when it's delivered:

```
/// Holds an order's total on the customer's card as the order is placed,
/// with no transaction open. Nothing is taken until the order arrives
/// ([#settle]); an order that never does lets the hold go ([#release]).
///
/// @return the hold's reference, or [#CASH] for an order paid in cash
/// - `ResponseStatusException` 402: when the card was refused
public String authorize(String orderId, String username, String methodId, long amountCents,
        String currency) throws IOException {
    if (CASH.equals(methodId)) {
        return CASH;
    }
    String[] references = chargeable(username, methodId);
    if (references == null) {
        throw new ResponseStatusException(402, "The card is no longer on the account");
    }
    try {
        return cut(provider.authorize("order-" + orderId, references[0], references[1],
                amountCents, currency, "Savor order"), 64);
```

```
    } catch (PaymentDeclinedException declined) {
        throw new ResponseStatusException(402, declined.getMessage());
    } catch (IOException unknown) {
        throw unavailable("card check", unknown);
    }
}
```

The provider interface Wayline's billing chapter describes gained the two calls that make it possible, `authorize` and `capture`, and a `release` for a hold that is let go:

```
public interface PaymentProvider {
    /// `simulated` or `stripe`: what the app is told, so it knows how to add a
    /// card.
    String name();

    /// Opens the processor's record of a customer and returns its reference.
    String createCustomer(String username, String displayName) throws IOException;

    /// Deletes the processor's record of a customer, and the cards saved to it
    /// with it. A record that is already gone is deleted: this is asked again
    /// when the first answer was lost.
    void forgetCustomer(String customer) throws IOException;

    /// Begins saving a card to `customer`. `setupId` is the server's own id
    /// for the attempt, for the processor to hand back.
    Setup startCardSetup(String customer, String setupId) throws IOException;

    /// Finishes a setup and returns the card it saved.
    ///
    /// @param reference what [#startCardSetup] returned as the setup's reference
    /// @param typed the card as typed into the app, for a processor whose setup
    ///     is not hosted; ignored by one whose setup is
    /// - `PaymentDeclinedException`: when the card was refused or the setup was
    ///   not finished
    Card finishCardSetup(String customer, String reference, CardDto typed) throws IOException;

    /// Takes a saved card off `customer`, so that it can't be charged again.
    /// A card that is already off, or gone, is detached: this is asked again
    /// when the first answer was lost.
    ///
    /// @param token what [#finishCardSetup] returned as the card's token
    void detachCard(String customer, String token) throws IOException;

    /// Charges a saved card with its owner absent.
    ///
    /// @param key names this charge and no other. A processor asked twice with
    ///     the same key charges once, so a request repeated after a timeout
    ///     cannot take the money twice.
    /// @return the processor's reference for the charge
    /// - `PaymentDeclinedException`: when the card was refused
    /// - `IOException`: when the processor could not be asked
    String charge(String key, String customer, String token, long amountCents, String currency,
            String description) throws IOException;
```

```
    /// Returns `amountCents` of a charge to the card it came from.
    ///
    /// A processor may take the refund and only later say whether the bank
    /// returned the money: such a refund comes back [Refund#pending], and is
    /// asked about with [#refundStatus] until it has an answer.
    ///
    /// @return the refund as the processor took it
    /// - `IOException`: when the processor could not be asked, or refused the
    ///   refund outright
    Refund refund(String chargeReference, long amountCents) throws IOException;

    /// What became of a refund that was [Refund#pending]: [#REFUND_SUCCEEDED],
    /// [#REFUND_PENDING] while the processor still does not know, or
    /// [#REFUND_FAILED] when the money did not go back.
    String refundStatus(String refundReference) throws IOException;
    /// Holds `amountCents` on a saved card without taking it, for an order
    /// that is paid for only once it arrives. Keyed as [#charge] is.
    ///
    /// @return the processor's reference for the hold, for [#capture] or [#release]
    /// - `PaymentDeclinedException`: when the card was refused
    String authorize(String key, String customer, String token, long amountCents,
            String currency, String description) throws IOException;
    /// Takes `amountCents`, at most what was held, from a hold. A hold that was
    /// already captured is captured: this is asked again when the first answer
    /// was lost.
    void capture(String reference, long amountCents) throws IOException;
    /// Lets a hold go, so the money is the cardholder's again. A hold that is
    /// already let go is released.
    void release(String reference) throws IOException;
```

- **Placed:** `Payments.authorize` holds the total. A refused card answers 402 and nothing is written. An order that couldn't be written lets its hold go at once.
- **Rejected or cancelled:** `Payments.release` lets the hold go. Nothing was taken, so there is nothing to refund.
- **Delivered:** `Payments.settle` captures the hold. A capture can still fail — a hold expires, or a bank declines then — and the receipt then says so, for an administrator to follow up.
- **After delivery:** a tip is a charge of its own; a refund, full or partial, is made against the captured payment.

The receipt is kept with the delivery. Before a delivery exists, a customer's receipt is built from the order itself and shows the hold.

With Stripe, a hold is a PaymentIntent created with manual capture. Card holds expire after about seven days, far longer than any meal takes. Turning Stripe on, and the hosted page that keeps a card number away from the server, are exactly as Section 51.13, "Billing" describes.

53.5. Restaurants near the door

A rider is matched to the nearest driver. A customer chooses a restaurant, from the ones that

deliver to their door. The search takes a box around the point from the database and then measures each restaurant in it, as Wayline does to find the drivers near a pickup:

```
/// The approved restaurants that deliver to a point, filtered by cuisine and
/// by a word in the name, the cuisine or a dish, and sorted.
@Transactional(readOnly = true)
public List<RestaurantSummaryDto> nearby(String viewer, double lat, double lng,
        String cuisine, String text, String sort) throws IOException {
    if (!Geo.isPoint(lat, lng)) {
        throw new ResponseStatusException(400, "Choose where to deliver to");
    }
    double straight = Quotes.MAX_METERS / Quotes.ROAD_FACTOR;
    double dLat = straight / Geo.METERS_PER_DEGREE;
    double dLng = dLat / Math.max(0.01d, Math.cos(Math.toRadians(lat)));
    List<Restaurant> box = restaurants.inBox(APPROVED, lat - dLat, lat + dLat, lng - dLng,
            lng + dLng);
    String word = text == null ? "" : text.trim();
    Set<String> dishMatches = word.length() == 0 ? Collections.<String>emptySet()
            : dishMatches(box, word);
    Set<String> kept = favoriteIds(viewer);
    PricingDto pricing = quotes.pricing();
    int minute = quotes.minuteOfDay(System.currentTimeMillis());
    List<RestaurantSummaryDto> out = new ArrayList<RestaurantSummaryDto>();
    for (int iter = 0; iter < box.size(); iter++) {
        Restaurant restaurant = box.get(iter);
        if (cuisine != null && cuisine.length() > 0
                && !cuisine.equalsIgnoreCase(restaurant.getCuisine())) {
            continue;
        }
        if (word.length() > 0 && !contains(restaurant.getName(), word)
                && !contains(restaurant.getCuisine(), word)
                && !dishMatches.contains(restaurant.getId())) {
            continue;
        }
        double meters = Quotes.roadMeters(restaurant.getLat(), restaurant.getLng(), lat, lng);
        if (meters > Quotes.MAX_METERS) {
            continue;
        }
        out.add(summary(restaurant, meters, pricing, minute,
                kept.contains(restaurant.getId())));
    }
    sort(out, sort);
    return out;
}
```

Couriers are found the same way, near the restaurant rather than the customer, because the restaurant is where they go first.

53.6. Prices

`order/Quotes` prices a cart, and does so on the server alone: the app shows the quote it’s given and

sends only the dishes, their choices, the promo code and the tip. The total is:

- The food, from the menu as it's when the order is placed, with each dish's choices checked against its groups' minimum and maximum.
- The delivery fee, a base plus a price per kilometer by road from the restaurant, times a surge an administrator can raise.
- A service fee, a percentage of the food.
- A flat small-order fee for food under a threshold.
- Tax, a percentage of the food after the discount.
- A promo code's discount, once per account.
- The tip.

An administrator sets the fees, the commission and the tax under **Pricing**. The commission is what the service keeps of the food; the merchant's sales show the rest.

53.7. Merchants

Applying to list a restaurant creates it waiting for approval, owned by the account that asked:

```
/// Asks for a restaurant to be listed. It waits, unseen by customers, for
/// an admin to approve it; the applicant then joins its staff and gets the
/// merchant role. One application at a time per account.
@Transactional
public RestaurantDto apply(String username, RestaurantEditDto form) throws IOException {
    // Two submissions at once would both find no application below and
    // both insert one; holding the profile first makes the second wait
    // and then see the first.
    profiles.hold(username);
    Restaurant last = restaurants.findFirstByApplicantOrderByCreatedAtDesc(username);
    if (last != null && !Catalog.REJECTED.equals(last.getStatus())) {
        throw new ResponseStatusException(409, Catalog.PENDING.equals(last.getStatus())
                ? "Your application is waiting for review" : "You already have a restaurant");
    }
    Restaurant restaurant = new Restaurant();
    restaurant.setId(Ids.next());
    restaurant.setStatus(Catalog.PENDING);
    restaurant.setApplicant(username);
    restaurant.setReason("");
    restaurant.setPhotoId("");
    long now = System.currentTimeMillis();
    restaurant.setCreatedAt(Instant.ofEpochMilli(now));
    restaurant.setUpdatedAt(Instant.ofEpochMilli(now));
    fill(restaurant, form);
    restaurants.insert(restaurant);
    return catalog.detail(restaurant, username, 0d, 0d, true);
}
```

Approving it grants the account the `merchant` role. Everything a merchant does is under

`/api/merchant/restaurants/{id}/⋯`, and each request checks that the account is a merchant of that restaurant, so one restaurant's staff can't read another's orders. The rules are in the same table as the rest of the server's:

```
.authorizeHttpRequests(auth -> auth
        .requestMatchers(AntPathRequestMatcher.antMatcher("POST",
                "/api/account/register")).permitAll()
        .requestMatchers("/api/courier/**").hasRole(Roles.COURIER)
        .requestMatchers("/api/admin/**").hasRole(Roles.ADMIN)
        .requestMatchers("/api/merchant/**").hasRole(Roles.MERCHANT)
        .anyRequest().authenticated())
```

The merchant's screen is built on the operations console's `Console`, so it's a list beside a detail on a wide screen and a list that opens a screen per order on a phone. A new order reaches it as a frame on the live channel, which makes it read the queue again: the frames say what changed, never the data, as in Wayline.

Menu photographs are uploaded the way couriers' documents are, stored by the server and served from it, so the seed data carries its own photographs rather than pointing at someone else's site.

53.8. Simulated kitchens and couriers

A development server simulates the two people a customer would otherwise wait for. `order/DemoKitchen` accepts, cooks and readies the orders of each restaurant that has no merchant, and `delivery/DemoFleet` takes deliveries while no real courier is online. Both are on only for the development profile, the way the simulated cards are: the test profile turns them off, because the tests play the kitchen and the courier themselves. A restaurant with a merchant is left to its staff, and the simulated courier stands aside while a real one is online.

53.9. Tests

```
mvn -pl shared,backend -Dcodename1.platform=backend test
mvn -pl shared,backend -Dcodename1.platform=backend test -Dcn1.backend.compiledTests=true
./run-e2e.sh
./run-web-e2e.sh
```

The backend tests run the server on the JVM and then compiled, against the order and delivery state machines, the holds and captures, the quotes and promo codes and who may call what. `run-e2e.sh` starts a server on the test profile and drives the app in the simulator through every role — an order placed, accepted, collected and delivered, a card held and charged, a tip and a refund — taking the screenshots in the user's guide. `run-web-e2e.sh` does the same for the app in a browser.

53.10. Making it yours

The ways to make Wayline your own apply here too: the name, icon and colors, the languages, the text-message and push providers, the database, hosting. A few apply to food in particular:

- **One restaurant or a small chain.** Ordering and delivery under the restaurant's own name, which Section 53.11, "Making it yours: A restaurant's own delivery service" describes.
- **Pickup.** An order with no delivery is one the kitchen hands over itself. Mark the order as collected, skip `dispatch` when the kitchen accepts it, and let the merchant move it from `READY` to `DELIVERED`, which captures the hold.
- **Scheduled orders.** Store the time the customer wants the food, and accept the order for the kitchen only when its preparation time before that's reached.
- **Before it's a product.** A real service needs restaurant payouts, tax rules for the places it sells in, menus that change by the hour, allergens and age checks. None of them are in the sample.

53.11. Making it yours: A restaurant's own delivery service

A marketplace takes a share of every order and keeps the customer. A restaurant, or a chain of a few, that runs its own ordering and delivery keeps both: the app carries its name, the customers' accounts and order history are its own, and the couriers are its staff or a courier company it contracts. Savor is most of that service already. What changes is that there is one brand instead of many, and nobody applies to sell. This section says what to change, and the class each change belongs in.

53.11.1. One brand, one or a few kitchens

A chain is a restaurant row per branch, each with its own address, hours, preparation time and menu. Seed them in place of `catalog/DemoRestaurants`, or create them through the admin console. Nothing else in the catalog changes: `Catalog.nearby` already answers the branches that deliver to the customer's door, nearest first, and the order goes to the branch the customer picked.

The customer's first screen changes. With one kitchen, open its menu instead of the list: where `Nav.build` makes the customer's home, call `RestaurantForm.show` with the restaurant's id. With a few, keep the list, which is now a list of branches, and drop the row of cuisines and the sort above it in `CustomerForm`, which only make sense for many restaurants.

The name, the icon and the colors are the ones Section 53.1, "Running it" and Wayline's chapter describe. Use the restaurant's own photographs: replace the files in `backend/photos`, which the development server reads into the database the first time it starts, and name them in the seed. In production, upload them from the merchant's menu editor.

53.11.2. Nobody applies to sell

Restaurants no longer join, so close that door:

- Remove the restaurant applications from the server's rules and from `Restaurants`: `apply`,

`application` and `applicationPhoto`. The admin's **Applications** pane then lists couriers only.

- Set the commission to zero under **Pricing**, or with `savor.fee.commissionPercent=0`. The commission is what a marketplace keeps of the food; a restaurant selling its own food keeps it all, and the merchant's sales should say so.
- Make each branch's staff merchants of their branch from the admin console. A merchant account works on one restaurant, the one `Restaurants.mine` finds. An owner who watches several branches needs a branch picker on `MerchantForm` and the restaurant's id in the merchant's calls in place of `mine`.

53.11.3. Couriers of its own

A restaurant's couriers are known people, so the courier side works unchanged, with the application step done by an admin. Approve couriers from **Applications**, or give the role straight from **People**, and remove **Deliver with Savor** from the customer's menu in `CustomerForm`, and the courier choice from `RegisterForm`, if the public shouldn't apply. Offers go to the nearest courier online, as before. With two or three couriers, lengthen `savor.offer.seconds` and `savor.search.seconds`, because the one courier nearby may be at a door.

Many restaurants deliver only part of the time, or hand deliveries to a courier company at busy hours. `Deliveries.dispatch` is the one place a delivery starts: send it to the company's API there instead of offering it to couriers, and move the delivery with the updates the company sends back.

53.11.4. Pickup

A customer who collects the order needs no courier. Mark the order as collected at checkout, skip `dispatch` when the kitchen accepts it in `Orders.accept`, and let the merchant move it from `READY` to `DELIVERED`, which captures the hold the way a delivery does.

53.11.5. Booking a table

A restaurant that delivers usually takes bookings too, and the parts are all in the sample. A booking isn't in it, so this is the outline:

- **The record.** A `Reservation` entity — restaurant, account, time, party size, a note and a state of requested, confirmed, declined, seated or cancelled — in a new migration, with a state machine of conditional moves like the order's, so a guest cancelling while the restaurant confirms can't both win.
- **The contract.** A `@RestClient` interface in `shared` for the guest's calls (the free times, book, cancel, their own bookings) and calls under `/api/merchant/restaurants/{id}/⋯` for the staff, behind the same rules as the merchant's other calls.
- **Free times.** Slots inside the restaurant's opening hours, each with the number of covers the room takes, less the bookings already confirmed.
- **The staff's screen.** A tab beside the order queue in `MerchantForm`, refreshed by a frame on the live channel when a booking arrives, as a new order is.
- **Telling the guest.** A text message through `SmsSender` and a push through the `push` package when a booking is confirmed, and a reminder before it.

A deposit for a large party is a card hold, as an order is: authorize when the booking is made, capture it for a no-show, and release it when the guest arrives.

Chapter 54. Skirmish: Making the game your own

Skirmish shares the module layout, the accounts and sign-in, push notifications and the operations console with Savor and Wayline. What it adds is a game: a deterministic simulation that the app, the server, the replay viewer and the tests all run, a 3D battle drawn over it, and the progression, store and moderation a live game needs. This chapter shows where each of those lives and what to change to make the game yours.

54.1. Running it

The project is in `scripts/skirmish`, and the Initializr generates it under your own package and name. Start the server on the development profile, which keeps its database in memory, seeds the demo accounts and simulates purchases and push notifications:

```
CN1_PROFILE=dev backend/server.sh run
```

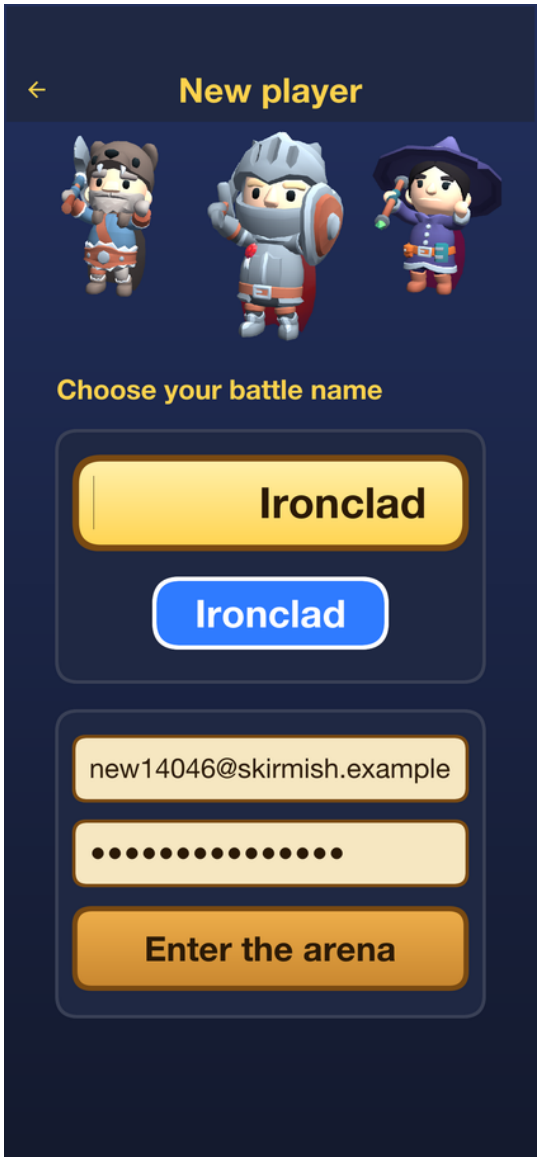
Then run the app in the simulator, from the project's directory:

```
mvn verify -Psimulator -DskipTests -Dcodename1.platform=javase
```

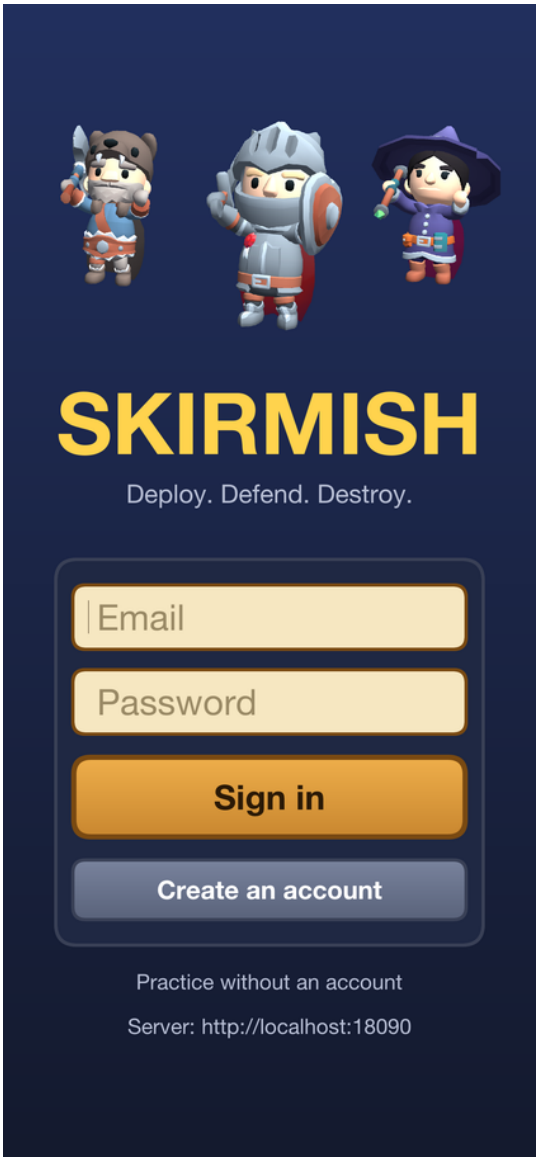
The app looks for the server at `http://localhost:8080/`; **Settings** changes the address, which is how a phone reaches a server on your computer. To build the native iOS app on a Mac, generate the Xcode project, which lands under `ios/target`, then open it and run it on a simulator or a device from Xcode:

```
mvn package -DskipTests -Dcodename1.platform=ios -Dcodename1.buildTarget=ios-source -Dopen=false
```

The development profile needs nothing installed, and four demo accounts exist, each with the password `skirmish-demo`:



Account	What it's for
`player@skirmish.example`	A player with some history: level 3, two chests waiting and a daily quest ready to claim.
`rival@skirmish.example`	A second player, to battle the first from another simulator or device.
`trouble@skirmish.example`	A player the server has already flagged, so the console has something to review.
`admin@skirmish.example`	The operator. Signs in to the same app and gets the admin console as well.

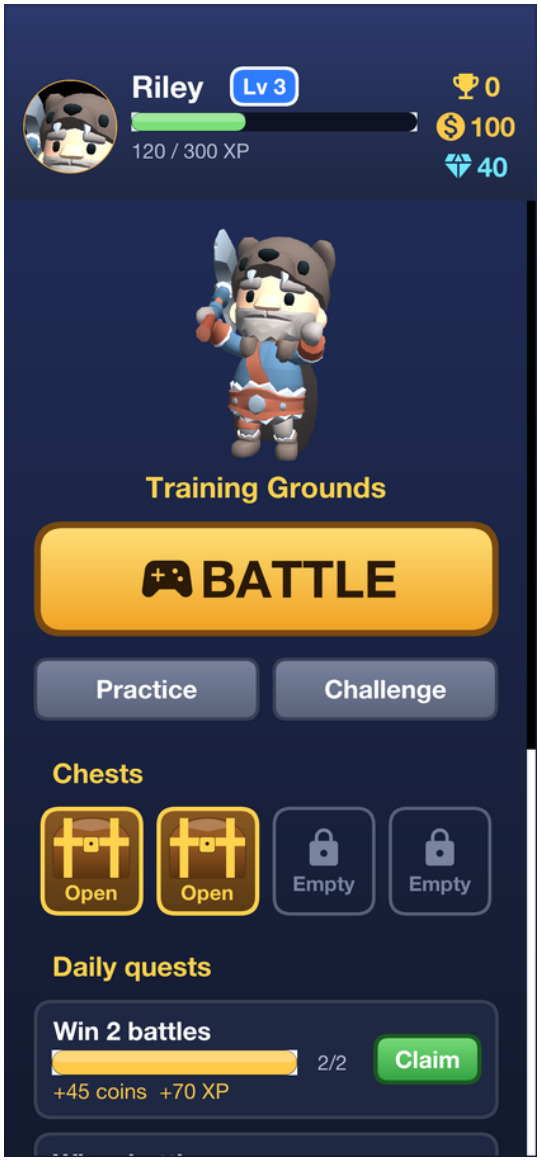


54.2. What the sample does

This tour follows a player through the app, with a pointer to the section that explains how each part is built.

54.2.1. Signing in

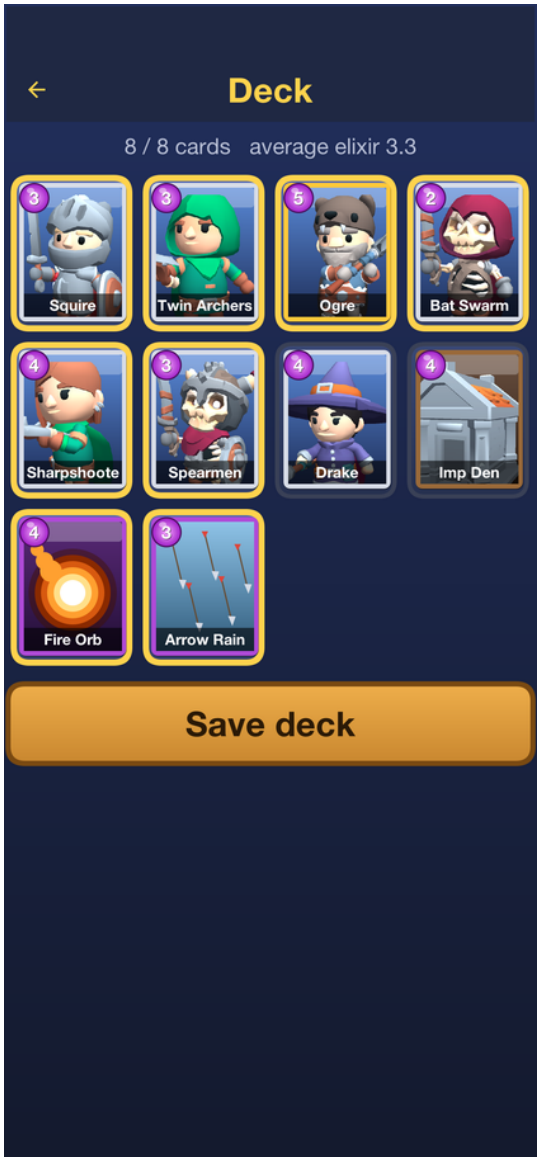
The first screen offers to sign in, to create an account, or to practice against the bot without one. A new account picks a battle name, which is what opponents and the leaderboard see.



A new player goes straight into the training battle, described in Section 54.16, “The training battle”.

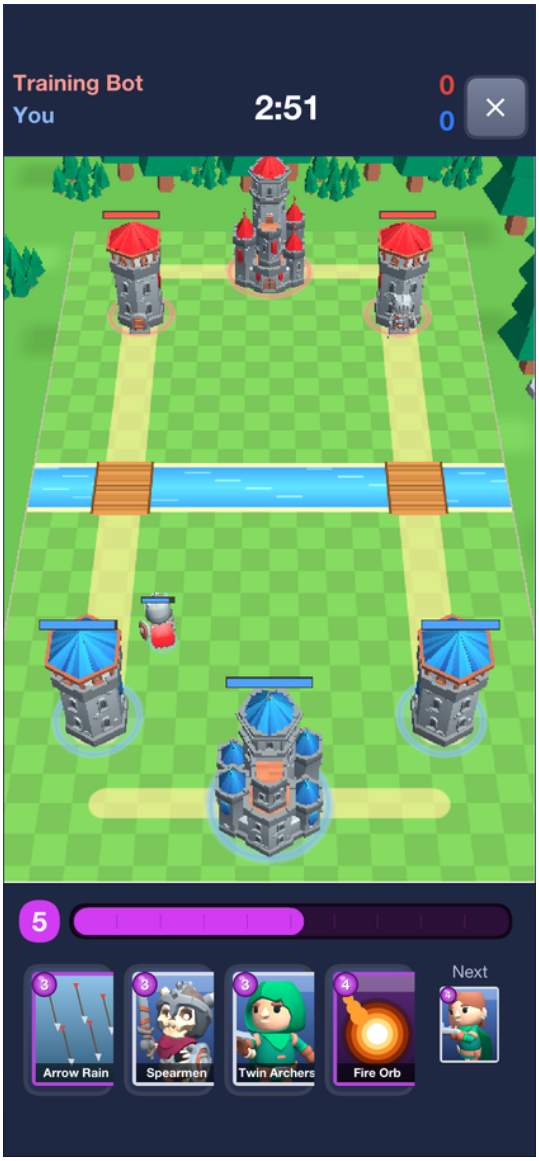
54.2.2. The home screen

The home screen shows the player’s progress at a glance: level and how close the next one is, coins, gems and trophies, the hero of the deck, the **BATTLE** button, chests, today’s quests and the deck.



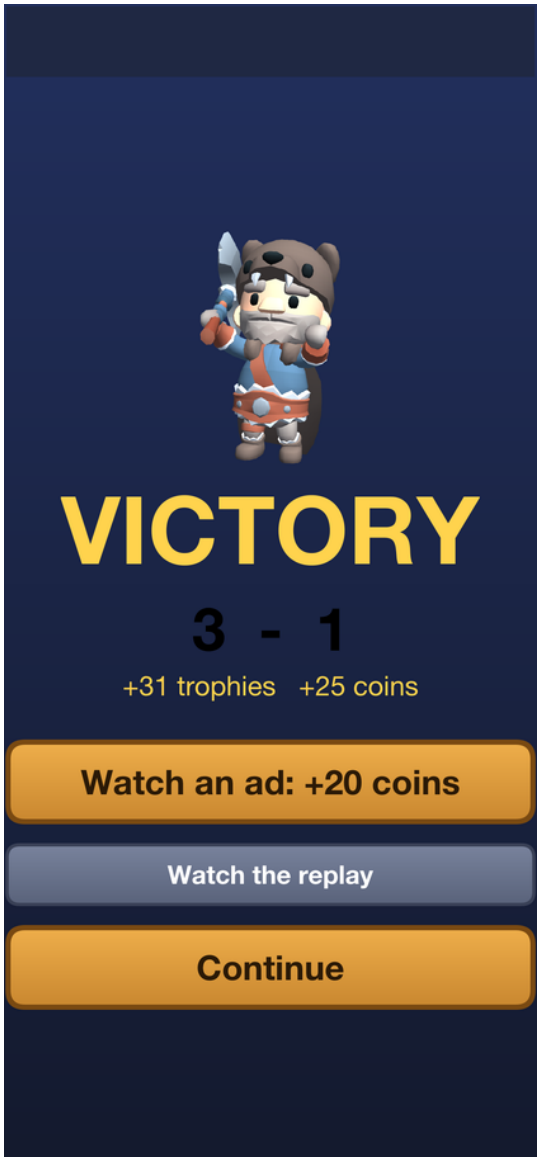
- Chests are earned by winning and by levelling up. A tap opens one.
- Daily quests change every day. Three are picked for each player, and a finished one is claimed with **Claim**.
- Achievements are long-term goals with gem rewards, listed in the **Trophies** room.

Every reward is shown in a popup with the player's hero cheering. The server decides every part of it, as Section 54.7, "Progression" shows.



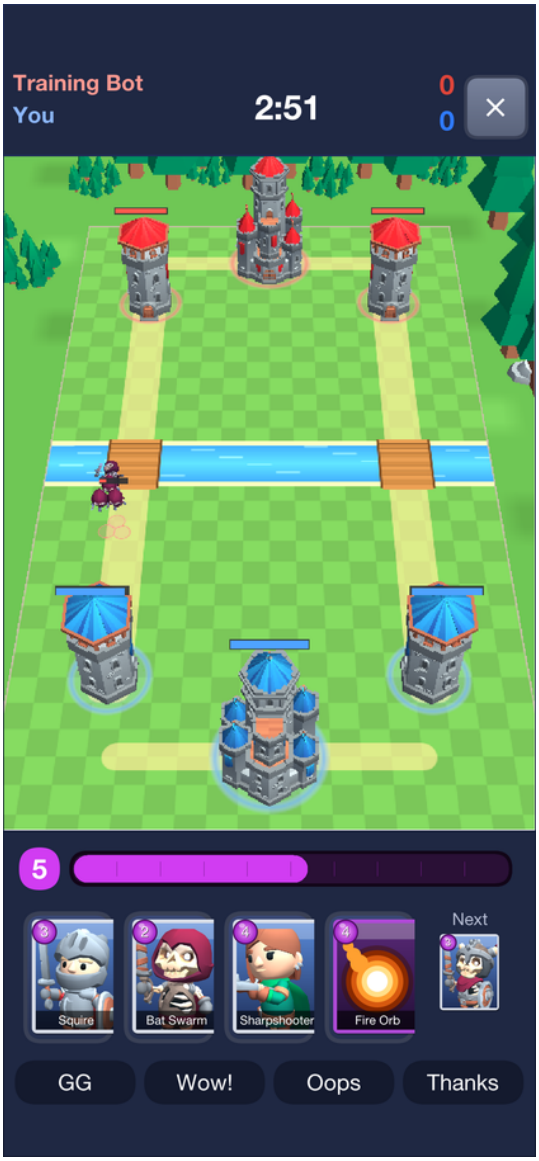
54.2.3. The deck

A deck is eight cards, and the battle hand is four of them at a time, with the next card waiting. **Deck** shows every card with its elixir cost, and the eight in use are framed in gold. A tap swaps a card in or out.



54.2.4. Battle

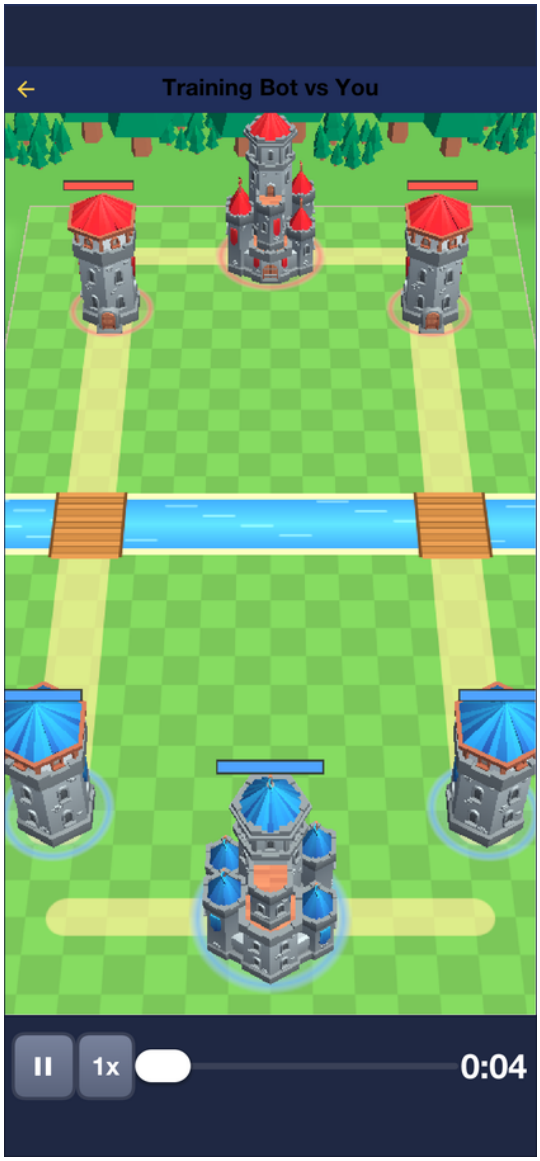
A battle lasts three minutes. Each side has a king's castle and two archer towers. Toppling a tower wins a crown, and toppling the castle wins outright. When the clock runs out, the side with more crowns wins. A tie goes to a minute of overtime where the next crown wins, and is a draw if nobody scores. Elixir comes twice as fast in the last minute of regular time.



Elixir fills the bar at the bottom, one drop at a time up to ten. A card is played by tapping it and then the field, or by dragging it there. Troops and buildings go on the player's own side of the river, and spells go anywhere. Troops walk to the nearest bridge and attack the first thing in their way.

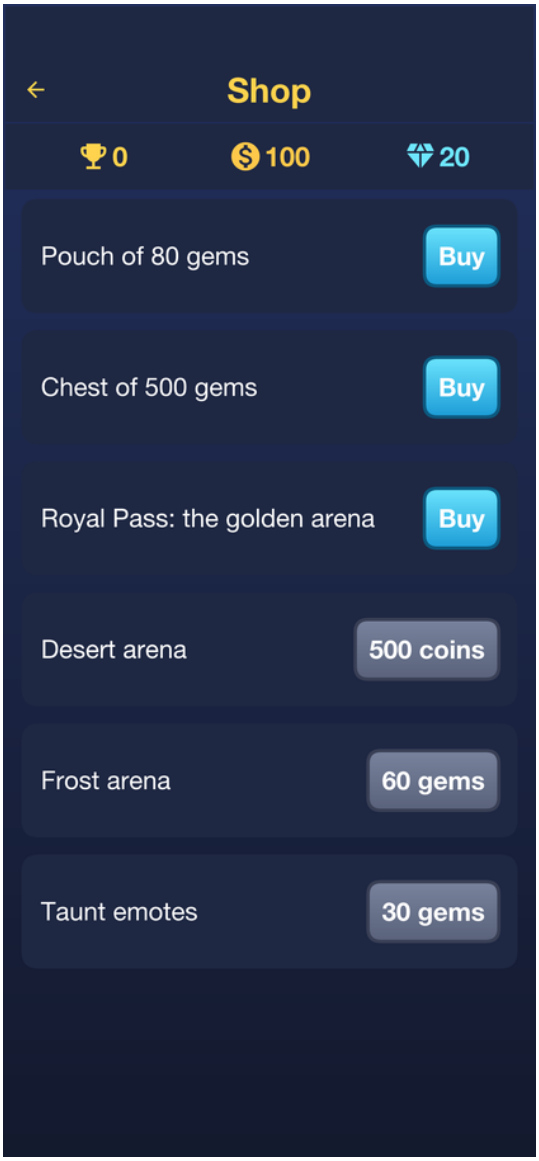
The result screen follows, with the crowns, trophies and coins won. From there a player can watch the replay, report the opponent, or watch a sponsored video for extra coins.

54.2.5. Finding an opponent



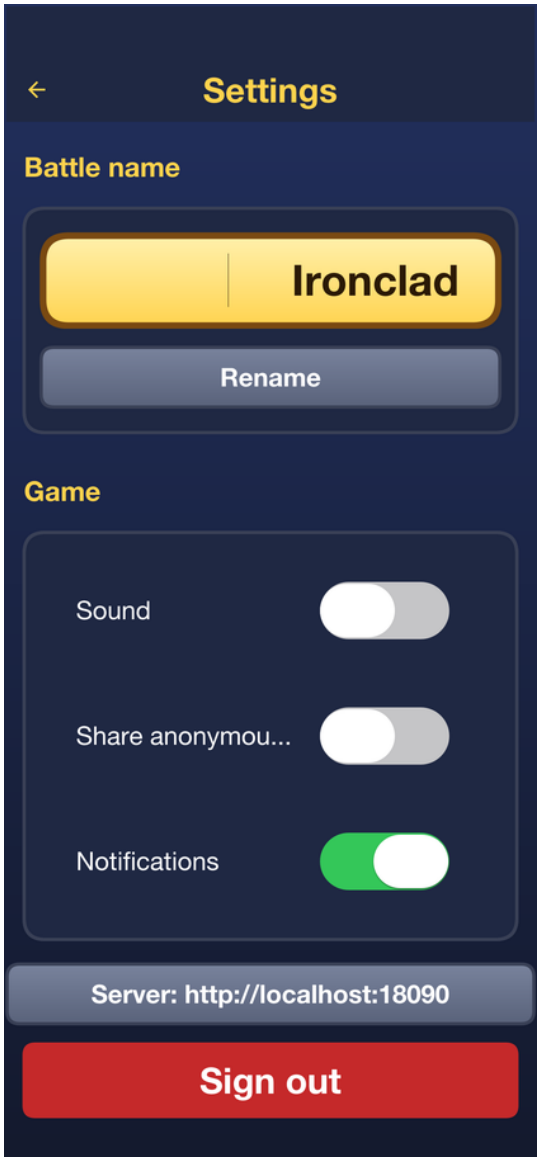
BATTLE puts the player in a queue that pairs players with similar trophy counts and falls back to the bot if nobody is found. During an online battle, the buttons under the hand send a quick emote to the opponent. Section 54.5, “The server is the referee” explains how the two phones stay in step.

Practice plays the bot straight away and earns nothing. **Challenge** makes a code and a link to send a friend, and opening the link starts the friend's app straight into the battle.



54.2.6. Replays

Every online battle is kept, and **Replays** lists them. Any signed-in player can watch any battle, with both players' names. A replay isn't a recording. It's the starting state and every card played, run again through the same rules. The viewer pauses, plays at two or four times speed, and a slider jumps to any moment.



54.2.7. The shop and settings

The shop sells gems for real money, and cosmetic items for gems: arenas, emote sets and a season pass. Purchases go through the platform's store, and the server checks every receipt before granting anything, as Section 54.9, "Purchases" shows. On the development profile the store is simulated, so a purchase completes immediately.

Settings renames the player, and switches the sound, push notifications and sharing anonymous usage statistics on or off. The server address can be changed here too, which is how the app reaches a server on another machine.

54.3. The modules

Module	What it holds
`rules`	The game itself: the cards, the arena, the units, the bot and replays. It uses nothing but a handful of `java.*` classes, no Codename One API and no floating point, so the app, the server and the tests compile the same classes.
`shared`	The contract: the data transfer objects and the `@RestClient` interfaces both sides compile against.
`common`	The app: the 3D battle, the menus, the store, ads, analytics, push and the admin console.
`backend`	The server: accounts, decks, matchmaking, the authoritative match rooms, replays, progression, receipts, push and moderation.
`ios`	The iOS build, for generating the Xcode project.

54.4. The rules run everywhere

Everything that decides a battle is in `Match.step`, and nothing else changes a match. It advances the game by one tick, a twentieth of a second, applying the cards played on that tick:

```
/// Advances one tick. `commands` may hold anything; only those stamped with
/// the current tick are applied, in the order given (the server's order).
public void step(List<Command> commands) {
    if (isOver()) {
        return;
    }
    events.clear();
    if (commands != null) {
        for (int i = 0; i < commands.size(); i++) {
            Command c = commands.get(i);
            if (c.tick == tick) {
                apply(c);
            }
        }
    }
    runWaves();
    regenElixir();
    int count = units.size();
    for (int i = 0; i < count; i++) {
        Unit u = units.get(i);
        if (u.hp > 0) {
            update(u);
        }
    }
    separate();
    removeDead();
    tick++;
    checkEnd();
}
```

Three rules keep every copy of a match identical:

- **No floating point.** Positions are thousandths of a tile, held in `int`, and `FixedMath` supplies the integer square root and distance checks. Floating point rounds differently on different processors and compilers, so a battle that used it would drift apart between a phone and the server.
- **No clock and no `java.util.Random`.** Time is the tick count, and chance comes from `Rng`, seeded by the server when the match starts.
- **The order is fixed.** Units act in the order they were created, and cards played on the same tick apply in the order the server received them, which the server’s log fixes for every copy of the match.

Because of that, a replay is only the seed, the two decks and the list of cards played. `Replay` re-runs

them through `Match` and arrives at the same battle, and the server and both players compare a hash of the state to detect a client that has gone its own way.

54.4.1. Adding a card

A card is a row in `Cards`:

```
add(new CardDef("squire", "Squire", CardDef.TROOP, 3)
        .hp(1450).damage(160).hitTicks(24).range(700).speed(45).radius(500));
```

Hit points and damage are whole numbers, ranges and radii are in thousandths of a tile, speed is thousandths of a tile per tick, and `hitTicks` is the time between attacks. `CardDef` also describes what a card targets, whether it splashes, how many units it spawns and how long a building lasts.

The look of a card on the field is a row in `Models`, the glTF character it uses, its height in tiles and its attack animation:

```
public final class Models {
    /// How one card looks on the field.
    public static final class Look {
        public final String model;
        /// Height in tiles for a character; footprint width in tiles for a
        /// building.
        public final float size;
        public final String attack;
        public final float hover;
        public final int tint;
        public final String idle;
        public final String run;
        public final String death;

        Look(String model, float size, String attack, float hover, int tint) {
            this(model, size, attack, hover, tint, "Idle", "Running_A", "Death_A");
        }

        Look(String model, float size, String attack, float hover, int tint, String idle, String run,
                String death) {
            this.model = model;
            this.size = size;
            this.attack = attack;
            this.hover = hover;
            this.tint = tint;
            this.idle = idle;
            this.run = run;
            this.death = death;
        }
    }

    private static final Map<String, Look> LOOKS = new HashMap<String, Look>();
    private static final Map<String, GltfScene> SCENES = new HashMap<String, GltfScene>();

    static {
        look("squire", "knight", 1.96f, "1H_Melee_Attack_Chop", 0f, 0xffffffff);
        look("twin-archers", "rogue_hooded", 1.67f, "1H_Ranged_Shoot", 0f, 0xffffffff);
        look("ogre", "barbarian", 3.04f, "2H_Melee_Attack_Chop", 0f, 0xffffffff);
        look("bat-swarm", "skeleton_rogue", 1.16f, "1H_Melee_Attack_Chop", 1.6f, 0xffb8c8ff);
        look("sharpshooter", "rogue", 1.89f, "2H_Ranged_Shoot", 0f, 0xffffffff);
        look("spearmen", "skeleton_warrior", 1.74f, "1H_Melee_Attack_Chop", 0f, 0xffffffff);
```

```
        look("drake", "mage", 2.03f, "Spellcast_Shoot", 1.8f, 0xffffffff);
        look("imp", "skeleton_minion", 1.38f, "Unarmed_Melee_Attack_Punch_A", 0f, 0xffffffff);
        look("imp-den", "crypt", 3.77f, null, 0f, 0xffffffff);
    }

    private Models() {
    }

    private static void look(String card, String model, float size, String attack, float hover, int tint) {
        LOOKS.put(card, new Look(model, size, attack, hover, tint));
    }

    /// The look of `card`, or null for a spell or a tower (drawn by the view).
    public static Look of(String card) {
        return LOOKS.get(card);
    }

    /// The look of a card from a Forge pack: its own model, bundled or
    /// uploaded, its size and tint, and the clips its author mapped. A card
    /// with no model of its own falls back to a bundled one by kind.
    public static Look of(CardDef card) {
        Look builtin = LOOKS.get(card.id);
        if (builtin != null || card.kind == CardDef.SPELL || card.kind == CardDef.TOWER) {
            return builtin;
        }
        String model = card.model();
        if (model == null || model.length() == 0) {
            model = card.kind == CardDef.BUILDING ? "crypt" : card.isFlying() ? "skeleton_rogue" : "knight";
        }
        float size = (card.kind == CardDef.BUILDING ? 3.5f : 1.9f) * Math.max(25, card.scalePercent()) / 100f;
        int tint = card.tint() < 0 ? 0xffffffff : 0xff000000 | card.tint();
        String clips = card.clips();
        String attack = GlbInspector.clip(clips, "attack");
        if (attack == null && card.kind != CardDef.BUILDING) {
            attack = card.range() > 1500 ? "1H_Ranged_Shoot" : "1H_Melee_Attack_Chop";
        }
        return new Look(model, size, attack, card.isFlying() ? 1.6f : 0f, tint,
                orElse(GlbInspector.clip(clips, "idle"), "Idle"), orElse(GlbInspector.clip(clips, "run"), "Running_A"),
                orElse(GlbInspector.clip(clips, "death"), "Death_A"));
    }

    private static String orElse(String v, String fallback) {
        return v == null ? fallback : v;
    }

    /// Whether `name` is one of the models that ship with the game.
    public static boolean isBundled(String name) {
        return CN.getResourceAsStream("/model_" + name + ".glb") != null;
    }

    /// The parsed model `name`, loaded once: `/model_<name>.glb` for a bundled
    /// one, or an uploaded file, `asset:<sha256>`, from [ForgeFiles].
    public static synchronized GltfScene scene(String name) {
        GltfScene s = SCENES.get(name);
        if (s == null) {
            InputStream in = name.startsWith("asset:") ? ForgeFiles.open(name.substring(6))
                    : CN.getResourceAsStream("/model_" + name + ".glb");
            if (in == null) {
                throw new IllegalStateException("missing model " + name);
            }
            try {
                s = GltfLoader.loadScene(in);
            } catch (java.io.IOException err) {
                Log.e(err);
                throw new IllegalStateException("unreadable model " + name);
            }
```

```
            SCENES.put(name, s);
        }
        return s;
    }
}
```

The card's portrait in the hand and the deck is a PNG in `common/src/main/resources`, `card_<id>.png`. `PortraitStudio` renders a portrait from the card's model, so a new card gets art that matches the others:

```
mvn -pl common test-compile surefire:test -Dtest=PortraitStudio \
    -Dskirmish.portraits="$PWD/common/src/main/resources"
```

Changing what any card does changes the outcome of recorded battles. Bump `RulesVersion.ID` with it: each replay records the version it was played under, and `GoldenReplayTest` fails until the golden replays are recorded again.

54.5. The server is the referee

An online battle is played in lockstep. Neither phone decides anything: each sends the card it wants to play, and the server's `MatchRoom` runs the match, stamps the play with the tick it takes effect on and sends it to both players:

```
final class MatchRoom {
    /// Plays a seat may make in [#FLOOD_WINDOW] ticks before the rest are dropped.
    static final int FLOOD_LIMIT = 6;
    static final int FLOOD_WINDOW = 20;

    final String id;
    final Match match;
    final Seat[] seats;
    final Bot bot;
    final List<Command> log = new ArrayList<Command>();
    final List<WebSocketSession> spectators = new ArrayList<WebSocketSession>();
    final long startedAt;
    /// Index into [#log] of the first command not yet sent.
    int sent;
    int lastSentTick = -1;
    int forfeit = -1;
    final java.util.Map<Integer, Long> hashes = new java.util.HashMap<Integer, Long>();

    MatchRoom(String id, long seed, Seat a, Seat b, long now) {
        this.id = id;
        this.seats = new Seat[] {a, b};
        this.match = new Match(seed, a.deck, b.deck);
        this.bot = b.isBot() ? new Bot(1, seed ^ 0x1234L) : null;
        this.startedAt = now;
    }
```

```
    int seatOf(String username) {
        for (int i = 0; i < 2; i++) {
            if (seats[i].username.equals(username)) {
                return i;
            }
        }
        return -1;
    }

    /// Accepts a play intent from `player`. Answers false when it was dropped.
    boolean intent(int player, String card, int x, int y) {
        if (match.isOver()) {
            return false;
        }
        Seat seat = seats[player];
        int now = match.tick();
        int inWindow = 0;
        for (int i = 0; i < seat.recentCount; i++) {
            if (now - seat.recent[i] < FLOOD_WINDOW) {
                inWindow++;
            }
        }
        if (inWindow >= FLOOD_LIMIT) {
            seat.floods++;
            return false;
        }
        seat.recent[seat.recentCount % seat.recent.length] = now;
        seat.recentCount = Math.min(seat.recentCount + 1, seat.recent.length);
        // A cheap early answer; the rules check again when the command executes.
        if (!match.canPlay(player, card, x, y)) {
            seat.rejected++;
            return false;
        }
        log.add(new Command(now + GameProtocol.INPUT_DELAY, player, card, x, y));
        return true;
    }

    /// Advances one tick, letting the bot decide first.
    void step() {
        if (bot != null) {
            Command c = bot.decide(match, GameProtocol.INPUT_DELAY);
            if (c != null) {
                log.add(c);
            }
        }
        match.step(log);
        if (match.tick() % GameProtocol.HASH_EVERY == 0) {
            hashes.put(Integer.valueOf(match.tick()), Long.valueOf(match.stateHash()));
            hashes.remove(Integer.valueOf(match.tick() - 10 * GameProtocol.HASH_EVERY));
        }
    }
```

```
    /// The result: [Match#result], or the side that did not leave.
    int result() {
        return forfeit >= 0 ? 1 - forfeit : match.result();
    }

    boolean isOver() {
        return forfeit >= 0 || match.isOver();
    }

    Replay replay() {
        return new Replay(match.seed(), seats[0].deck, seats[1].deck, log);
    }
}
```

The play is scheduled a few ticks ahead, so it reaches both phones before it's due, and each phone advances its own copy of the match only as far as the server has said. `OnlineDriver` is the client's half:

```
public final class OnlineDriver extends Driver {
    /// What the battle screen wants to hear besides the ticks.
    public interface Listener {
        void emote(int seat, String id);

        void ended(int result, int crowns0, int crowns1, int trophies, int coins, String matchId);

        void lost();
    }

    private final GameLink link;
    private final boolean spectator;
    private Listener listener;
    private String matchId;
    private String[] names = {"", ""};
    private int allowed;

    public OnlineDriver(GameLink link, Map<String, Object> start, boolean spectator) {
        this.link = link;
        this.spectator = spectator;
        restart(start);
    }

    public void setListener(Listener listener) {
        this.listener = listener;
    }

    public String matchId() {
        return matchId;
    }

    /// A `start` message: the first one, or the server's answer to a hash

            }
        }
        return out;
    }
}
```

A play that isn't legal is dropped by the rules, and a player who floods the room is flagged for the console. Practice against the bot and the replay viewer use the same screen with another `Driver`, which is why all three look and behave the same.

54.6. The finishing camera

The battle is a `com.codename1.gaming` 3D scene, and only the renderer knows about it. When the match is over, `BattleView` swings the camera around the field and down beside the fallen castle before the result screen appears:

```
/// The finishing move: once the match is decided the camera leaves its
/// fixed battle view, swings around the field and comes down low beside
/// the fallen king tower, so the last blow is seen from the ground. The
/// rules are already over, so this is purely the renderer's -- a replay
/// or a spectator sees the same sweep.
private void startFinale(Match m) {
    previewFinale(m.result());
}

/// Runs the sweep toward `winner`'s victory (or a draw) without the match
/// being over: the screenshot tests use it to photograph the finale.
public void previewFinale(int winner) {
    int loser = winner < 0 ? -1 : 1 - winner;
    if (loser < 0) {
        // A draw: look at the bridge between the two sides.
        finaleX = 0f;
        finaleZ = 0f;
    } else {
        Arena.Tower king = arena().king(loser);
        finaleX = wx(king.x, king.y);
        finaleZ = wz(king.x, king.y);
```

```
    }
    finale = 0f;
}

private void finale(float dt) {
    finale = Math.min(FINALE_SECONDS, finale + dt);
    float t = finale / FINALE_SECONDS;
    // Ease in and out, so the sweep starts and settles without a jolt.
    float e = t * t * (3f - 2f * t);
    // Orbit from straight behind the player's side to a three-quarter view
    // beside the tower, dropping from the battle height to eye level.
    double angle = Math.toRadians(e * 125f);
    float radius = 42f - e * 22f;
    float height = 33f - e * 24f;
    float cx = finaleX * e;
    float cz = 1.6f + (finaleZ - 1.6f) * e;
    float ex = cx + (float) Math.sin(angle) * radius;
    float ez = cz + (float) Math.cos(angle) * radius * (30f / 42f + e * (1f - 30f / 42f))
            - 1.6f * (1f - e);
    GameCamera cam = getCamera();
    cam.setPosition(ex, height, ez);
    cam.setTarget(cx, 1.6f * e, cz);
}

/// True while the finishing sweep still has frames to show.
public boolean finaleRunning() {
    return finale >= 0f && finale < FINALE_SECONDS;
}
```

Particle effects and the camera are cosmetic: they read the match and never change it, so they can be changed without touching a replay.

54.7. Progression

Levels, experience, chests, daily quests and achievements are all decided on the server, after it has recorded a result. The app only shows what the server says was earned:

```
@Component
public class Progression {
    /// Chests wait in slots; a win with every slot full earns none.
    public static final int CHEST_SLOTS = 4;
    public static final int WIN_XP = 40;
    public static final int DRAW_XP = 20;
    public static final int LOSS_XP = 15;
    public static final int CROWN_XP = 5;
    public static final int TUTORIAL_XP = 100;
    public static final int TUTORIAL_COINS = 100;
    public static final int LEVEL_UP_COINS = 60;
    public static final int LEVEL_UP_GEMS = 5;

    private final ProgressRepository progress;
    private final ProfileRepository profiles;
```

```
    public Progression(ProgressRepository progress, ProfileRepository profiles) {
        this.progress = progress;
        this.profiles = profiles;
    }

    /// Counts a finished battle for one side. Called from inside the
    /// transaction that records the match, with the profile it is about to
    /// save, so the coins and gems this grants are saved with it.
    public RewardDto afterMatch(Profile p, boolean won, boolean draw, int crowns, int cards, int spells)
            throws IOException {

                    unlocked(g, a.id)));
        }
        return new ProgressDto(level, g.getXp(), Goals.levelStart(level), Goals.levelStart(level + 1),
                g.isTutorialDone(), g.getChests(), p.getCoins(), p.getGems(), g.getStreak(), g.getWins(),
                quests, achievements);
    }

    /// A reward being put together; granting through it keeps the popup and
    /// the balances in step.
    private static final class Reward {
        final String title;
        final List<String> unlocked = new ArrayList<>();
        int coins;
        int gems;
        int xp;
        int chests;
        boolean levelUp;

        Reward(String title) {
            this.title = title;
        }

        void coins(Profile p, int n) {
            p.setCoins(p.getCoins() + n);
            coins += n;
        }

        void gems(Profile p, int n) {
            p.setGems(p.getGems() + n);
            gems += n;
        }

        /// Adds experience; each level gained pays coins, gems and a chest.
        void xp(Progress g, Profile p, int n) {
            int from = Goals.levelOf(g.getXp());
```

```
            g.setXp(g.getXp() + n);
            xp += n;
            int to = Goals.levelOf(g.getXp());
            for (int l = from; l < to; l++) {
                levelUp = true;
                coins(p, LEVEL_UP_COINS);
                gems(p, LEVEL_UP_GEMS);
                if (g.getChests() < CHEST_SLOTS) {
                    g.setChests(g.getChests() + 1);
                    chests++;
                }
            }
        }

        RewardDto dto(Progress g) {
            return new RewardDto(title, coins, gems, xp, chests, Goals.levelOf(g.getXp()), levelUp, unlocked);
        }
    }
}
```

The amounts and the quests are tables in that class, so balancing the economy is a change to one file.

54.8. Re-skinning

The menus are ordinary Codename One components, and the game's look is `common/src/main/css/theme.css`. Its palette is a set of variables at the top:

```
--night: #141a2e;
--night-alt: #1f2843;
--stone: #59627a;
--stone-light: #7a849e;
--stone-dark: #3a4157;
--wood: #c8862f;
--wood-light: #f0b04c;
--wood-dark: #7a4a12;
--gold: #ffd34d;
--parchment: #f6e7c1;
--ink: #2b1a07;
--blue: #2f7bff;
--red: #e0453a;
--elixir: #d13cf2;
--elixir-glow: #f7a8ff;
--text: #ffffff;
--text-muted: #b9c0d6;
--danger: #c5292a;
```

The wooden buttons are a style like any other, a gradient with a border and a shadow, so they need no images and stay sharp at any density:

```
/* The big carved button: a wooden plank with a darker rim and a lighter top
```

```
   edge, pressed in when touched. */
WoodButton {
    background: linear-gradient(to bottom, var(--wood-light), var(--wood));
    border: 0.6mm solid var(--wood-dark);
    border-radius: 2mm;
    color: var(--ink);
    font-family: "native:MainBold";
    font-size: 4mm;
    text-align: center;
    padding: 2.5mm;
    /* The same 2mm inset as the section titles and panels above it. */
    margin: 1.2mm 2mm;
}

WoodButton.pressed {
    background: linear-gradient(to bottom, var(--wood), var(--wood-dark));
    color: var(--parchment);
}

WoodButton.disabled {
    background-color: var(--stone-dark);
    color: var(--stone-light);
}
```

The characters and buildings are glTF files in `common/src/main/resources`. They're KayKit models, packed from the original downloads by `tools/pack-models.py`; any rigged glTF character with the same animation names can replace one.

54.9. Purchases

The shop sells gems through the platform's store. The app's `Store` starts the purchase, and the server grants nothing until it has checked the receipt with Apple or Google:

```
public interface ReceiptValidator {
    /// The store's transaction id when `receipt` proves a purchase of `sku`, or
    /// null when it does not.
    String verify(String store, String sku, String transactionId, String receipt) throws IOException;
}
```

The server picks the validator from its configuration:

```
/// `skirmish.iap.provider` is one of:
///
/// - `store`: receipts are checked with Apple (`skirmish.iap.apple.secret`)
///   and Google Play (`skirmish.iap.google.package` and
///   `skirmish.iap.google.token`). A store with no settings refuses its
///   receipts; the other keeps working.
/// - `simulated`: every receipt is accepted, on a development profile only.
///
```

```
/// Unset, it is `simulated` on a development profile and `store` otherwise.
@Bean
public ReceiptValidator receipts(Config config,
        @Value("${skirmish.iap.provider:}") String chosen,
        @Value("${skirmish.iap.apple.secret:}") String appleSecret,
        @Value("${skirmish.iap.google.package:}") String googlePackage,
        @Value("${skirmish.iap.google.token:}") String googleToken) {
    String kind = chosen.trim().length() > 0 ? chosen.trim()
            : config.isDevelopmentProfile() ? "simulated" : "store";
    if ("simulated".equalsIgnoreCase(kind)) {
        if (!config.isDevelopmentProfile()) {
            return new MisconfiguredReceipts("skirmish.iap.provider=simulated grants every "
                    + "purchase for free and is refused on the '" + config.getProfile()
                    + "' profile; set it to store");
        }
        return new SimulatedReceipts();
    }
    if (!"store".equalsIgnoreCase(kind)) {
        return new MisconfiguredReceipts("skirmish.iap.provider is '" + kind
                + "', which is neither store nor simulated");
    }
    if (appleSecret.trim().length() == 0 && (googlePackage.trim().length() == 0
            || googleToken.trim().length() == 0)) {
        return new MisconfiguredReceipts("in-app purchases are not configured; set "
                + "skirmish.iap.apple.secret, or skirmish.iap.google.package and "
                + "skirmish.iap.google.token");
    }
    return new StoreReceipts(appleSecret.trim(), googlePackage.trim(), googleToken.trim());
}
```

The product identifiers and the ad units are in `AppConfig`, and the server's `Catalog` names the same products. Replace both with your own before release:

```
/// Google's published test ad units. They always fill, never pay, and are
/// safe to click; replace them with your own AdMob units before release.
public static final String REWARDED_AD_UNIT = "ca-app-pub-3940256099942544/5224354917";
public static final String INTERSTITIAL_AD_UNIT = "ca-app-pub-3940256099942544/1033173712";
public static final String BANNER_AD_UNIT = "ca-app-pub-3940256099942544/6300978111";
/// The store products, as configured in App Store Connect and the Play
/// Console. The server's `Catalog` names the same ones.
public static final String SKU_GEMS_80 = "skirmish.gems_80";
public static final String SKU_GEMS_500 = "skirmish.gems_500";
public static final String SKU_ROYAL_PASS = "skirmish.royal_pass";
```

54.10. Ads

`Ads` shows an interstitial between battles and a rewarded video for extra coins after one. The units in `AppConfig` are Google's test units, which always fill and never pay:

```
public final class Ads {
```

```
    private static final int INTERSTITIAL_EVERY = 3;
    private static int battlesSinceAd;

    private Ads() {
    }

    public static void start() {
        if (AdManager.getProvider() != null) {
            AdManager.initialize(new AdConfig().testMode(true), ready -> { });
        }
    }

    /// Plays a rewarded ad and runs `granted` once the network says it was
    /// watched to the end.
    public static void rewarded(final Runnable granted, final Runnable unavailable) {
        Telemetry.adWatched("rewarded_offer");
        if (!AdManager.isInitialized() || !AdManager.isSupported(AdFormat.REWARDED)) {
            standIn(granted);
            return;
        }
        final RewardedAd ad = new RewardedAd(AppConfig.REWARDED_AD_UNIT);
        // Server-side verification: the network calls the game's server with
        // this user id, so a reward could be granted there and nowhere else.
        String who = Session.user() == null ? "" : Session.user().username();
        ad.setServerSideVerificationOptions(new ServerSideVerificationOptions(who, "coins"));
        ad.setAdListener(new AdListener() {
            @Override
            public void onLoaded() {
                ad.show(reward -> CN.callSerially(granted));
            }

            @Override
            public void onFailedToLoad(AdError error) {
                CN.callSerially(unavailable);
            }
        });
        ad.load();
    }

    /// Called after every battle; shows an interstitial every few.
    public static void betweenBattles(boolean adFree) {
        battlesSinceAd++;
        if (adFree || battlesSinceAd < INTERSTITIAL_EVERY || !AdManager.isInitialized()
                || !AdManager.isSupported(AdFormat.INTERSTITIAL)) {
            return;
        }
        battlesSinceAd = 0;
        final InterstitialAd ad = new InterstitialAd(AppConfig.INTERSTITIAL_AD_UNIT);
        ad.setAdListener(new AdListener() {
            @Override
            public void onLoaded() {
                ad.show();
            }
        });
        ad.load();
    }

    /// A banner for the home screen, or null where there is no network.
    public static Component banner(boolean adFree) {
        if (adFree || !AdManager.isInitialized() || !AdManager.isSupported(AdFormat.BANNER)) {
            return null;
```

```
        }
        BannerAd banner = new BannerAd(AppConfig.BANNER_AD_UNIT);
        banner.load();
        return banner;
    }

    private static void standIn(final Runnable granted) {
        Dialog d = new Dialog("Sponsored", new com.codename1.ui.layouts.BorderLayout());
        d.setUIID("AdDialog");
        d.add(com.codename1.ui.layouts.BorderLayout.CENTER,
                new com.codename1.components.SpanLabel("An ad would play here. Install an ad network cn1lib "
                        + "to show real ones."));
        d.setTimeout(1500);
        d.show();
        granted.run();
    }
}
```

A rewarded video is only a request: the server pays the coins, up to three times a day.

54.11. Push notifications and analytics

The server tells a player when a chest is ready or a friend has challenged them. It sends through the Codename One push service once the app's push key is set:

```
/// The app's push key, from the Push section of the Codename One console.
/// Empty, the app registers for no notifications: everything still works,
/// and a phone in a pocket simply hears nothing until it is opened.
public static final String PUSH_APP_KEY = "";
```

```
/// `skirmish.push.provider` is one of:
///
/// - `cloud`: the Codename One push service. It needs `skirmish.push.app`,
///   the app's push id, and `skirmish.push.key`, a server key with the push
///   scope; both are in the Push section of the Codename One console.
/// - `console`: prints each notification, on a development profile only.
/// - `recording`: keeps each notification for the tests to read, on a
///   development profile only.
///
/// Unset, it is `recording` on the `test` profile, `console` on the other
/// development profiles and `cloud` otherwise. A server whose push settings
/// are missing still starts and still serves deliveries: it logs a configuration
/// error at start-up and again for every notification it could not send.
@Bean
public PushSender pushSender(Config config,
        @Value("${skirmish.push.provider:}") String chosen,
        @Value("${skirmish.push.app:}") String app,
        @Value("${skirmish.push.key:}") String key,
        @Value("${skirmish.push.url:}") String url) {
    String kind = chosen.trim().length() > 0 ? chosen.trim()
            : "test".equals(config.getProfile()) ? "recording"
```

```
            : config.isDevelopmentProfile() ? "console" : "cloud";
    if ("console".equalsIgnoreCase(kind) || "recording".equalsIgnoreCase(kind)) {
        if (!config.isDevelopmentProfile()) {
            return new MisconfiguredPushSender("skirmish.push.provider=" + kind
                    + " sends nothing and is refused on the '" + config.getProfile()
                    + "' profile; set it to cloud");
        }
        return "console".equalsIgnoreCase(kind) ? new ConsolePushSender()
                : new RecordingPushSender();
    }
    if (!"cloud".equalsIgnoreCase(kind)) {
        return new MisconfiguredPushSender("skirmish.push.provider is '" + kind
                + "', which is none of cloud, console or recording");
    }
    String missing = missing("skirmish.push.", new String[] {"app", app, "key", key});
    if (missing.length() > 0) {
        return new MisconfiguredPushSender(unset("push", "cloud", missing));
    }
    try {
        CloudPush push = new CloudPush(app.trim(), key.trim());
        return new CloudPushSender(url.trim().length() > 0 ? push.withEndpoint(url.trim())
                : push);
    } catch (IllegalArgumentException err) {
        return new MisconfiguredPushSender("push provider 'cloud' is misconfigured: "
                + err.getMessage());
    }
}
```

`Telemetry` records what a game is measured by: sign-ups and sign-ins, every battle and its result, the cards played, deck changes, spending, purchases, ad rewards and shares. It sends nothing unless the player allows it in **Settings**.

54.12. Moderation

The console is part of the same app, shown only to an account with the admin role. The server flags players on its own, as well as on reports:

```
@Component
public class Flags {
    public static final String REPORT = "REPORT";
    public static final String AUTO = "AUTO";

    private final FlagRepository flags;
    private final ProfileRepository profiles;
    private final MatchRecordRepository matches;
    private final GamePushes pushes;
    private final AdminChannel channel;
    private final List<String> adminNames;

    public Flags(FlagRepository flags, ProfileRepository profiles, MatchRecordRepository matches,
            GamePushes pushes, AdminChannel channel, @Value("${skirmish.admin.notify:}") String adminNames) {
        this.flags = flags;
        this.profiles = profiles;
        this.matches = matches;
```

```
        this.pushes = pushes;
        this.channel = channel;
        this.adminNames = com.codenameone.examples.skirmish.account.Lists.split(adminNames);
    }

    /// A player reporting the opponent of a match they played.
    @Transactional(rollbackFor = IOException.class)
    public FlagDto report(String reporter, String matchId, String reason) throws IOException {
        MatchRecord m = matchId == null ? null : matches.findById(matchId);
        if (m == null || !(reporter.equals(m.getPlayer0()) || reporter.equals(m.getPlayer1()))) {
            throw new ResponseStatusException(404, "No such match");
        }
        String accused = reporter.equals(m.getPlayer0()) ? m.getPlayer1() : m.getPlayer0();
        if (accused.length() == 0) {
            throw new ResponseStatusException(400, "The training bot cannot be reported");
        }
        if (flags.countByReporterAndMatchId(reporter, matchId) > 0) {
            throw new ResponseStatusException(409, "You already reported this match");
        }
        String why = Text.required(reason, 255, "what happened");
        return raise(accused, REPORT, why, matchId, reporter);
    }

    /// Something the server noticed itself. Transactional on its own because
    /// the demo seeding calls it with no transaction open; inside one (a match
    /// being recorded) it joins that one.
    @Transactional(rollbackFor = IOException.class)
    public void auto(String username, String reason, String matchId) {

            profiles.save(p);
        }
        return toDto(f, p);
    }

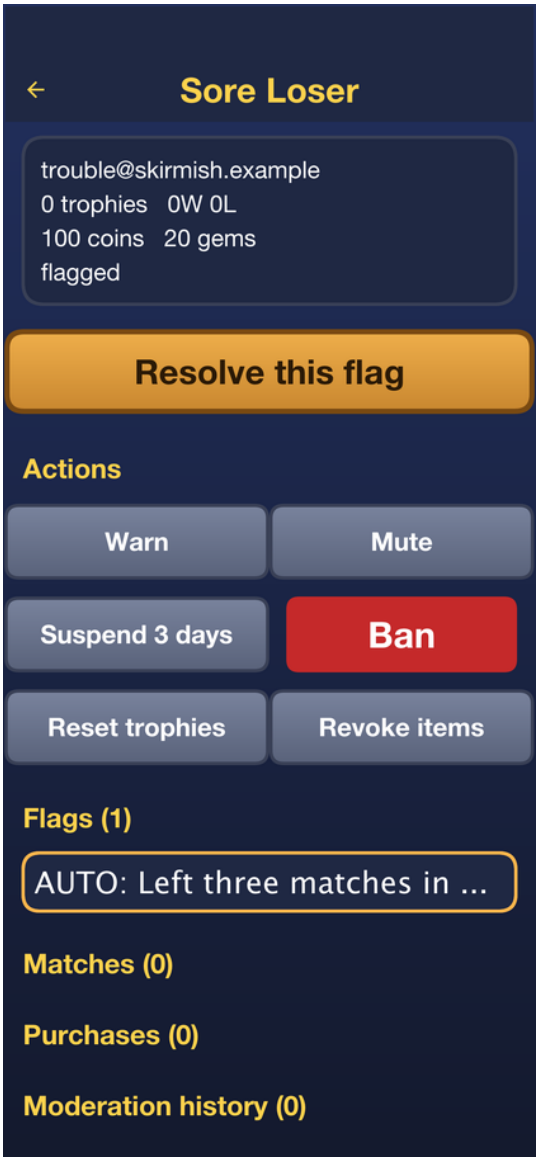
    @Transactional(readOnly = true)
    public List<FlagDto> list(boolean pending) {
        List<FlagDto> out = new ArrayList<FlagDto>();
        for (Flag f : flags.inState(pending, new PageRequest(0, 200))) {
            out.add(toDto(f, profiles.findById(f.getUsername())));
        }
        return out;
    }

    @Transactional(readOnly = true)
    public List<FlagDto> of(String username) {
        List<FlagDto> out = new ArrayList<FlagDto>();
        Profile p = profiles.findById(username);
        for (Flag f : flags.of(username, new PageRequest(0, 50))) {
            out.add(toDto(f, p));
        }
        return out;
    }

    public long pendingCount() {
        return flags.countByPendingTrue();
    }

    static FlagDto toDto(Flag f, Profile p) {
        return new FlagDto(f.getId(), f.getUsername(), p == null ? f.getUsername() : p.getDisplayName(),
                f.getKind(), f.getReason(), f.getMatchId(), f.getReporter(), f.getCreatedAt().toEpochMilli(), f.
isPending());
    }
}
```

Every action an operator takes goes through `Moderation`, which records it with its reason and removes a suspended or banned player from any battle they're in.



The admin account sees **Admin console** on the home screen. Its tabs are:

- **Overview** counts players online, matches and purchases.
- The **Live matches** tab lists the battles being played, and any of them can be watched as it happens.
- The **Flags** tab lists reports from players and signals the server raises on its own: a player who keeps leaving matches, whose game state keeps diverging from the server's, or who floods it with invalid plays.
- **Players** finds an account by name or e-mail and shows its matches, purchases and moderation history.
- **Promote** is where the game is marketed, as described in the next section.
- **Forge** lists reported and hidden packs, and the models and images players uploaded.

An operator can warn, mute, suspend or ban a player, reset their trophies or revoke purchased items, and the history of actions sits beside the player’s numbers.

54.13. Inviting friends and promoting the game

Growth uses what Codename One already has, and the game counts nothing of its own. An invitation link comes from `com.codename1.analytics.invite`. The app makes it, with a campaign, a channel and the player's code as its payload:

```
/// Opens the share sheet with the player's invite link.
public static void share(InviteDto mine) {
    Invite invite = Invites.create(InviteRequest.create()
            .campaign(CAMPAIGN)
            .channel("share_sheet")
            .payload(mine.code())
            .title("Join me in Skirmish")
            .description("A real-time card battle. Build a deck and fight me.")
            .build());
    Invites.share(invite, "Battle me in Skirmish! You get " + mine.friendCoins()
            + " coins to start with: " + invite.getUrl());
    Telemetry.inviteSent(CAMPAIGN);
}
```

The friend's app reads it back on its first start, whether the link opened the installed app or went through the store first:

```
/// From the app's start(): pick up an invite this launch carries.
public static void start() {
    Invites.setInviteListener(new InviteListener() {
        @Override
        public void inviteReceived(InviteAttribution a) {
            if (a.getPayload() == null || a.getPayload().length() == 0) {
                // A campaign link from the console: attributed in
                // analytics, nobody to reward.
                return;
            }
            Preferences.set(PENDING + "code", a.getPayload());
            Preferences.set(PENDING + "campaign", a.getCampaign() == null ? "" : a.getCampaign());
            Preferences.set(PENDING + "channel", a.getChannel() == null ? "" : a.getChannel());
            Preferences.set(PENDING + "match", a.getMatchType() == null ? "" : a.getMatchType());
            if (Session.user() != null) {
                Ui.later(Friends::claimPending);
            }
        }

        @Override
        public void attributionUnavailable(String reason) {
            // The ordinary case: most installs were not invited.
        }
    });
    Invites.checkForInvite();
}
```

The **Friends** screen shows the player's invite code and what an invitation pays, and its **Invite friends** button opens the share sheet. A friend who opens the link starts with extra coins, and the screen lists everyone who joined through the player's link and whether they have played yet.

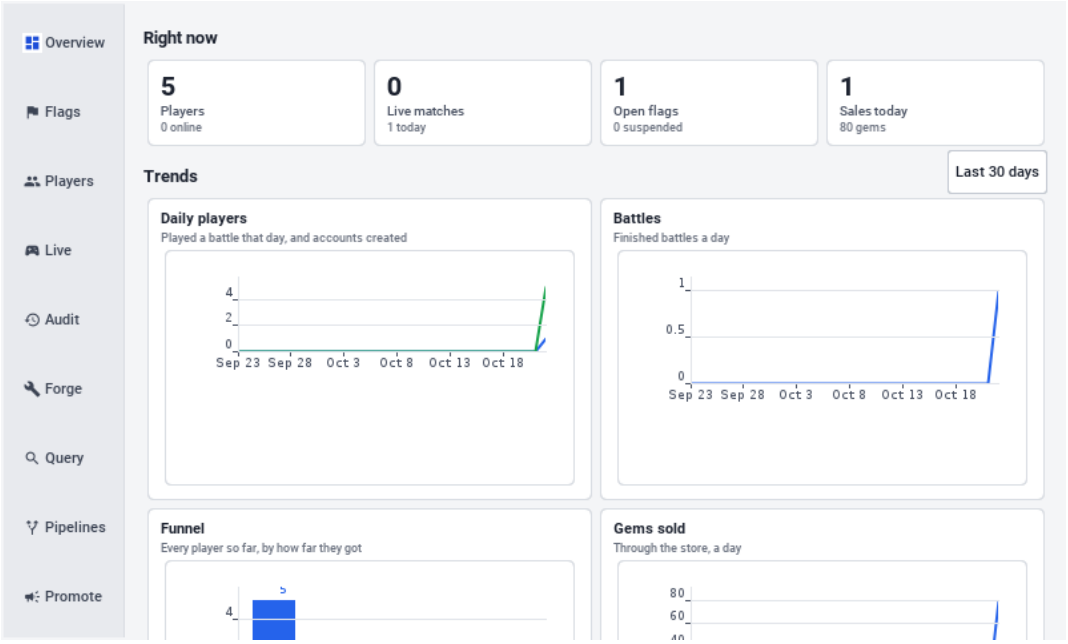
From then on, everything the friend's app reports through Codename One analytics carries the campaign and the referrer, so the invite funnel, retention and revenue per campaign are read in the Codename One console. `Telemetry` adds the player's level and trophy band as user properties, which the console slices every report by.

The server keeps only what's part of the game: the codes, who joined through whom, and the rewards. A claim is refused for an account older than a week, for a player's own code and for a second code, and the inviter is paid once the friend has played a battle, for at most ten friends:

```
/// The friend's side: the app found an invite and the player is signed in.
@Transactional(rollbackFor = IOException.class)
public RewardDto claim(String username, InviteClaimDto claim) throws IOException {
    String code = claim == null || claim.code() == null ? "" : claim.code().trim();
    ReferralCode owner = code.length() == 0 ? null : codes.findById(code);
    if (owner == null) {
        throw new ResponseStatusException(404, "That invite is not known");
    }
    String inviter = owner.getUsername();
```

```
    if (inviter.equals(username)) {
        throw new ResponseStatusException(400, "That is your own invite");
    }
    if (referrals.findById(username) != null) {
        throw new ResponseStatusException(409, "An invite was already counted for you");
    }
    Referral back = referrals.findById(inviter);
    if (back != null && back.getInviter().equals(username)) {
        throw new ResponseStatusException(400, "You invited that player");
    }
    Profile p = profiles.findById(username);
    if (p == null || p.getCreatedAt().isBefore(Instant.now().minusMillis(CLAIM_DAYS * Clock.DAY))) {
        throw new ResponseStatusException(400, "Invites count for new players only");
    }
    Referral r = new Referral();
    r.setInvitee(username);
    r.setInviter(inviter);
    r.setCode(code);
    r.setCampaign(clip(claim.campaign(), 40));
    r.setChannel(clip(claim.channel(), 40));
    r.setMatchType(clip(claim.match(), 20));
    r.setState(JOINED);
    r.setJoinedAt(Instant.now());
    referrals.insert(r);
    Profile from = profiles.findById(inviter);
    pushes.friendJoined(inviter, p.getDisplayName());
    return progression.missionReward(username,
            "A gift from " + (from == null ? "your friend" : from.getDisplayName()), FRIEND_COINS, 0);
}
```

The **Promote** tab in the console is where the operator works. It opens the analytics console, and it sends Codename One push notifications to a segment of players: everyone, players away for some days, new players, or those who came through an invitation. A broadcast is counted before it's confirmed, the server sends at most five a day, and each one carries a campaign name in its data, which the app reports when the notification is tapped:



```
@Transactional(rollbackFor = IOException.class)
public BroadcastDto broadcast(String admin, BroadcastDto b) throws IOException {
    check(b, true);
    long now = Clock.now();
    if (broadcasts.countBySentAtGreaterThan(Instant.ofEpochMilli(now - Clock.DAY)) >= MAX_BROADCASTS_PER_DAY) {
        throw new ResponseStatusException(429, "At most " + MAX_BROADCASTS_PER_DAY
                + " broadcasts a day: players who are pushed too often switch notifications off");
    }
    String id = Ids.next();
    String campaign = b.campaign() == null || b.campaign().trim().length() == 0
            ? "broadcast-" + id.substring(0, 8) : b.campaign().trim();
    int reached = pushes.broadcast(audienceOf(b), id, b.title().trim(), b.body().trim(), screen(b.screen()),
            campaign);
    Broadcast row = new Broadcast();
    row.setId(id);
    row.setSegment(b.segment());
    row.setDays(b.days());
    row.setTitle(b.title().trim());
    row.setBody(b.body().trim());
    row.setScreen(screen(b.screen()));
    row.setCampaign(campaign.length() > 40 ? campaign.substring(0, 40) : campaign);
```

```
    row.setTargets(reached);
    row.setSentBy(admin);
    row.setSentAt(Instant.ofEpochMilli(now));
    broadcasts.insert(row);
    record(admin, "BROADCAST", b.segment() + ": " + b.title().trim());
    return dto(row);
}
```

The same tab sets the spotlight, a banner at the top of every player's home screen, and makes campaign links for adverts and posts: invite links without a player's code, which reward nobody and attribute everyone they bring in.

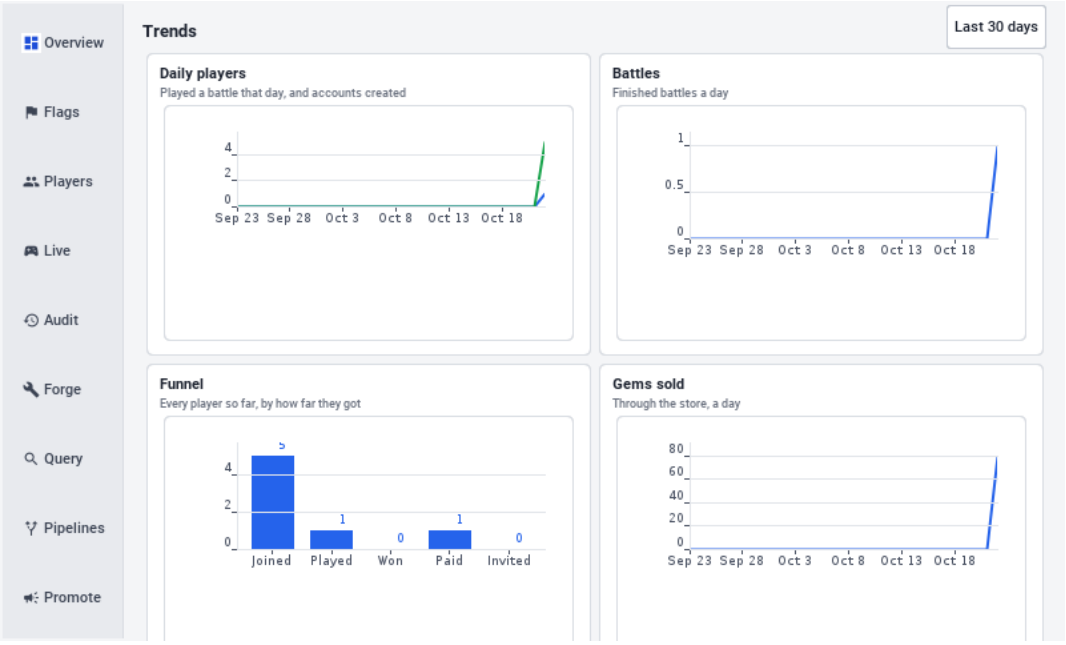
The store's rating prompt is Codename One's `AppReview`, asked after a win and only of a player who keeps coming back:

```
// The store's own rating prompt, asked only of a player who has come
// back: five launches over three days, and never twice in a month.
// ResultForm asks after a win, the moment a player is happiest.
AppReview.getInstance().setMinimumLaunches(5).setMinimumDaysInstalled(3)
        .setDaysBetweenPrompts(30).registerSession();
```

On a desktop or a tablet, the console puts its tabs in a sidebar:

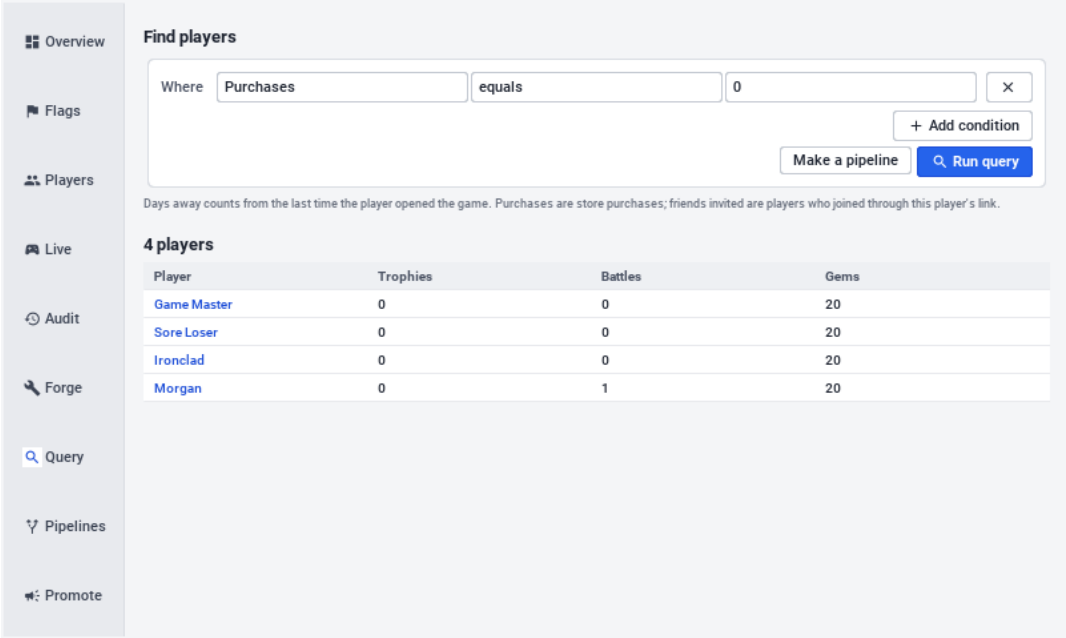
```
// On a desktop or a tablet the console is a side bar and a page, the
// way an operator's tools usually are; on a phone, tabs along the top.
if (wide()) {
    tabs.setTabPlacement(Component.LEFT);
    tabs.setTabTextPosition(Component.RIGHT);
} else {
    // Nine tabs do not fit across a phone: they scroll sideways.
    tabs.getTabsContainer().setScrollableX(true);
    tabs.setTabTextPosition(Component.BOTTOM);
```

```
}
```



`run-e2e.sh` runs its tests a second time on Linux with the simulator as a desktop window, and that pass captures the console's tabs.

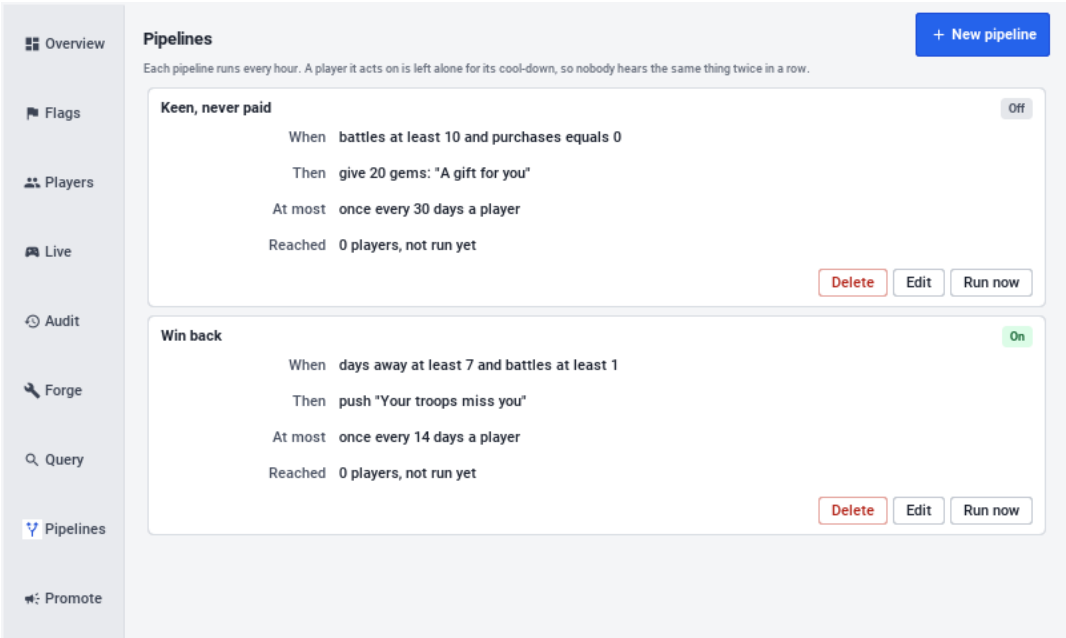
54.14. Reports, queries and engagement pipelines



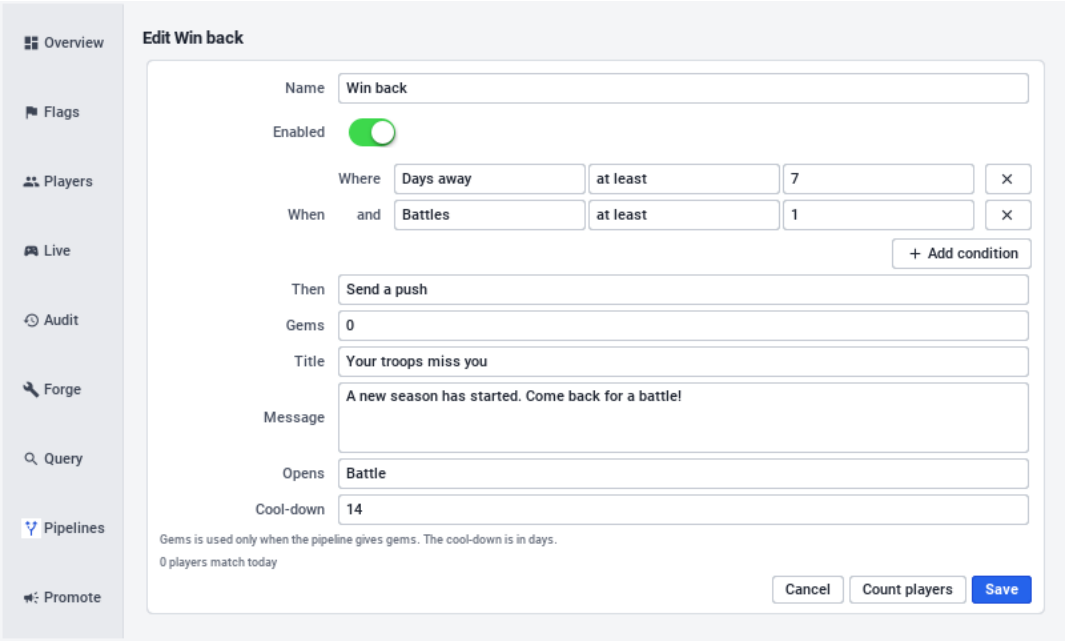
The console is an operator's tool, so it doesn't wear the game's theme. Its styles are a separate set of `Desk` UIIDs in the same `theme.css`: a light page, cards with thin borders, and one accent colour. Every form puts its labels in a right-aligned column of one width, so the fields start at the same place:

```
/// A label and its field on one line, the label in a column of its own,
/// right aligned, so every field of a form starts at the same place.
static Container field(String label, Component input) {
    Label l = new Label(label, "DeskLabel");
    l.setPreferredW(CN.convertToPixels(AdminConsole.wide() ? WIDE_LABEL_MM : LABEL_MM));
    Container c = new Container(new BorderLayout());
    c.setUIID("DeskFieldRow");
    c.add(BorderLayout.WEST, l).add(BorderLayout.CENTER, input);
    return c;
}
```

The **Overview** tab draws its trends with Codename One's charts package: daily players and new accounts, battles, gems sold, the funnel from joining to paying, retention, and the trophy ladder. The server's `Insights` builds them from the game's own records, accounts, battles and purchases, so they need no extra tracking. What players do inside the app, the screens they open and the pushes they read, is in Codename One analytics, one button away.



The **Query** tab finds players by conditions on what the server knows about them: days since they last played or joined, trophies, battles, wins, gems, coins, purchases and friends invited. **Make a pipeline** turns the same conditions into an automated pipeline.



A pipeline is a rule of the form "players who match these conditions get this": a push that opens a chosen screen, or gems. Each player is reached at most once per cool-down, and the server runs every enabled pipeline once an hour, on one server at a time:

```
/// Every enabled pipeline, once an hour, on one server at a time.
/// Transactional itself: a call to [#run] from here is a call on `this`,
/// which does not go through the transaction wrapper.
@Scheduled(fixedDelay = EVERY, initialDelay = 5L * 60 * 1000, lock = "skirmish-pipelines")
@Transactional(rollbackFor = IOException.class)
public void runAll() throws IOException {
    for (Pipeline p : pipelines.byName()) {
        if (p.isEnabled()) {
            run(p.getId());
        }
    }
}
```

The demo seeds two. **Win back** pushes "Your troops miss you" to a player away for a week who has played before, and **Keen, never paid** gives 20 gems to a player with ten battles and no purchases. The **Count players** button shows how many players match today before a pipeline is saved.

54.15. Tutorial: Growing your game

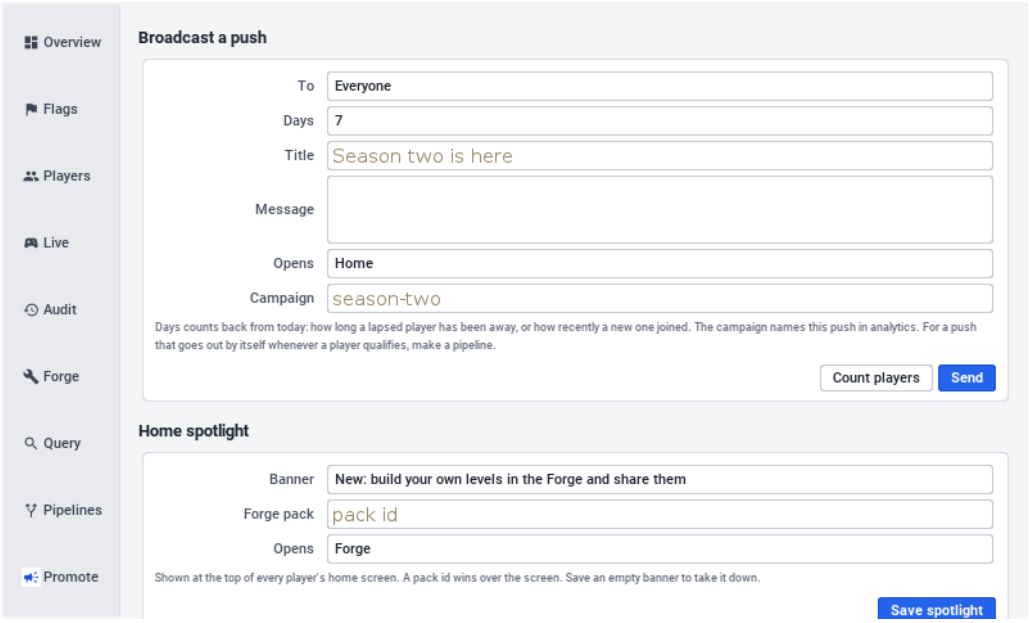
A game that's finished still needs players, and players who come back. This tutorial walks through the levers Skirmish already has, in the order a new game usually needs them, and what to read in the analytics console to know whether each one is working. Everything here is measured by Codename One analytics, so nothing needs a dashboard of its own.

54.15.1. Step 1: Switch the measurements on

1. Turn on analytics for the app in the Codename One console. `Telemetry` sends through `CodenameOneAnalyticsProvider` once the player agrees on the consent screen; without that agreement nothing leaves the device.
2. Set `AppConfig.PUSH_APP_KEY` to the app's push key from the console's Push section. Without it the game works, but sends no notifications.
3. Run a few battles in the simulator. The events, `battle_start`, `battle_end`, `share` and the rest, appear in the console's event list, and every report can be sliced by the `level_band` and `trophy_band` user properties.

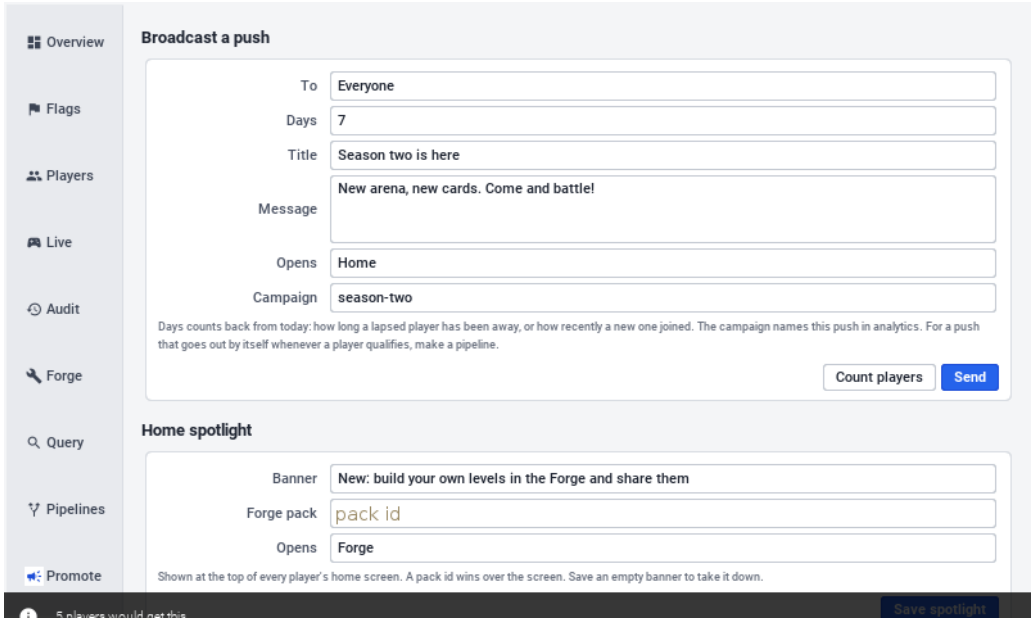
54.15.2. Step 2: Read the funnel

The first report to open is the funnel a new player walks: `sign_up`, the training battle's reward, the first `battle_end` with a win, `deck_saved`, `purchase`. The step where most players stop is the one to work on first:

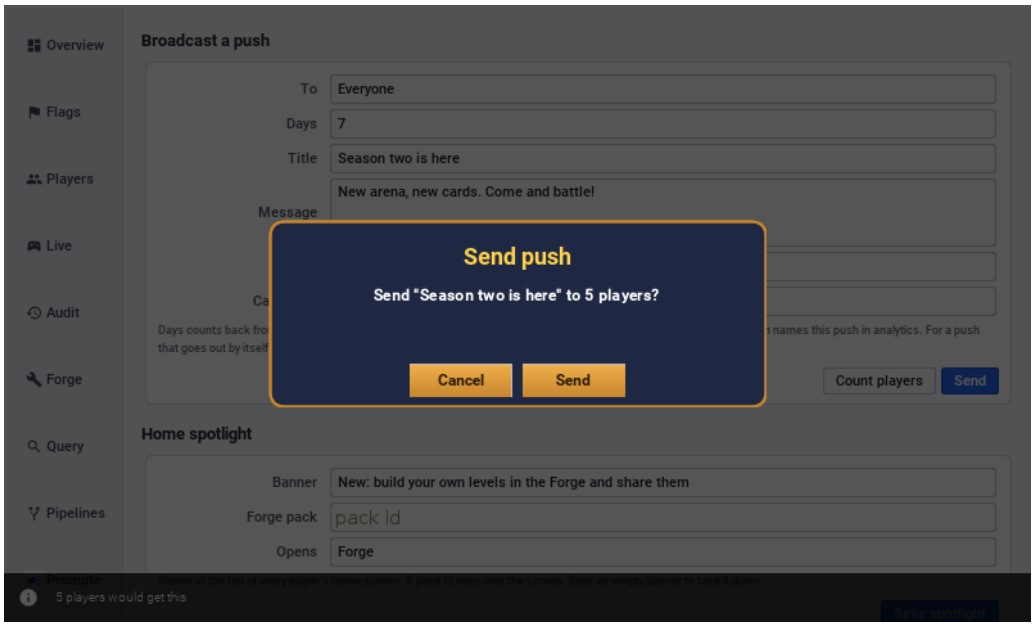


- Players who sign up and never battle need a shorter way in. The training battle is in `Tutorial`; its lines are in a `MissionDef`, and a shorter one is a smaller list.
- Players who battle once and leave need a reason to return. That's what the next steps are for.

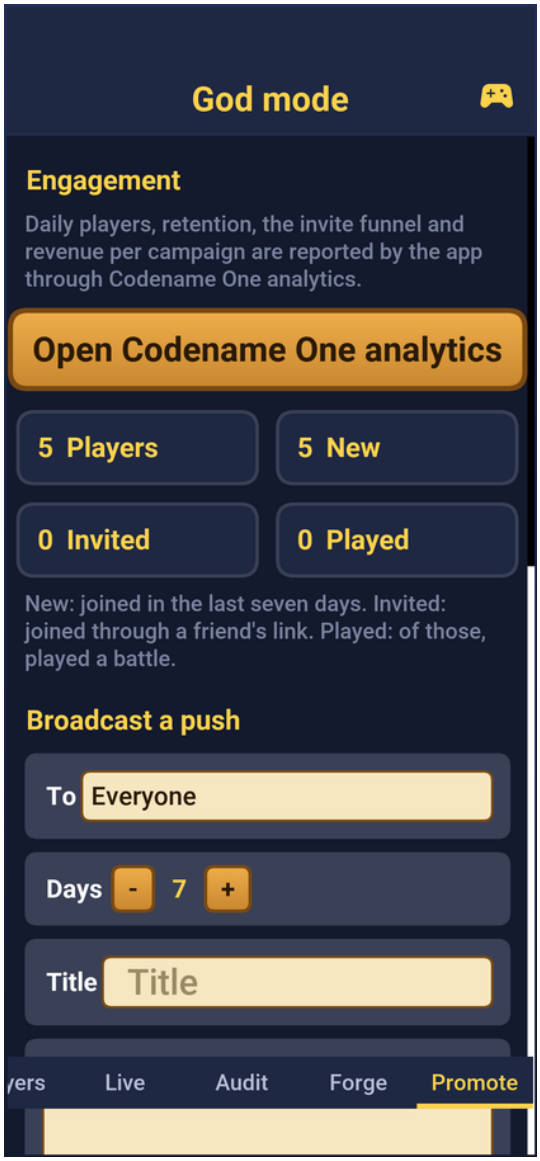
- Players who play but never spend may need a cheaper first offer. The prices are in the server's `Catalog`.



54.15.3. Step 3: Bring players back with push



Retention, the share of players who return a day and a week after they installed, is the number most games live or die by. Push brings players back, but only when it's rare and worth reading.



1. Sign in as the administrator, open the console, and choose **Promote**.

2. Under **Broadcast a push**, choose who it's for. **Away for a while** with 3 days reaches players who stopped recently and still remember the game.
3. Write a title and a message about something new, and choose the screen a tap opens: the shop for a sale, the Forge for new content.
4. Give it a campaign name, such as `comeback-march`. The app reports a `push_open` event with that name when the notification is tapped, and the campaign is how the console tells broadcasts apart.
5. Choose **Count players**, then **Send**, and confirm.

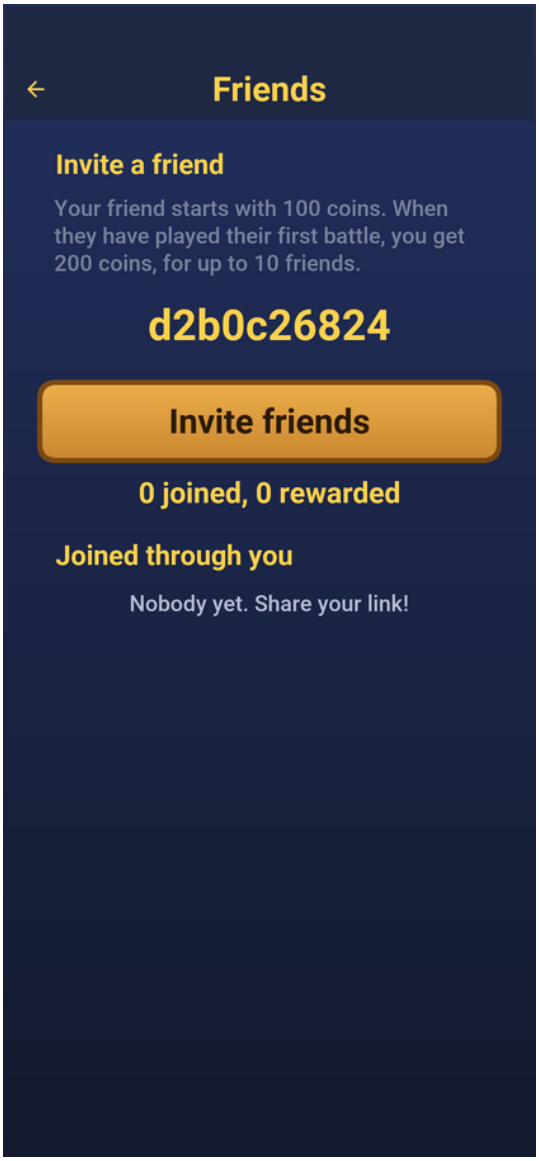
5 players would get this

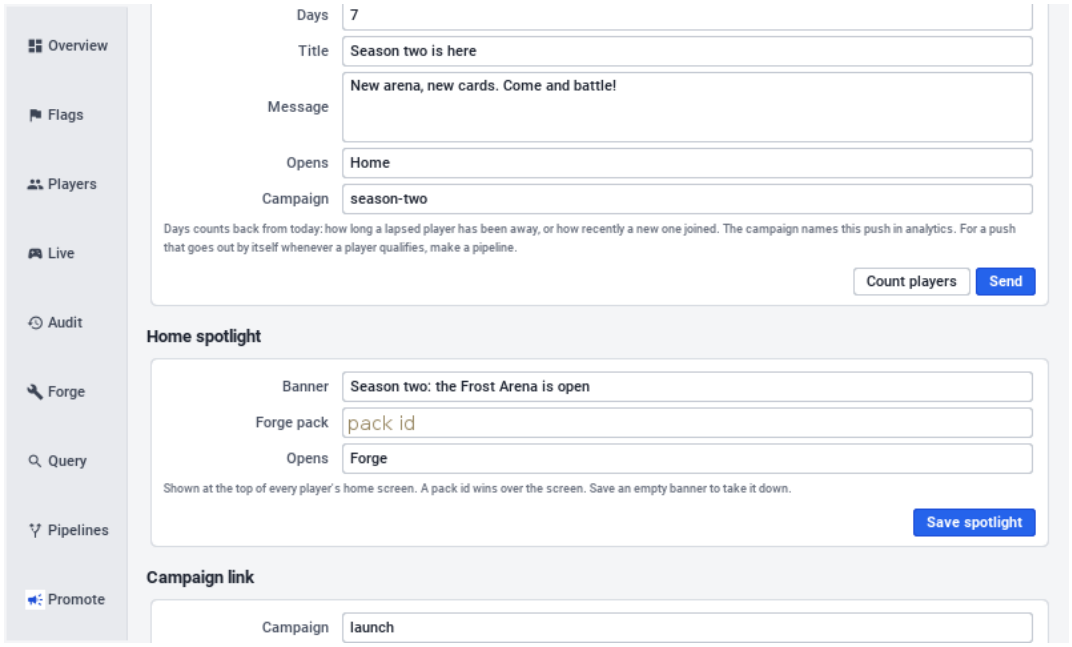


A day later, compare that campaign's `push_open` count with the number of players it was sent to, and the cohort's return rate with the week before. A broadcast that nobody opens is worse than none: it teaches players to ignore the next one. The server allows five a day for that reason, and `MAX_BROADCASTS_PER_DAY` in `Promotion` is the place to lower it.

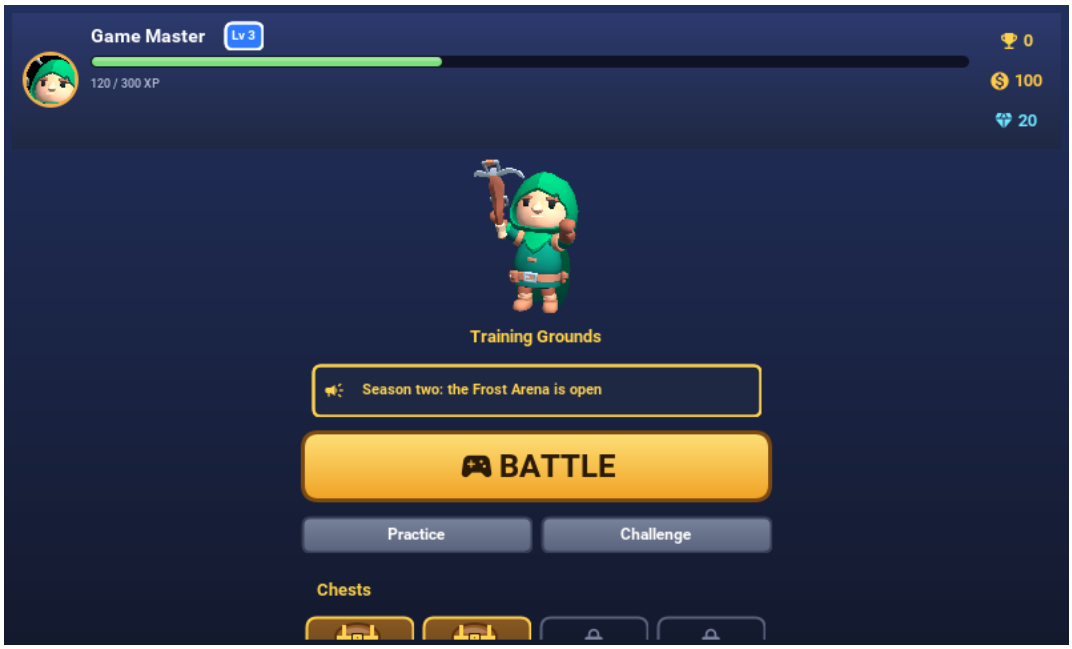
54.15.4. Step 4: Grow through invitations

An invitation is the cheapest player a game gets, because a friend is already playing. The rewards decide how often players send one:

1. The amounts are constants at the top of the server's `Referrals`: `FRIEND_COINS` for the friend, `INVITER_COINS` and `INVITER_XP` for the player who invited them, and `MAX_REWARDED` for how many friends pay.
2. The inviter is paid only once the friend has played a battle, so a reward can't be farmed with empty accounts, and the friend must claim within a week of joining.
3. In the console, compare the `share` events with `content` set to `invite` against the installs attributed to the `friends` campaign and their `first_battle` and `first_win` conversions. When many links are shared and few bring anyone in, raise the friend's reward; when few are shared at all, make the **Friends** screen easier to reach.



Set the `invite.domain` build hint to a domain of your own before release, so the links carry the game's name rather than the default service.



54.15.5. Step 5: Campaign links for the world outside

An advert, a post or a newsletter gets a link from **Campaign link** on the same tab. It's an invitation without a player's code: it opens the store for anyone without the game, rewards nobody, and every player it brings in is reported under its campaign. Use one name per channel, such as `newsletter-may` and `video-launch`, and the console compares what each one brought in, down to revenue.

54.15.6. Step 6: The home screen spotlight

The banner at the top of every player's home screen is the quickest message there is: no notification permission, no store review. Set it under **Home spotlight** with a line of text and either a Forge pack, which opens that pack, or a screen. Use it for what's new this week; take it down by saving an empty banner.

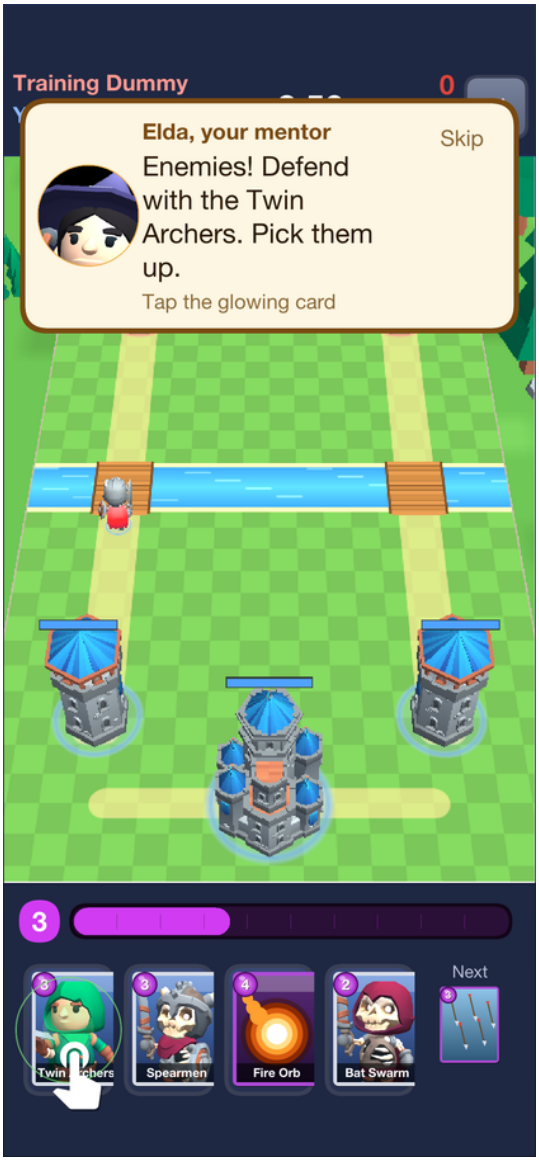
54.15.7. Step 7: Ratings

A store's rating is what a stranger sees first. `AppReview` asks only players who've launched the game five times over three days, never more than once a month, and only after a win. A low score goes to feedback rather than the store. Tune those numbers in `Skirmish.runApp`.

54.16. The training battle

`Tutorial` is a script of steps run over an ordinary practice battle. Each step freezes the clock, shows Elda's line and, if it asks for something, the finger and the one card that can be played. Changing the lesson means changing the list of steps.



The mentor, Elda, explains one idea at a time while the clock is frozen: the red towers are the targets, cards cost elixir, and elixir refills by itself. Then she asks for something and a finger shows how. It points at the card to pick, then slides from the card to the spot to drop it, and only that card can be picked while she's teaching it.

The lesson covers attacking, defending when the enemy sends troops, and throwing a spell at a tower. Finishing the battle against a slow opponent pays once: coins, experience, a chest and the first achievement. A player can replay the lesson from **How to play** on the home screen.

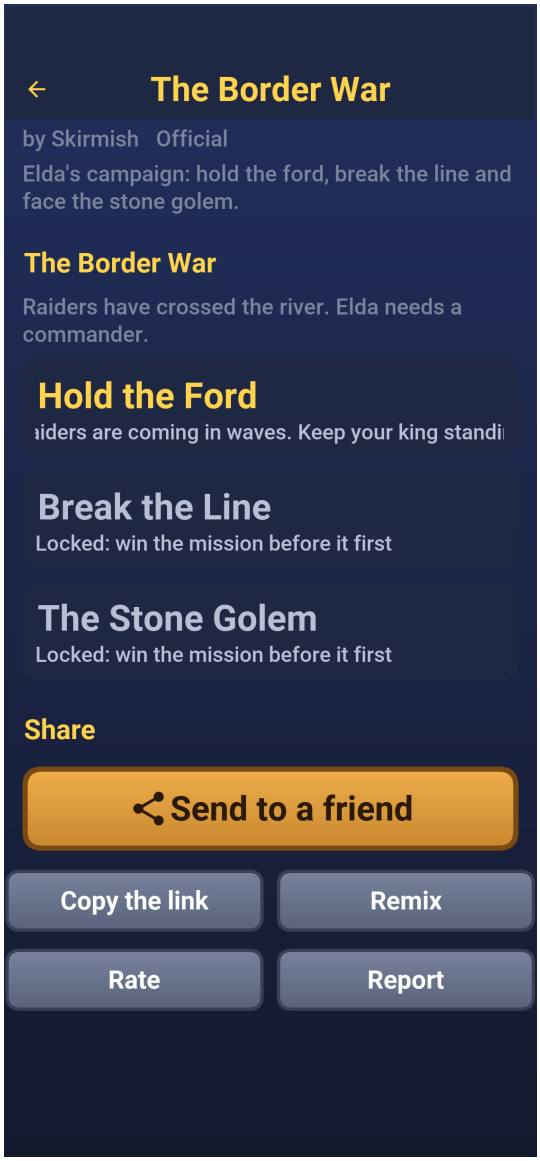
The app can also drive itself through its own screens: `Tour` signs in, collects rewards, visits the deck and plays a battle, which is how the promotional video is recorded. Any Codename One app can be driven the same way without code of its own, through its built-in MCP server; see the MCP headless API.

54.17. Content packs and the Forge

Everything the Forge edits is data in `rules`: a `ContentPack` holds cards (`CardDef`), arenas (`Arena`), missions (`MissionDef`) and campaigns (`CampaignDef`), and `PackCodec` reads and writes it as JSON. The classic game is the same model: `Arena.CLASSIC` and the built-in cards describe the field and the cards the battle always had, so the golden replays still pass. A mission is played by `MissionRun`, which builds a `Match` from the pack's arena and cards, plays the scripted waves and the bot, and decides the stars.



The Forge is the game's own level editor, in the same app on every platform. Players build packs of new cards, arenas, missions and campaigns, share them with a link, and play what others made. The game's designers use the same editor: a pack an operator marks official appears first, for everyone. **Forge** on the home screen lists the packs. **Official** comes with the game, **Popular** and **New** are what players published, and **Yours** holds a player's own drafts and packs.

54.17.1. Playing a pack

A pack shows its campaigns, each a list of missions that open one after another, and the stars won in each. A mission can be anything the author wrote: hold the castle for two minutes, win three crowns against waves of enemies, or beat a bot with a fixed deck. Its story is told during the battle, and a line that stops the clock waits for **Next**, the way the training battle does.

A mission pays up to three stars. The first is for winning, and the second and third are for what the author asked, such as keeping towers standing or winning before a set second. Rewards come once per star, and the server plays every mission again before it believes the stars, as Section 54.17.4, “Results are played again” shows.

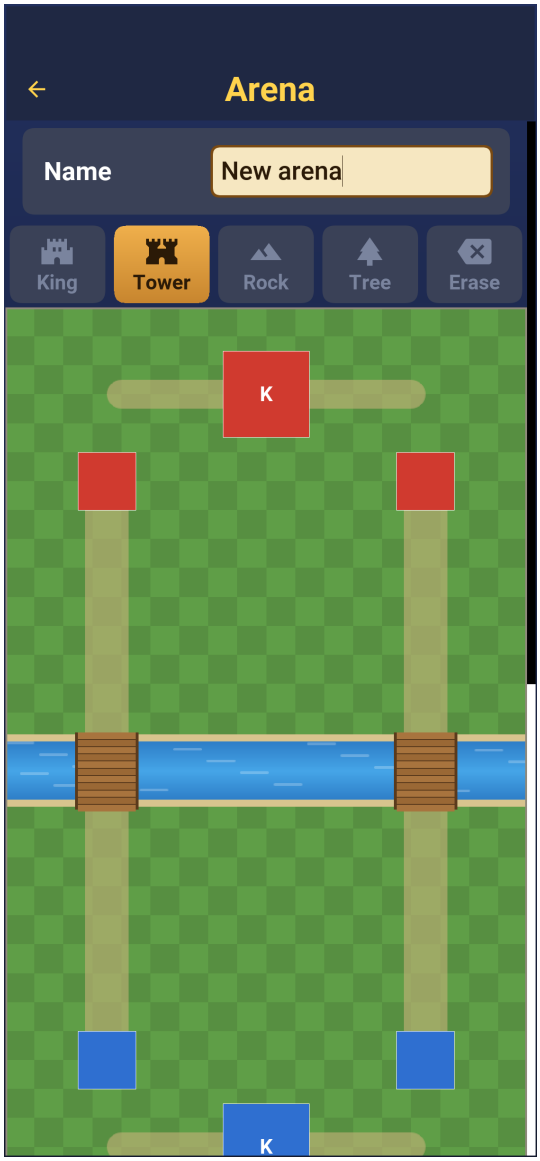
Share sends a link that opens the pack in the app, and **Remix** copies a pack into a new one of the player's own to change.



54.17.2. Making a pack

Create a pack starts one with a single mission against the bot, ready to play. The pack editor lists its cards, arenas, missions and campaigns, shows any problem that would stop it from being published, and saves a draft that only its author sees until **Publish**.

- Cards start from any card in the game and change its cost, hit points, damage, speed, range, targets and what it spawns. A card can look like any of the game's characters, or like a rigged glTF model imported from a `.glb` file, with its animations matched to walking, attacking and dying on a turntable preview. An imported model is visible to the author and to anyone they share the pack with straight away, and to everyone once a moderator has approved it.
- Arenas are drawn on a grid: castles, towers, rocks and trees placed with a tap, mirrored to the enemy's half as they're placed, on a field of any size with one to three lanes and a frost or desert theme.
- Missions pick an arena, the goal, the length of the battle, each side's elixir and deck, the waves of enemies that arrive at set seconds, the lines of the story, the stars and the reward. **Test play** plays the mission at once.
- Campaigns put missions in order, with a story before the first and after the last.

54.17.3. Limits

A pack comes from a stranger, so `Validator` checks every number in it before the server publishes it and before the app loads it. The limits keep a pack from stalling a phone, a server or the economy, not from being odd:

```
public static final int MAX_CARDS = 40;
public static final int MAX_ARENAS = 10;
public static final int MAX_MISSIONS = 60;
public static final int MAX_CAMPAIGNS = 10;
public static final int MAX_CAMPAIGN_MISSIONS = 30;
public static final int MAX_ASSETS = 40;
public static final int MAX_DIALOG = 60;
public static final int MAX_TEXT = 280;
public static final int MAX_LONG_TEXT = 1200;
/// A model travels base64 encoded in one request, under the server's 8 MB body limit.
public static final int MAX_MODEL_BYTES = 5 * 1024 * 1024;
public static final int MAX_IMAGE_BYTES = 1024 * 1024;
/// What any one mission may pay, on top of the server's caps for packs that
/// are not official.
```

```
public static final int MAX_REWARD_COINS = 500;
public static final int MAX_REWARD_XP = 200;
```

An uploaded model is checked by `GlbInspector` on the server: the size, the `.glb` header, and caps on its nodes, meshes, joints, and animations. It's stored by its SHA-256 and waits in the console's **Forge** tab until a moderator approves it.

54.17.4. Results are played again

The app plays a mission locally and sends its replay. The replay names the pack, its content hash and the mission, so the server finds the exact version that was played, plays the player's commands again with `MissionRun.verify` and pays only for stars it saw won, and only once:

```
Match played;
try {
    played = MissionRun.verify(pack, ref.mission, replay);
} catch (IllegalArgumentException e) {
    throw new ResponseStatusException(400, e.getMessage());
}
int won = mission.stars(played);

String key = Ids.sha256(username + "|" + p.getId() + "|" + ref.mission);
MissionStars row = stars.findById(key);
if (row == null) {
    row = new MissionStars();
    row.setId(key);
    row.setUsername(username);
    row.setPackId(p.getId());
    row.setMissionId(ref.mission);
    stars.insert(row);
}
row.setPlays(row.getPlays() + 1);
row.setStars(Math.max(row.getStars(), won));
int newStars = Math.max(0, won - row.getPaidStars());
row.setPaidStars(row.getPaidStars() + newStars);
row.setUpdatedAt(Instant.now());
stars.save(row);
p.setPlays(p.getPlays() + 1);
packs.save(p);

int coins = mission.rewardCoins * newStars / 3;
int xp = mission.rewardXp * newStars / 3;
if (username.equals(p.getOwner())) {
    // Testing your own mission is free, and pays nothing.
    coins = 0;
    xp = 0;
} else if (!p.isOfficial()) {
    coins = Math.min(coins, COMMUNITY_MISSION_COINS * newStars / 3);
    xp = Math.min(xp, COMMUNITY_MISSION_XP * newStars / 3);
```

```
    coins = spendDailyAllowance(username, coins);
}
```

The app's side starts the battle, fetches the pack's files first, and posts the result when it ends; a test play from the editor posts nothing:

```
public final class MissionPlay {
    private MissionPlay() {
    }

    public static void start(final ContentPack pack, final String missionId, final boolean test,
            final Runnable back) {
        List<String> files = new ArrayList<String>();
        for (CardDef c : pack.cards) {
            if (c.model() != null && c.model().startsWith("asset:")) {
                files.add(c.model().substring(6));
            }
        }
        ForgeFiles.fetch(files, () -> Ui.later(() -> battle(pack, missionId, test, back)), Ui::failed);
    }

    private static void battle(final ContentPack pack, String missionId, final boolean test, final Runnable back) {
        MissionDef m = pack.mission(missionId);
        CardSet cards = pack.cardSet();
        CardArt.use(cards);
        MissionDriver driver = new MissionDriver(pack, missionId, System.currentTimeMillis(),
                m.playerDeck == null ? ownDeck(cards) : null);
        BattleForm.mission(driver, new BattleForm.MissionEnd() {
            @Override
            public void finished(MissionDriver d) {
                CardArt.use(null);
                int stars = d.run().stars();
                if (test) {
                    Dialog.show(stars > 0 ? "Won" : "Lost", stars > 0 ? PackScreen.starText(stars)
                            + "  -- a test battle counts for nothing." : "The enemy won this one.", "OK", null);
                    back.run();
                    return;
                }
                Api.forge().result(new MissionResultDto(d.run().replay().encode()), Net.to(

            String[] deck = d.toArray(new String[d.size()]);
            if (cards.isValidDeck(deck)) {
```

```
                return deck;
            }
        }
        return Deck.starter();
    }
}
```

54.17.5. Shipping official content

The official pack is seeded from `Samples.official()` when the server starts. A designer can instead build a campaign in the Forge, publish it, and mark it official in the console; an official pack is listed first and pays the rewards its missions set, while a community pack's rewards are capped per star and per day. The amounts are constants at the top of the server's `Forge` class.

54.18. Tests

`rules` has the determinism tests and the golden replays; `backend` plays whole online matches over its sockets and checks receipts, progression, moderation and the Forge's publishing and mission results, the invite rewards and their refusals, and the broadcast limits; `run-e2e.sh` drives the app through its screens in the simulator against a running server and takes the screenshots in this guide:

```
mvn -pl rules test
mvn -pl rules,shared,backend -Dcodename1.platform=backend test
./run-e2e.sh
```

Chapter 55. Dash: Making the runner your own

Dash is an endless runner built around the things a game engine leaves to you. Friends race on the same track at the same moment and talk while they run, their voices going peer to peer over WebRTC (Section 55.6, “Races in lockstep”). A player picks two points on a real street map and runs that route through their own city, the street names overhead and the landmarks beside the track (Section 55.8, “City runs”). And every score on a board is a run the server played again from its inputs, by the same Java rules module the game runs. In other game frameworks each of those is a plugin, a second language or a separate backend. Here they’re ordinary Codename One code in one project, beside the levels that are data, the camera that swings from side on into 3D halfway down a track, and the console that runs the game.

Dash shares the module layout, the accounts and sign-in, push notifications and the operations console with Skirmish. This chapter shows where each part lives and what to change to make the game yours.

55.1. Running it

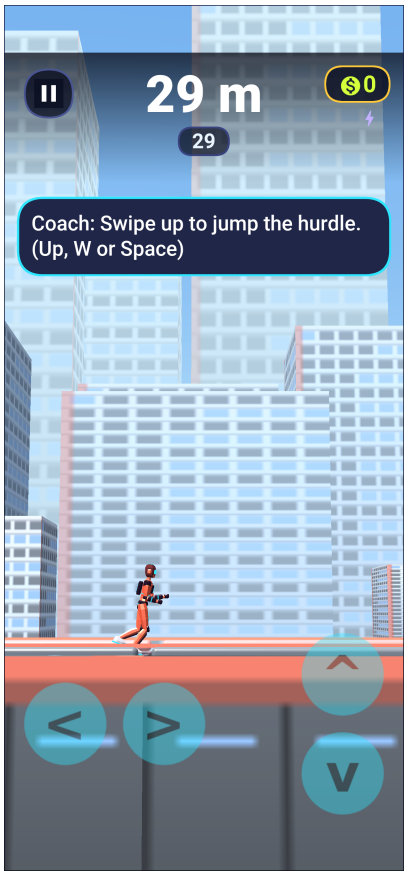
The project is in `scripts/dash`, and the Initializr generates it under your own package and name. Start the server on the development profile, which keeps its database in memory, seeds the demo accounts and simulates purchases and push notifications:

```
CN1_PROFILE=dev backend/server.sh run
```

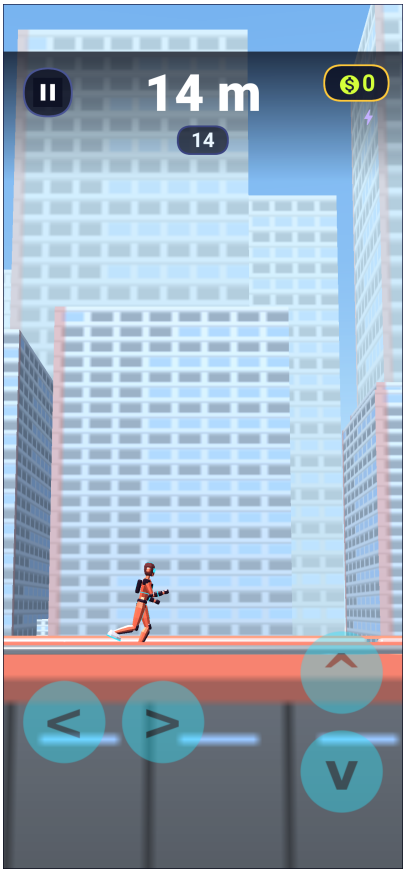
Then run the app in the simulator:

```
mvn verify -Psimulator -DskipTests -Dcodename1.platform=javase
```

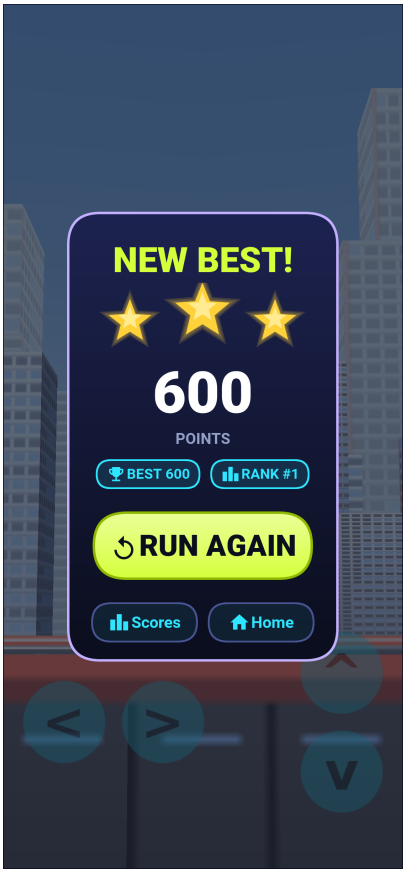
The demo accounts are `player@`, `rival@`, `trouble@` and `admin@dash.example`, each with the password `dash-demo`. For the native iOS app, generate the Xcode project on a Mac and open it:



```
mvn package -DskipTests -Dcodename1.platform=ios -Dcodename1.buildTarget=ios-source -Dopen=false
```

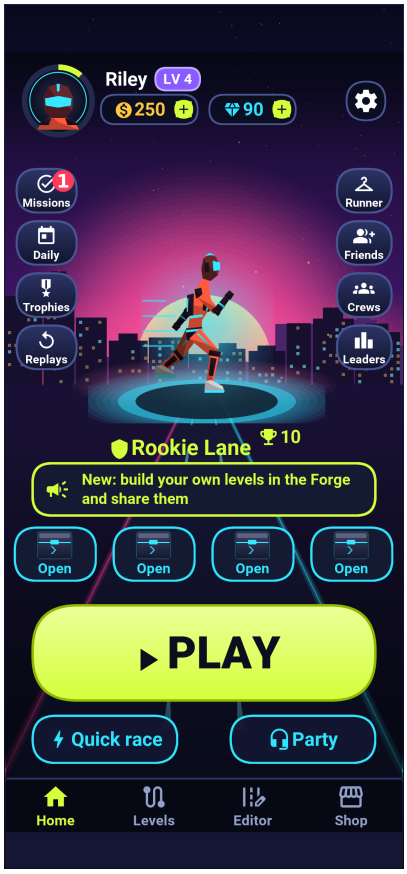


The tests run in three layers: the rules on their own, the server with whole races over its rooms, and the app in the simulator against a real server:

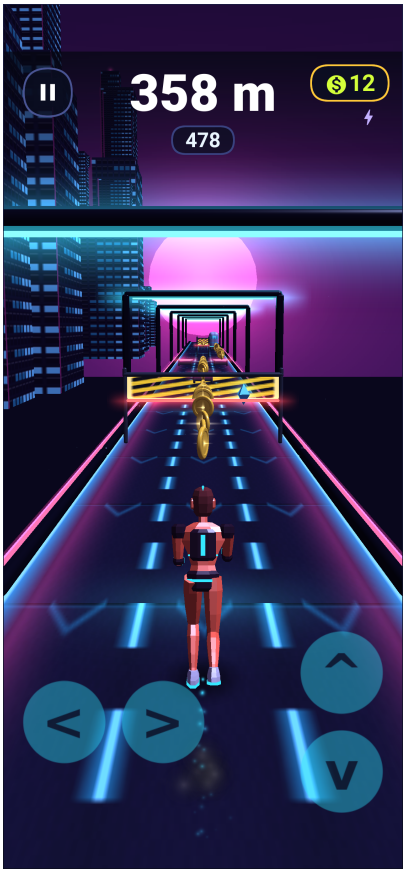


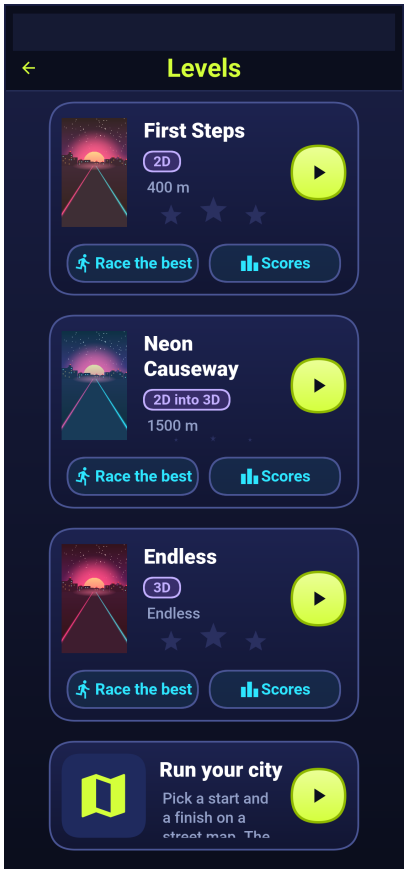
```
mvn -pl rules test
mvn -pl rules,shared,backend -Dcodename1.platform=backend test
./run-e2e.sh
```

55.2. What the sample does



A new player is taken straight into **First Steps**, a short level in which a coach introduces one move at a time: jump the hurdle, slide under the barrier, change lanes around the hauler. On a touch screen four buttons sit under the thumbs — left with slide above it in one corner, right with jump above it in the other — drawn by the framework's `TouchControls`; swipes and taps work anywhere else, and the settings can hide the buttons. On a desktop the keyboard (arrows, WASD and space) drives the same four inputs.





The home screen leads to the **Levels**. Each official level shows its stars and has three buttons: **Run** plays this week's track for it, **Race the best** runs it against the ghost of the week's best run, and **Scores** opens its boards — all time, this week, today, friends, and one per crew. Any row on a board opens that run's replay, with a scrubber, a pause, speeds, and a choice of whom the camera follows.

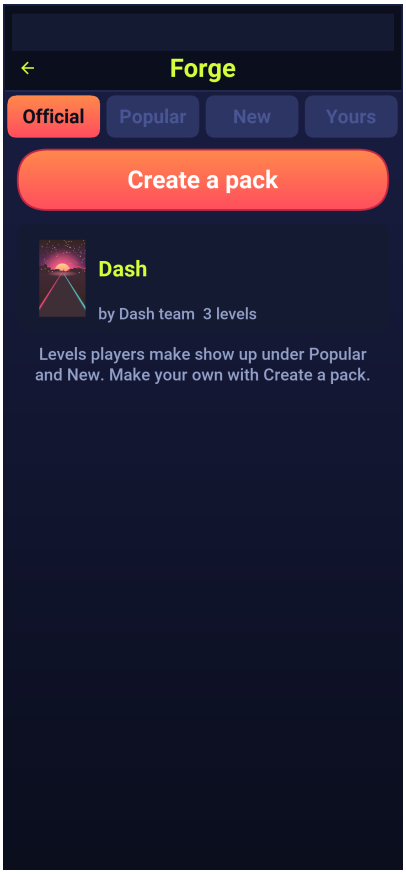
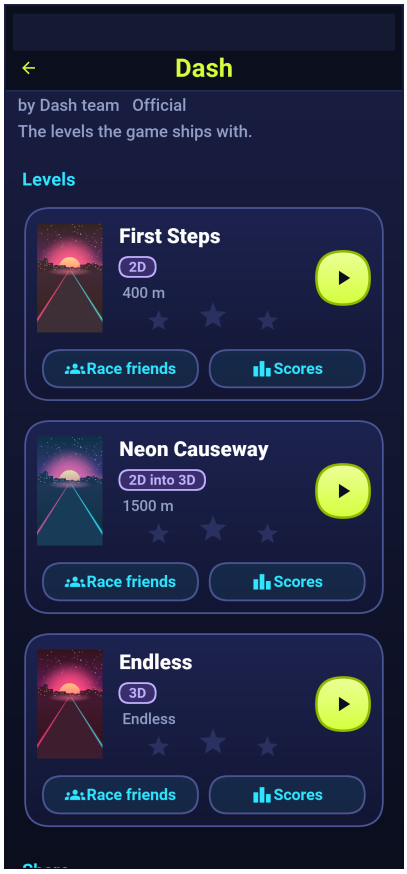
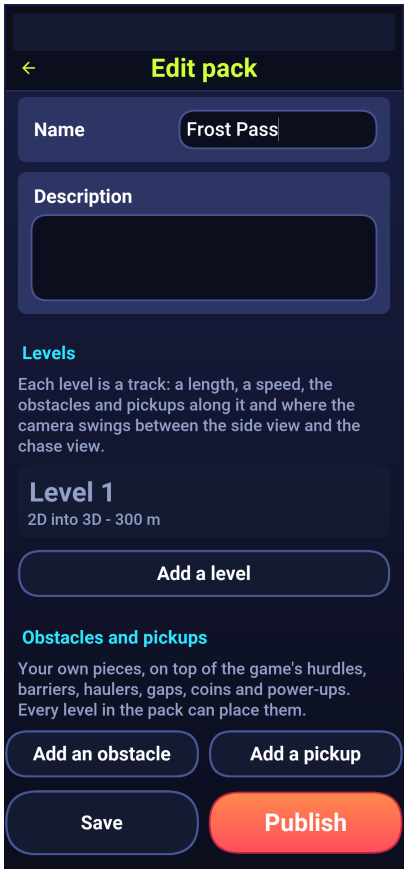
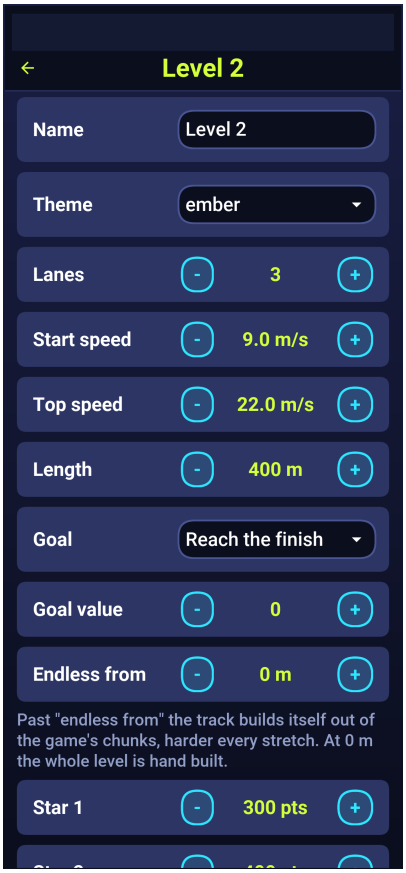
Quick race drops the player into a race with whoever is waiting for that level, and fills the empty lanes with bots after a few seconds. The **Race friends** button opens a party with a code and a link to share. Everyone who joins can talk: the microphone button connects each pair of players directly, and a muted player shows as muted to the rest. When the host starts, every phone runs the same seed in lockstep, the other runners appear in their own lanes, and the result screen ranks the

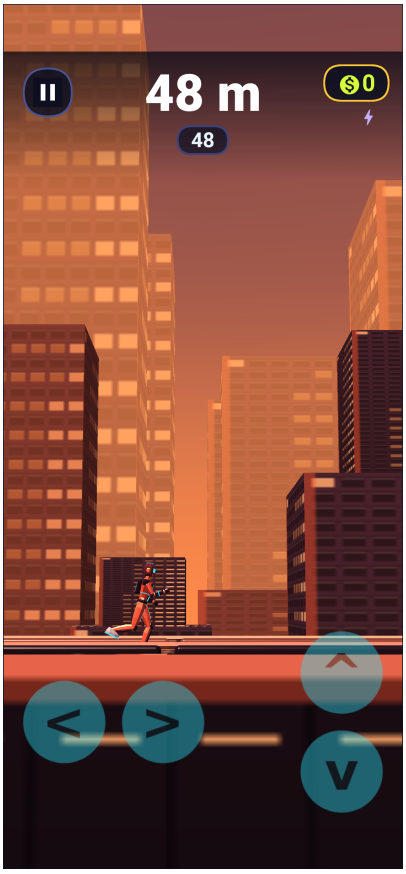


places and pays out trophies and coins. The **Daily dash** is one endless track a day, the same for everyone, with its own board.









Track editor is where players make levels. A pack holds levels and the pieces they use, and is published for others to play, rate, race, and remix. Every level in a pack has its own board.

55.3. The modules

Module	What it holds
`rules`	The deterministic simulation: tracks, runners, obstacles, pickups, camera cues, the bot, replays and level packs. No floating point, no clock, no `java.util.Random`.
`shared`	The data transfer objects and `@RestClient` interfaces.
`common`	The app: the 3D track, the menus, the track editor, the race lobby and voice, the store, the admin console.
`backend`	The server: accounts, re-simulated scores and leaderboards, the lockstep race rooms, level packs and moderation, progression, receipts, push.

55.4. One simulation, two cameras

A level is a `LevelDef`: a number of lanes, a speed curve, a length or a goal, the obstacles and pickups placed along it, a procedural tail built from chunks that get harder with distance, the coach's lines, and **camera cues**. Here is the official level that starts as a side-scroller and becomes a 3D runner:

```
/// Opens side-on and swings into the chase camera at 300 metres, where the
/// lanes appear: the faux-2D-to-3D level.
public static LevelDef causeway() {
    LevelDef d = new LevelDef(CAUSEWAY, "Neon Causeway");
    d.theme = "neon";
    d.length = 1500 * Track.UNIT;
    d.stars = new int[] {900, 1400, 1800};
    d.cue(0, ViewMode.SIDE_2D, 0);
    d.cue(300, ViewMode.CHASE_3D, 40);
    for (int m = 60; m < 280; m += 45) {
        d.place(m, (m / 45) % 2 == 0 ? HURDLE : BARRIER, Placement.ALL_LANES);
        d.place(m + 15, COIN, Placement.ALL_LANES);
    }
    d.dialog.add(new DialogLine(290 * Track.UNIT, "Vee", "The road opens up. Swipe sideways!", Input.LEFT));
    d.proceduralFrom = 340 * Track.UNIT;
    d.difficultyStep = 180 * Track.UNIT;
    d.chunks.addAll(chunks());
    return d;
}
```

The cues never reach the simulation. A runner always has a lane, a height and a distance, and a hurdle is cleared the same way whether the player sees it from the side or from behind. The camera is the renderer's business: `RunView` reads the cue under the runner, eases between the two framings, and leaves the rules alone. Because of that, a level can change its view anywhere without changing who wins.

```
/// Places the camera for `mode`, into `out`: eye x, y, z, target x, y, z,
/// field of view, then the up vector's z (0 for upright, -1 looking down).
private static void framing(ViewMode mode, float x, float y, float z, float[] out) {
    if (mode == ViewMode.SIDE_2D) {
        // Off to the right, at the deck's height and tilted up: the runner
        // a third in from the left with the track ahead in view, the deck
        // in the lower third, and open sky over the skyline. A portrait
```

```
        // frame is narrow along the track, so the camera stands well back
        // to see enough of it ahead.
        out[0] = 24f;
        out[1] = 0.9f + y * 0.3f;
        out[2] = -z - 1.3f;
        out[3] = 0f;
        out[4] = 4.6f + y * 0.3f;
        out[5] = -z - 1.3f;
        out[6] = 42f;
        out[7] = 0f;
    } else if (mode == ViewMode.TOP_DOWN) {
        out[0] = x * 0.4f;
        out[1] = 26f;
        out[2] = -z + 2f;
        out[3] = x * 0.4f;
        out[4] = 0f;
        out[5] = -z - 6f;
        out[6] = 40f;
        out[7] = -1f;
    } else {
        out[0] = x * 0.6f;
        out[1] = 3.4f + y * 0.5f;
        out[2] = -z + 6.5f;
        out[3] = x * 0.6f;
        out[4] = 1.0f + y * 0.3f;
        out[5] = -z - 9f;
        out[6] = 62f;
        out[7] = 0f;
    }
}

private final float[] from = new float[8];
private final float[] to = new float[8];
private final float[] blended = new float[8];

private void camera(Run run, Runner me, float x, float y, float z) {
    Track t = run.track();
    int mz = me.z;
    float k = t.blendAt(mz) / 1000f;
    k = k * k * (3f - 2f * k);
    framing(t.previousViewAt(mz), x, y, z, from);
    framing(t.viewAt(mz), x, y, z, to);
    float[] v = blended;
    for (int i = 0; i < 8; i++) {
        v[i] = from[i] + (to[i] - from[i]) * k;
    }
    GameCamera cam = getCamera();
    cam.setPerspective(v[6], 0.5f, 400f);
    cam.setPosition(v[0], v[1], v[2]);
    cam.setTarget(v[3], v[4], v[5]);
    cam.setUp(0f, 1f + v[7], v[7]);
```

```
}
```

The view runs the rules on a fixed tick of 60 per second, whatever the frame rate, and draws between ticks by interpolating. A slow phone drops frames, never ticks, so the run stays the same run:

```
@Override
protected void update(double dt) {
    if (device == null || getWidth() <= 0 || getHeight() <= 0) {
        return;
    }
    time += (float) dt;
    input();
    if (driver.countdownTicks() > 0) {
        accumulator = 0;
    } else {
        accumulator += dt * driver.speedPercent() / 100.0;
    }
    int steps = 0;
    while (accumulator >= TICK && steps < MAX_STEPS_PER_FRAME) {
        if (!driver.canStep()) {
            // Online and waiting for the server: hold at the last tick.
            accumulator = Math.min(accumulator, TICK);
            break;
        }
        remember();
        if (beforeTick != null) {
            beforeTick.run();
        }
        driver.step();
        events();
        accumulator -= TICK;
        steps++;
    }
    alpha = (float) Math.min(1, accumulator / TICK);
```

Gestures and keys become the four input bits in one place, and the same bits reach every kind of run — solo, race, replay and playtest — through a `Driver`:

```
/// Swipes, the on-screen buttons and keys become [Input] bits. A tap jumps;
/// a swipe goes the way it points. Arrow keys and WASD do the same, Space
/// jumps.
private void input() {
    if (!driver.interactive()) {
        return;
    }
    GameInput in = getInput();
    int bits = 0;
    if (in.wasPointerPressed()) {
        boolean button = onButton(in.getPointerX(), in.getPointerY());
        pressX = button ? -1 : in.getPointerX();
```

```
        pressY = in.getPointerY();
    }
    if (in.wasPointerReleased() && pressX >= 0) {
        int dx = in.getPointerX() - pressX;
        int dy = in.getPointerY() - pressY;
        int min = CN.convertToPixels(SWIPE / 8f);
        if (Math.abs(dx) < min && Math.abs(dy) < min) {
            bits |= Input.JUMP;
        } else if (Math.abs(dx) > Math.abs(dy)) {
            bits |= dx < 0 ? Input.LEFT : Input.RIGHT;
        } else {
            bits |= dy < 0 ? Input.JUMP : Input.SLIDE;
        }
        pressX = -1;
    }
    bits |= edge(0, in.isGameKeyDown(Display.GAME_LEFT) || in.isKeyDown('a') || in.isKeyDown('A'), Input.LEFT);
    bits |= edge(1, in.isGameKeyDown(Display.GAME_RIGHT) || in.isKeyDown('d') || in.isKeyDown('D'), Input.RIGHT);
    bits |= edge(2, in.isGameKeyDown(Display.GAME_UP) || in.isKeyDown('w') || in.isKeyDown('W')
            || in.isKeyDown(' '), Input.JUMP);
    bits |= edge(3, in.isGameKeyDown(Display.GAME_DOWN) || in.isKeyDown('s') || in.isKeyDown('S'), Input.SLIDE);
    if (bits != 0) {
        driver.input(bits);
    }
}
```

55.5. The server is the referee

A run is never reported as a number. When it ends, the app sends the seed and the input log — a few hundred bytes for a long run — and the server builds the same level, plays the log through the same rules, and reads the score off its own simulation. A score that was typed in, or a log edited to dodge an obstacle the player hit, simply doesn't reproduce:

```
Run played;
try {
    played = LevelRun.verify(pack, levelId, replay);
} catch (IllegalArgumentException e) {
    throw new ResponseStatusException(400, e.getMessage());
}
int won = played.stars(0);
int score = played.runner(0).score();
int paidBefore = paidStars(username, p.getId(), levelId);
LevelStars row = record(username, p.getId(), levelId, won, score);
int newStars = row.getPaidStars() - paidBefore;
p.setPlays(p.getPlays() + 1);
packs.save(p);

int coins = OFFICIAL_STAR_COINS * newStars;
int xp = OFFICIAL_STAR_XP * newStars;
if (username.equals(p.getOwner())) {
    // Testing your own level is free, and pays nothing.
    coins = 0;
    xp = 0;
} else if (!p.isOfficial()) {
```

```
    coins = Math.min(coins, COMMUNITY_LEVEL_COINS * newStars / 3);
    xp = Math.min(xp, COMMUNITY_LEVEL_XP * newStars / 3);
    coins = spendDailyAllowance(username, coins);
}
```

The verified run is then entered on every board it qualifies for. The endless stretch of a level is built from the seed, so no board takes a seed the app picked for itself: `all` takes only the seeds the server hands out, and `week` and `day` count only the board's own seed, so everyone is running the same track there:

```
@Component
public class Scores {
    public static final String ALL = "all";
    public static final String WEEK = "week";
    public static final String DAY = "day";
    public static final String FRIENDS = "friends";

        if (theirs != null && theirs.getScore() < score && theirs.getScore() >= before) {
            pushes.scoreBeaten(f, p.getDisplayName(), level, score);
            sent++;
        }
    }
}
```

55.6. Races in lockstep

A race is run by the server in rooms. Every phone sends its inputs as they happen; the room collects them per tick, steps its own copy of the run, and broadcasts each tick's inputs to every seat. A phone only advances when it has the server's tick, so they all see the same race, and the server's copy is the one that decides the places:

```
final class RaceRoom {
    /// Inputs one seat may send in [#FLOOD_WINDOW] ticks. A thumb manages
    /// about eight a second; a script manages sixty.
    static final int FLOOD_LIMIT = 16;
    static final int FLOOD_WINDOW = Run.TICKS_PER_SECOND;

    final String id;
    final String level;
    final Seat[] seats;
    final Run run;
    final Replay replay;
    final Bot[] bots;
    /// When tick 0 runs: the end of the countdown.
    final long startedAt;
    final List<WebSocketSession> spectators = new ArrayList<WebSocketSession>();
    /// Every input in stamp order, as `{tick, seat, bits}`; what TICKS sends.
    final List<int[]> log = new ArrayList<int[]>();
    private final Map<Integer, int[]> pending = new HashMap<Integer, int[]>();
    /// The server's hash every [GameProtocol#HASH_EVERY] ticks, for SYNC.
```

```
    final Map<Integer, Long> hashes = new HashMap<Integer, Long>();

}
```

A mesh suits a party of four. For larger groups, put a media server (an SFU) behind the same signalling messages; the client code above doesn't change.

55.7. The track editor

The editor draws the level as a strip: distance runs left to right, one row per lane, an all-lanes row on top, and the camera cues as flags along the bottom. Tapping a cell puts the selected piece there:

```
public final class TrackTimeline extends Component {
    /// What a tap does.
    public interface Tool {
        /// Applies the tool at `metres` in `lane` ([Placement#ALL_LANES] for
        /// the top row); returns true when the level changed.
        boolean apply(LevelDef level, int metres, int lane);
    }

    /// Hears about every change, to refresh the problems list.
    public interface Changed {
        void changed();
    }

    private static final int STEP_METRES = 5;

}
```

Playtest runs the draft as a player would, on the same rules, and is never submitted. Publishing runs the validator the server runs too, and that includes sending the bot down the level: a level that the bot can't finish can't be published, so every published level can be beaten.

55.8. City runs

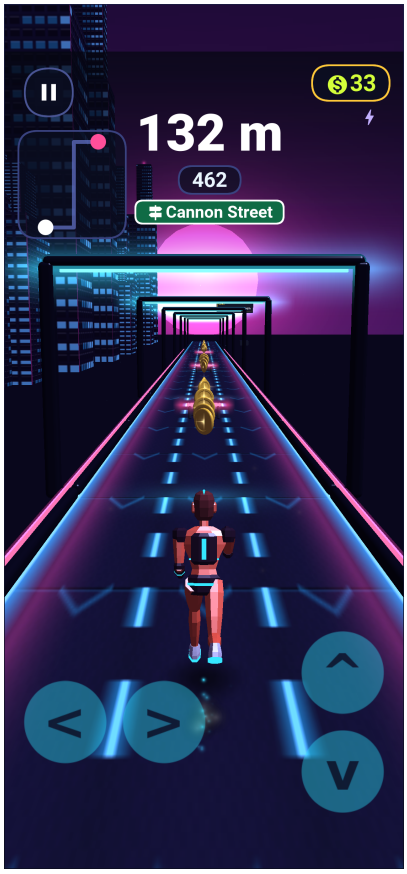
Run your city on the levels screen opens a street map. The player taps a start and a finish, a routing service finds the way between them, and the route becomes a level: every street a stretch of track, every turn a corner taken on the side it turns to, with the next street's name called out before it. What lies between the corners is drawn from the game's own chunks, harder as the run goes on.

The map is Codename One's `MapView`, which draws OpenStreetMap data itself on every platform, and the route comes from `Routing`. `CityForm` reduces the route to streets and turns (`CityForm.toRoute`), reading each turn off the geometry where two streets meet, and hands the result to the rules as a `CityRoute`:

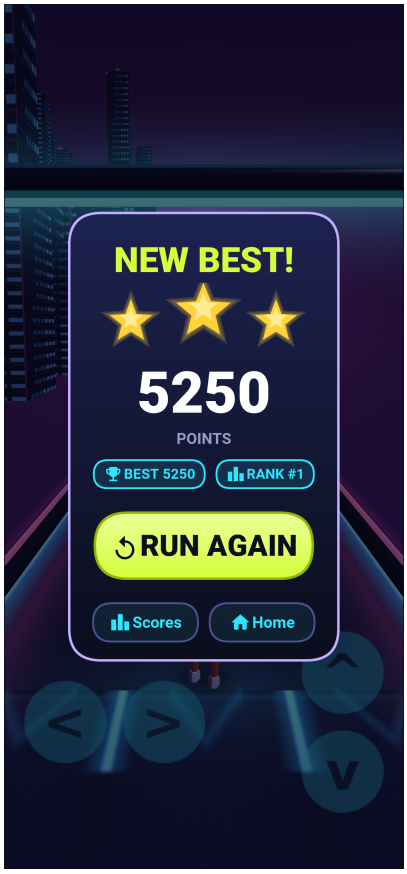
```
CityRoute route = new CityRoute("Old Harbour")
        .leg(420, CityRoute.STRAIGHT, "Quay Street")
        .leg(310, CityRoute.LEFT, "Rope Walk");
LevelDef level = route.level();
```

`level()` is deterministic, so the server needs no map. A city run's result carries the encoded route next to its replay; the server builds the same level from it and plays the replay on it as it would any other. The level's id is a hash of the route, so each route has a board of its own, and editing a route into an easier one names a different level with a different board. Since any edit makes a new level, a city run's coins and experience both come out of the community levels' daily allowance; a new route never pays beyond it.

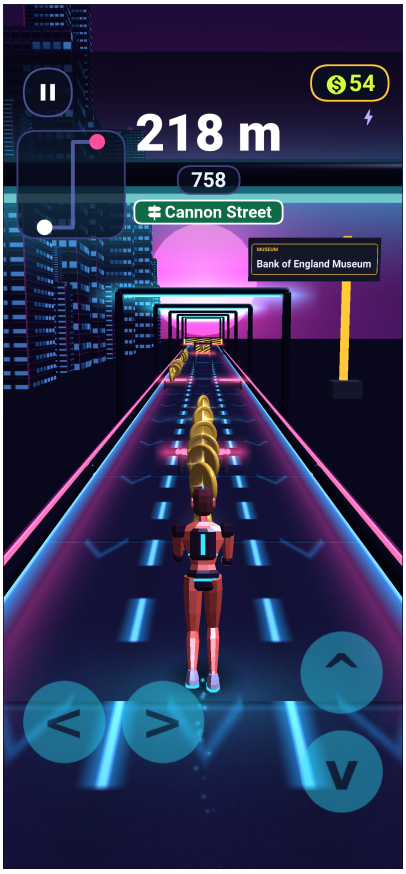
55.8.1. Street names and landmarks



The run follows the map, not just its turns. The street the runner is on sits under the score and changes at every corner, a green street sign spans the track where a new street begins, and the places along the way — churches, museums, stations, parks, monuments — stand beside the track with their names on a board as the runner passes, and the coach calls them out ("Passing Guildhall."). The small map in the corner shows how far along the route the runner is.



The places come from OpenStreetMap through the Overpass API: `Landmarks` asks for named tourist, historic, religious, station and park features within 70 meters of the route, projects each onto the line, keeps them at least 60 meters apart and at most twelve, and adds them to the `CityRoute`. They're part of the route the server receives, so they're part of the level and its hash, and the server places the same boards:



```
CityRoute withPlace = new CityRoute("Old Harbour")
        .leg(420, CityRoute.STRAIGHT, "Quay Street")
        .landmark(180, CityRoute.MUSEUM, "Maritime Museum");
```

The public Overpass server is shared and rate limited. A game with players points `Landmarks.setSource` at an Overpass instance of its own, or at any other source of places: the interface is one method that takes the route's path.

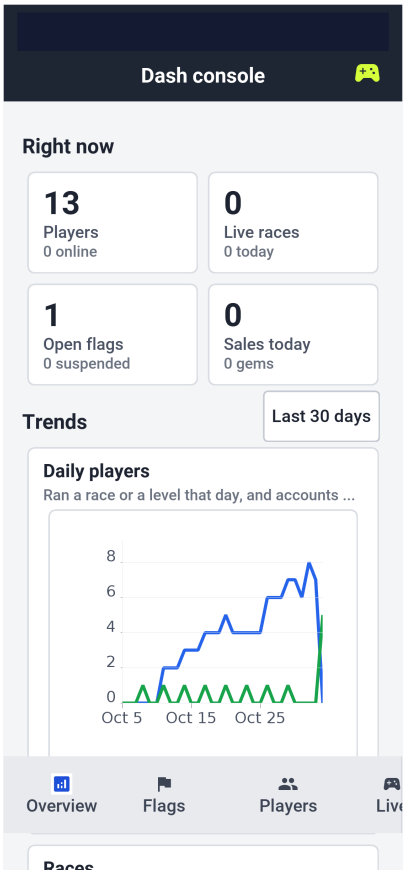
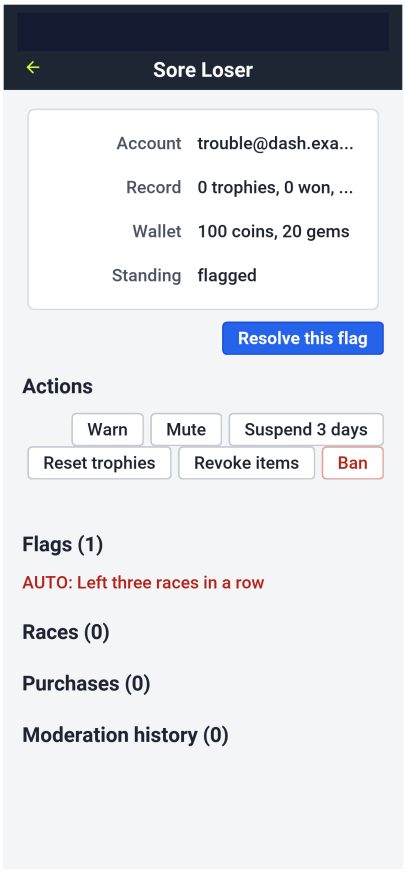
Before you ship this, point `Routing` at a routing server of your own: `Routing.setService(new OsrmRouteService("https://osrm.example.com"))`. The default is OSRM's public demo server, which is rate limited, has no service guarantee and serves only its car profile, whatever travel mode the request asks for. The map data is OpenStreetMap's, whose license asks for credit wherever it's shown; the city screen carries that line, and a reskin has to keep it.

55.9. Engagement and live operations

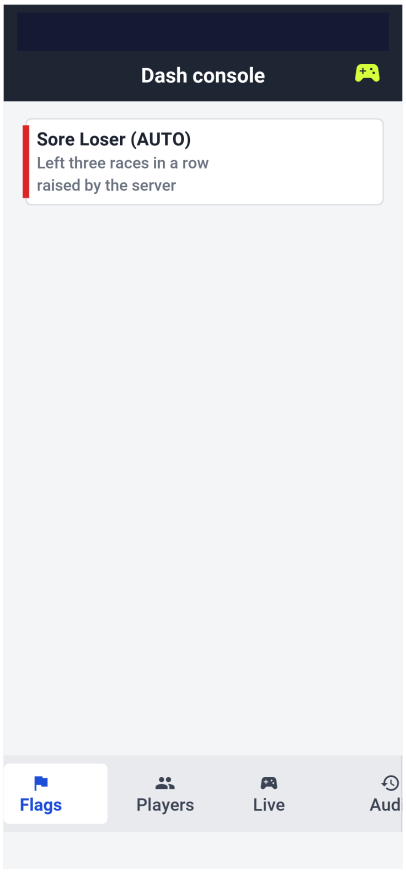
Players come back for what changes: three quests a day, picked per player from `Goals` (run 500 meters, collect 100 coins, win a race…), a daily dash with one track for everyone and its own board, chests that open over time, a level and trophies to climb, achievements, and boards that reset every week. Rivals already on the boards from the first run keep a new player company: on a development server `DemoAccounts` seeds a field of runners whose scores are the rules' bot playing each week's track, submitted and verified like anyone's.



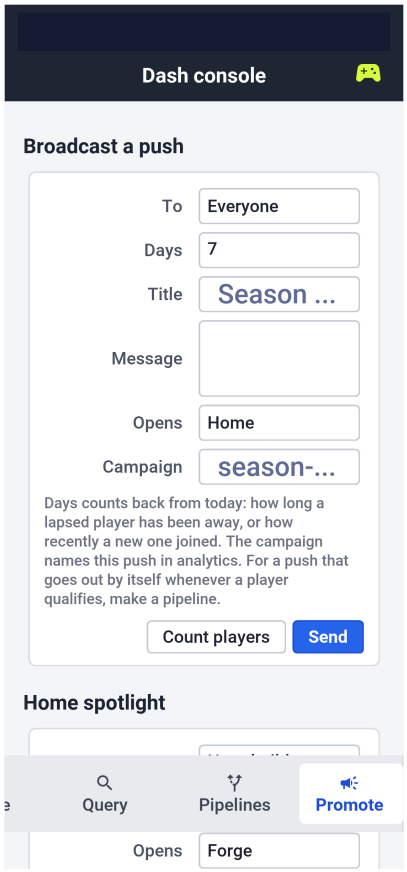
The operator's side is in the admin console:



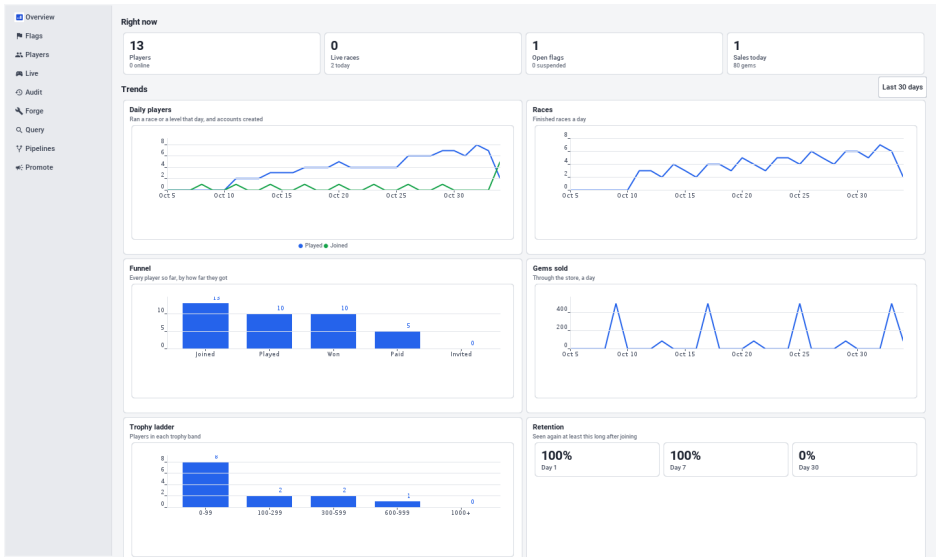
- **Reports** chart players, runs, races, purchases and invitations over time.
- **Query** finds players by what the game knows about them — days away, races, purchases, invitations, trophies — with conditions such as `daysAway >= 7`.
- **Pipelines** turn a query into an action that runs every hour: a push to players away for a week that opens the shop, 20 gems to a player who reached 300 trophies and never bought anything. Each player is acted on once per cool-down, and a push carries the campaign `pipeline-<name>`, so its opens show in Codename One analytics.
- **Promote** sends a push to a segment (**broadcast**) and sets the banner on every player's home



screen (**spotlight**), which can open a level, the shop or the editor.



```
/// Every enabled pipeline, once an hour, on one server at a time.
/// Transactional itself: a call to [#run] from here is a call on `this`,
/// which does not go through the transaction wrapper.
@Scheduled(fixedDelay = EVERY, initialDelay = 5L * 60 * 1000, lock = "dash-pipelines")
@Transactional(rollbackFor = IOException.class)
public void runAll() throws IOException {
    for (Pipeline p : pipelines.byName()) {
        if (p.isEnabled()) {
            run(p.getId());
        }
    }
}
```



On a phone the console is a list of pages; on a desktop or a tablet it's a sidebar and a page, and the **Promote** tab is shown:

55.10. Moderation

Published packs, reports and automatic flags — a run that doesn't re-simulate, a race hash that disagrees — land in the admin console. A moderator can hide, restore or promote a pack, look at its files, and act on a player:

```
@Component
public class Moderation {
    public static final String WARN = "WARN";
    public static final String MUTE = "MUTE";
    public static final String UNMUTE = "UNMUTE";
    public static final String SUSPEND = "SUSPEND";
    public static final String BAN = "BAN";
    public static final String UNBAN = "UNBAN";
    public static final String RESET_TROPHIES = "RESET_TROPHIES";
    public static final String REVOKE_ITEMS = "REVOKE_ITEMS";
    static final String[] ACTIONS = {WARN, MUTE, UNMUTE, SUSPEND, BAN, UNBAN, RESET_TROPHIES, REVOKE_ITEMS};

    private final Accounts accounts;
    private final ProfileRepository profiles;
    private final AdminActionRepository audit;
    private final Rooms rooms;

    public Moderation(Accounts accounts, ProfileRepository profiles, AdminActionRepository audit, Rooms rooms) {
        this.accounts = accounts;
        this.profiles = profiles;
        this.audit = audit;
        this.rooms = rooms;
    }

    public PlayerDto act(String admin, String username, AdminActionDto request) throws IOException {
        if (request == null) {
            throw new ResponseStatusException(400, "Choose an action");
        }
        String action = Text.oneOf(request.action(), ACTIONS, "", "the action");
        if (action.length() == 0) {
            throw new ResponseStatusException(400, "Choose an action");
        }
        if (admin.equals(username) && !WARN.equals(action)) {
            throw new ResponseStatusException(400, "Not on your own account");
        }
        String reason = Text.required(request.reason(), 255, "the reason");
        boolean closes = apply(admin, username, action, reason, request.days());
        if (closes) {
            rooms.kick(username);
        }
        return accounts.describe(username);
    }

    @Transactional(rollbackFor = IOException.class)

    public void liftExpired() {
        lift(Clock.now());
    }

    @Transactional
    public int lift(long now) {
        int lifted = 0;
        for (Profile p : profiles.findAll()) {
            if (!p.isBanned() && p.getSuspendedUntil().isAfter(Instant.EPOCH)
                    && p.getSuspendedUntil().toEpochMilli() <= now) {
                p.setSuspendedUntil(Instant.EPOCH);
                profiles.save(p);
                accounts.setEnabled(p.getUsername(), true);
                lifted++;
            }
        }
        return lifted;
    }

    @Transactional(readOnly = true)
    public List<AuditDto> newest() {
        return toDtos(audit.newest(new PageRequest(0, 200)));
    }

    @Transactional(readOnly = true)
    public List<AuditDto> of(String username) {
        return toDtos(audit.of(username, new PageRequest(0, 50)));
    }

    private static List<AuditDto> toDtos(List<AdminAction> rows) {
        List<AuditDto> out = new ArrayList<AuditDto>();
        for (AdminAction a : rows) {
            out.add(new AuditDto(a.getId(), a.getAdmin(), a.getUsername(), a.getAction(), a.getReason(),
                    a.getCreatedAt().toEpochMilli()));
        }
        return out;
    }
```

```
}
```

The console also lists every race being run, and any of them can be watched live from the same lobby a player uses to spectate.

55.11. Making it yours

- **Levels**: `Content` in `rules` holds the official levels and the chunks the procedural tails are built from. Change one and run `mvn -pl rules test`: the golden replays will tell you which recorded runs no longer end the same way, and the bot test whether every level can still be finished. Bump `RulesVersion.ID` when you change the rules themselves, so old replays aren't judged by new rules.
- **Obstacles and pickups**: add a definition in `Content.catalog()`, a colour or a model in `RunView`, and the editor offers it at once.
- **Runners**: there are no model files. `Rig` builds every runner from capsules, rounded boxes and glowing trim and poses each joint in code, and `Portraits` paints the same figure flat for the menus. Both take their colours from an `Outfit`, so a new runner is one line:

```
/// The outfit for a shop runner id; `fallback` picks one for a bot.
public static Outfit of(String runnerId, int fallback) {
    if ("runner-nova".equals(runnerId)) {
        return new Outfit(runnerId, 0xff6c4dff, 0xffc8ff3d, 0xff1a1440);
    }
    if ("runner-kite".equals(runnerId)) {
        return new Outfit(runnerId, 0xff0fb5a8, 0xffffe14d, 0xff0b2f33);
    }
    if ("runner-dash".equals(runnerId) || runnerId == null && fallback == 0) {
        return new Outfit("runner-dash", 0xffff5a3c, 0xff35e8ff, 0xff241326);
    }
    return CROWD[Math.abs(fallback) % CROWD.length];
}
```

- **The track**: `Theme` holds each level theme's sky, light, surface, rails and skyline, and paints the textures it needs at startup.
- **The look**: every colour is a variable at the top of `theme.css`:

```
--bg: #0b0e1d;
--surface: #151a33;
--surface-light: #1f2647;
--edge: #2c3563;
--edge-light: #4a5594;
--coral: #ff4d5e;
--coral-light: #ff8a4c;
--coral-dark: #c22745;
--volt: #d4ff3a;
--volt-dark: #8fb800;
```

```
--cyan: #2ee6ff;
--violet: #8a5cff;
--violet-glow: #c3b0ff;
--ice: #eaf6ff;
--ink: #0b0e1d;
--text: #ffffff;
--text-muted: #93a0c8;
--danger: #ff3b5c;
```

- **Store, ads and push**: these work as they do in Skirmish. The product ids are in `AppConfig`, the receipt validator is chosen in `Services`, and the push key is read the same way:

```
/// Google's published test ad units. They always fill, never pay, and are
/// safe to click; replace them with your own AdMob units before release.
public static final String REWARDED_AD_UNIT = "ca-app-pub-3940256099942544/5224354917";
public static final String INTERSTITIAL_AD_UNIT = "ca-app-pub-3940256099942544/1033173712";
public static final String BANNER_AD_UNIT = "ca-app-pub-3940256099942544/6300978111";
/// The store products, as configured in App Store Connect and the Play
/// Console. The server's `Catalog` names the same ones.
public static final String SKU_GEMS_80 = "dash.gems_80";
public static final String SKU_GEMS_500 = "dash.gems_500";
public static final String SKU_ROYAL_PASS = "dash.royal_pass";
```

```
/// `dash.iap.provider` is one of:
///
/// - `store`: receipts are checked with Apple (`dash.iap.apple.secret`)
///   and Google Play (`dash.iap.google.package` and
///   `dash.iap.google.token`). A store with no settings refuses its
///   receipts; the other keeps working.
/// - `simulated`: every receipt is accepted, on a development profile only.
///
/// Unset, it is `simulated` on a development profile and `store` otherwise.
@Bean
public ReceiptValidator receipts(Config config,
        @Value("${dash.iap.provider:}") String chosen,
        @Value("${dash.iap.apple.secret:}") String appleSecret,
        @Value("${dash.iap.google.package:}") String googlePackage,
        @Value("${dash.iap.google.token:}") String googleToken) {
    String kind = chosen.trim().length() > 0 ? chosen.trim()
            : config.isDevelopmentProfile() ? "simulated" : "store";
    if ("simulated".equalsIgnoreCase(kind)) {
        if (!config.isDevelopmentProfile()) {
            return new MisconfiguredReceipts("dash.iap.provider=simulated grants every "
                    + "purchase for free and is refused on the '" + config.getProfile()
                    + "' profile; set it to store");
        }
        return new SimulatedReceipts();
    }
    if (!"store".equalsIgnoreCase(kind)) {
        return new MisconfiguredReceipts("dash.iap.provider is '" + kind
                + "', which is neither store nor simulated");
```

```
    }
    if (appleSecret.trim().length() == 0 && (googlePackage.trim().length() == 0
            || googleToken.trim().length() == 0)) {
        return new MisconfiguredReceipts("in-app purchases are not configured; set "
                + "dash.iap.apple.secret, or dash.iap.google.package and "
                + "dash.iap.google.token");
    }
    return new StoreReceipts(appleSecret.trim(), googlePackage.trim(), googleToken.trim());
}
```

The engagement tools — campaign links, invitations, the home screen spotlight, pushes to an audience and scheduled pipelines — are the ones the Skirmish chapter walks through step by step, and they work in Dash unchanged.

Chapter 56. Splat: Making the paintball game your own

Splat is a first-person team paintball shooter, four against four, that takes itself with the same gravity as a dad in a borrowed tactical vest. Every match opens with a grim mission briefing ("Operation: Borrowed Bedsheet"). Every hit lands a big red **PAINTED** stamp, and every player who is out may try to wipe the paint off before the referee notices. Under the jokes it's a real-time shooter that most game frameworks would split across an engine, a networking product and a separate server:

- The server referees every match. Phones send their inputs, the server runs the match and sends snapshots back, and each phone predicts its own player so the marker fires with no wait (Section 56.6, "The server referees, the phone predicts").
- A shot from a phone with a slow connection still lands where it was aimed: the rules make up for the shooter's lag (Section 56.6.1, "Making up for lag").
- Bots think inside the rules, so a practice match, a match the server fills with bots and a replay all play the same way from the same seed.

Everything is ordinary Codename One code in one project: the 3D field drawn with `GameView`, the HUD as a component layered over it, and the server as a Codename One Backend. Splat shares the module layout, the accounts, push notifications, the shop and the operations console with Dash and Skirmish. This chapter shows where each part lives and what to change to make the game yours.

56.1. Running it

The project is in `scripts/splat`, and the Initializr generates it under your own package and name. Start the server on the development profile, which keeps its database in memory, seeds the demo accounts and simulates purchases and push notifications:

```
CN1_PROFILE=dev backend/server.sh run
```

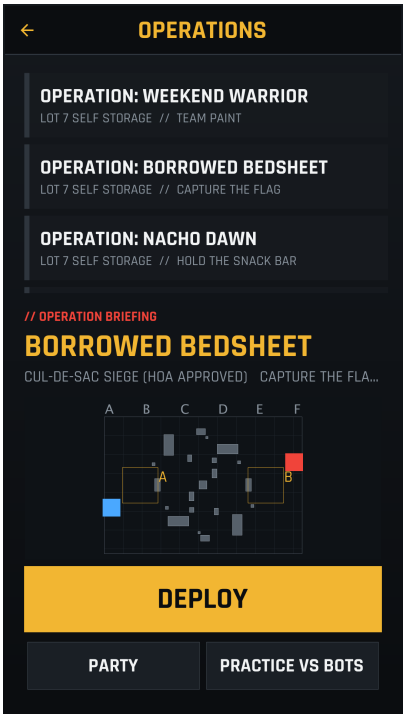
Then the app in the simulator:

```
mvn verify -Psimulator -DskipTests -Dcodename1.platform=javase
```

For a device build, generate the Xcode project:

```
mvn package -DskipTests -Dcodename1.platform=ios -Dcodename1.buildTarget=ios-source -Dopen=false
```

The rules have their own tests, the server has its own, and `run-e2e.sh` drives the app through its real screens against a running server:

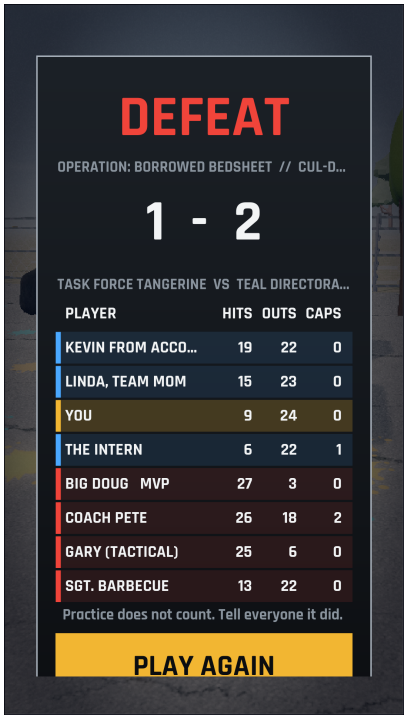


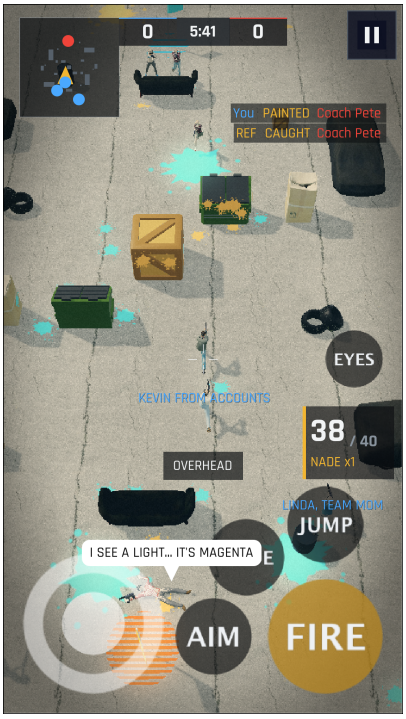
```
mvn -pl rules test
```

```
mvn -pl rules,shared,backend -Dcodename1.platform=backend test
./run-e2e.sh
```

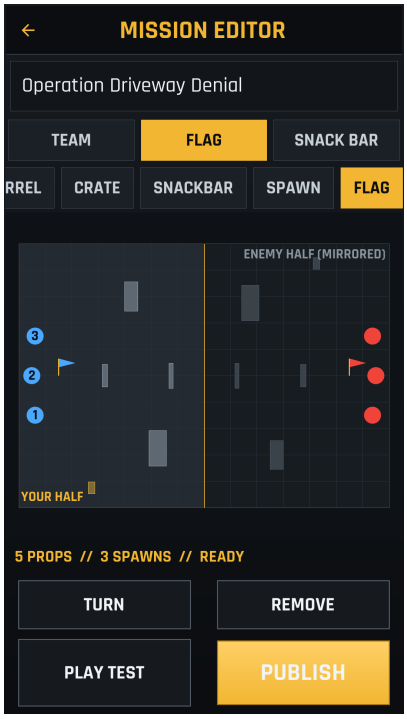
56.2. What the sample does

A player signs in, or plays a practice match as a guest, and lands on the main menu: a vertical list of modes on the left over a 3D operator holding the equipped marker, and a rank card with level, XP and currencies on the right. **OPERATIONS** opens the playlist: two fields, the Lot 7 Self Storage yard and the Cul-de-Sac Siege, each with three modes and a tactical map of the field drawn from its cover. Team Paint is first to 25 paints, Capture the Flag is three captures with a flag that’s clearly a bedsheet, and Hold the Snack Bar is king of the hill. Each operation can be played as a quick match, with a party of friends or as practice against bots.

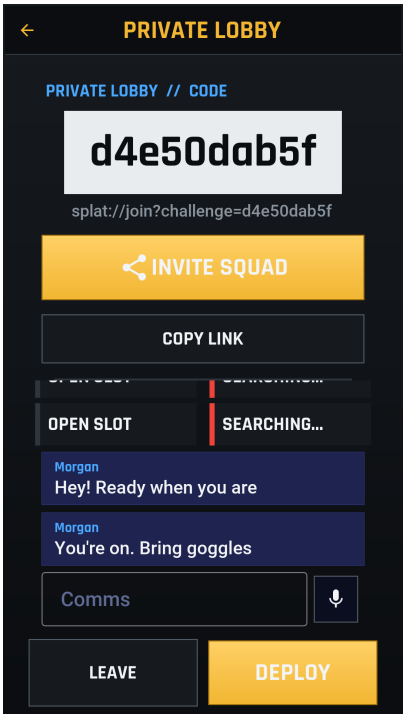


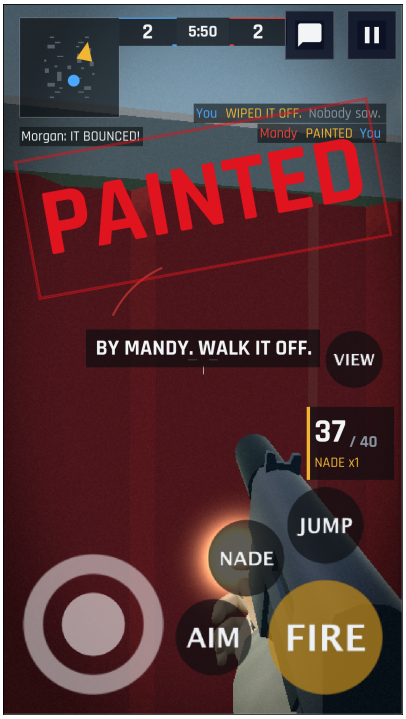


A match opens on a letterboxed briefing that types itself out, redactions included, then hands over to the field in first person: the marker in hand bobs, sways and kicks, and aiming down the sights zooms in and tightens the spread. The HUD has a minimap, the score bar and clock, a killfeed, the hopper count, hit markers and damage arcs. The controls are a virtual stick on the left, look by dragging on the right, and buttons to fire, aim, jump, throw a paint grenade and wipe. On a desktop the keyboard and mouse do the same. A hit player is out until the respawn, arms up the way the rules of every field require, and may try to wipe the paint off. One try in three goes unnoticed; the others cost three more seconds.



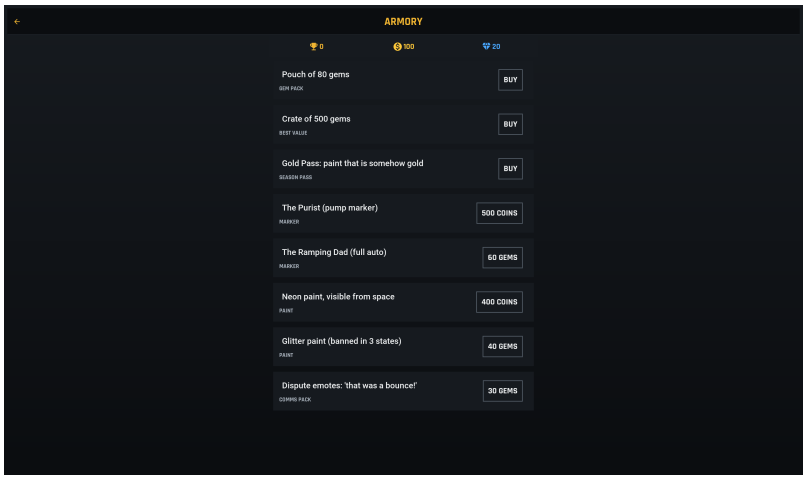
The view button lifts the camera to a bird’s-eye view of the whole field, in a match, while spectating and in a replay. When a ball finds you, the match shows an instant replay of the last seconds from the shooter’s eyes, at half speed, while the live match runs on under it.





The Mission Builder lets a player lay out half a field on a grid: drag props, place spawns and the flag, pick the mode and write the briefing. The other half is the mirror image, so every mission is fair. A play test puts the draft in front of bots at once, and publishing it lets friends and parties play it like any built-in field.

A party is a private lobby: a code, two rosters and a chat. The friends who join it play the next match together, talk over WebRTC voice and trade emotes during it ("It bounced!" and "REF!").



On a desktop the same app is a window, not a phone. The menus keep to a readable column, small text is sized for a monitor instead of being scaled down from a phone, and the match drops the touch controls for the keyboard and mouse, with a wider view and a fuller HUD.

56.3. The modules

- `rules` is the game: a deterministic simulation in fixed-point integers with no dependencies. The app predicts with it, the server runs it as the authority and the replay viewer re-runs it.
- `shared` holds the REST interfaces and the objects they carry.
- `backend` is the server: accounts, matchmaking, the match rooms, results, the shop, social features and the admin API.
- `common` is the app. `play/` is the match itself, `ui/` the surrounding screens, `engage/` ads, analytics, push and the store, and `admin/` the operations console.

What every full-stack sample needs and none of them is about comes from the `cn1-app-kit` library: `Net`, the app's error handling around a REST call, and on the server `Caller`, `Text` and the push senders.

56.4. The rules are data

The fields and markers are tables. A marker is a handful of numbers (time between shots, muzzle speed, spread, hopper size, reload and how fast you move carrying it), and rebalancing the game is editing one of them:

```
public static final MarkerDef[] MARKERS = {
    new MarkerDef("pump", "The Purist",
            "One shot, one paint. Owned exclusively by men who say 'back in my day'.",
            18, 2000, 0, 14, 70, 105),
    new MarkerDef("semi", "Tactical Office Supply",
            "Semi-automatic. Comes with a rail for a flashlight you will never attach.",
            6, 1700, 16, 40, 80, 100),
    new MarkerDef("ramp", "The Ramping Dad",
            "Fully automatic, fully unnecessary. Banned at three fields and one barbecue.",
            3, 1500, 44, 90, 105, 90),
};
```

A field is a size, a base, a hill for the snack bar mode, the spawns, and boxes of cover given by center and size in decimeters. `mirror` places each box twice, once per side, so a field is fair by construction:

```
// Every box is the footprint of the prop the app draws there (see
// tools/pack-art.py): centre and size in decimetres, height last.
new Arena.Builder("lot7", "Lot 7 Self Storage", 40, 60)
        .base(200, 110).hill(45)
        .spawn(140, 25).spawn(200, 20).spawn(260, 25).spawn(170, 45).spawn(230, 45)
        .spawn(200, 55)
        .mirror("sandbags", 130, 150, 34, 9, 13)
        .mirror("sandbags", 270, 150, 34, 9, 13)
        .mirror("sandbags-small", 95, 120, 25, 9, 10)
        .mirror("sandbags-small", 305, 120, 25, 9, 10)
        .mirror("container", 90, 175, 44, 21, 21)
        .mirror("container", 310, 195, 44, 21, 21)
        .mirror("barrier", 145, 235, 38, 7, 32)
        .mirror("car", 260, 245, 26, 55, 18)
        .mirror("tank", 335, 280, 24, 25, 21)
        .mirror("boxes", 55, 260, 13, 12, 22)
        .mirror("tires", 120, 295, 18, 11, 11)
        .mirror("barrier-single", 250, 175, 19, 7, 6)
        .mirror("snackbar", 200, 300, 22, 21, 21)
        .build(),
```

A box's kind (`bunker`, `minivan`, `snackbar`) picks its color and shape in the client; the rules only see its

extent. Change any of these and run `mvn -pl rules test`: the golden replays report which recorded matches no longer end the same way. Bump `RulesVersion.ID` when you change the rules themselves, so old replays aren't judged by new rules.

56.5. Drawing the field

`ArenaView` is a `GameView`. It builds the field from the arena's boxes when it starts, keeps a pool of paintballs and paint splats, and places the camera at the player's eyes on every frame. It tells the HUD what happened through one small interface, once per drawn frame and once per event:

```
public class ArenaView extends GameView {
    /// What the view tells the HUD once per drawn frame and once per event.
    public interface Hud {
        void frame(Match match, int me, float lookYaw, float lookPitch);

        void event(Event e);
    }
```

The simulation runs at a fixed 30 ticks a second, whatever the frame rate, and the view draws between the last two ticks:

```
@Override
protected void update(double dt) {
    if (device == null || getWidth() <= 0 || getHeight() <= 0) {
        return;
    }
    controlsFor(driver.match());
    govern(dt);
    accumulator += dt * driver.speedPercent() / 100.0;
    int steps = 0;
    while (accumulator >= TICK && steps < MAX_STEPS_PER_FRAME) {
        if (!driver.canStep()) {
            // The briefing, or online and the server has gone quiet.
            accumulator = Math.min(accumulator, TICK);
            break;
        }
        remember();
        Input in = !driver.interactive() ? Input.IDLE : autopilot != null
                ? com.codenameone.examples.splat.rules.Bot.think(driver.match(), driver.match().player(driver.me()),
autopilot)
                : input();
        if (heldButtons != 0 && driver.interactive()) {
            in = new Input(in.strafe, in.forward, in.yaw, in.pitch, in.buttons | heldButtons, in.viewTick);
        }
        driver.step(in);
        // every tick, not every frame: a slow frame steps several
        record();
        accumulator -= TICK;
        steps++;
    }
    alpha = (float) Math.min(1, accumulator / TICK);
    // and once a frame for a driver whose ticks arrive from the server
    record();
    events();
    bodySounds((float) dt);
    draw((float) dt);
    tick((float) dt);
```

```
}
```

The look is the engine's, not a texture pack's: haze that thins with height, an open sky with clouds and the sun, shadows from the props and trees, and a color grade with bloom on the paint. It's a dozen lines at the start of the view, and the menu backdrop uses the same calls with dusk colors:

```
getEnvironment().setFog(HAZE, 0.0075f, 0.05f).setHemisphere(0xffa9bdd2, 0xff4f5a3c)
        .setToneMapping(true).setExposure(1.3f)
        .setSky(0xff4f7fb8, HAZE, 0xfffff0d0, 0.45f);
setPostProcess(new PostProcess().setBloom(0.78f, 0.55f)
        .setGrade(1.12f, 0.86f, 0xff0b1720, 0xfffff2dc).setVignette(0.42f).setGrain(0.035f));
```

What ticks the match is a `Driver`. Practice, an online match and a replay are three drivers behind the same view and the same screen:

```
public abstract class Driver {
    protected Match match;
    /// The player the camera looks out of.
    protected int me;
    protected String[] names = new String[0];
    private final List<Event> events = new ArrayList<Event>();

    public Match match() {
        return match;
    }

    public int me() {
        return me;
    }

    public String name(int player) {
        if (interactive() && player == me) {
            return "You";
        }
        return player < names.length ? names[player] : "Player " + (player + 1);
    }

    /// Whether the next tick may be simulated now.
    public abstract boolean canStep();

    /// Simulates one tick with `in` as the player's input (ignored when not
    /// [#interactive()]).
    public abstract void step(Input in);

    /// What happened since the view last asked: splats, PAINTED, captures.
    public List<Event> drainEvents() {
        List<Event> out = new ArrayList<Event>(events);
        events.clear();
        return out;
```

```
    }

    protected void emit(List<Event> happened) {
        events.addAll(happened);
    }

    protected void emit(Event e) {
        events.add(e);
    }

    public boolean interactive() {
        return true;
    }

    public int speedPercent() {
        return 100;
    }

    /// Ticks still to wait before the first step: the briefing.
    public int countdownTicks() {
        return 0;
    }

    public void dispose() {
    }
}
```

The HUD is a plain component layered over the view, so it's styled from `theme.css` and respects the safe area like any other screen. On a phone it's compact — a small minimap, a two line killfeed, the hopper in one tab — and on a desktop or tablet it shows everything. It steps aside entirely for the briefing and the result card, so nothing in a match ever draws over a menu:

```
public final class MatchForm implements ArenaView.Hud, OnlineDriver.Listener {
    private final Driver driver;
    private final String mode;
    private final Runnable back;
    private final ArenaView view;
    private final Hud hud;
    private final Form form;
    private final Container layers;
    private Container chrome;
    private boolean endShown;

    private MatchForm(Driver driver, String mode, Runnable back) {
        this.driver = driver;
        this.mode = mode;
        this.back = back;
        view = new ArenaView(driver);
        view.setName("arena");
        hud = new Hud(driver);
```

```
        hud.attach(view);
        view.setHud(this);
        form = new Form(driver.match().mode().operation, new BorderLayout());
        form.setName("match");
        form.setUIID("MatchScreen");
        form.getToolbar().hideToolbar();

        chrome = new Container(new BorderLayout());
        chrome.setSafeArea(true);
        Button quit = Ui.button("", "HudButton", "quit", e -> quit());
        quit.setMaterialIcon(FontImage.MATERIAL_PAUSE, 4.4f);
        Container top = new Container(new BorderLayout());
        Container corner = new Container(BoxLayout.y());
        if (driver instanceof OnlineDriver && driver.interactive()) {
            // Comms stay folded behind one button: open, they cover the
            // killfeed and nothing else, and they fold again once you speak.
            final Container emotes = new Container(BoxLayout.y());
            emotes.setUIID("EmoteBar");
            emotes.setHidden(true);
            Button comms = Ui.button("", "HudButton", "comms", null);
            comms.setMaterialIcon(FontImage.MATERIAL_CHAT_BUBBLE, 4.4f);
            comms.addActionListener(e -> showComms(emotes, emotes.isHidden()));
            String[] ids = {"bounce", "cover", "ref", "gg"};
            for (final String id : ids) {
                emotes.add(Ui.button(emoteText(id), "EmoteButton", "emote-" + id, e -> {
                    ((OnlineDriver) driver).emote(id);
                    showComms(emotes, false);
                }));
            }
            corner.add(FlowLayout.encloseRight(comms, quit));
            corner.add(emotes);
        } else {
            corner.add(FlowLayout.encloseRight(quit));
        }
        top.add(BorderLayout.EAST, corner);
        if (driver instanceof ReplayDriver) {
            top.add(BorderLayout.WEST, replayControls((ReplayDriver) driver));
        }
        chrome.add(BorderLayout.NORTH, top);
        layers = new Container(new LayeredLayout());
        layers.add(view);
        layers.add(hud);
        layers.add(chrome);
        form.add(BorderLayout.CENTER, layers);
    }
```

56.6. The server referees, the phone predicts

An online match is a room on the server. It collects each player’s newest input, steps the match, and every second tick sends a snapshot of the whole state with the newest input it has applied for that

player:

```
final class MatchRoom {
    /// Inputs one seat may send in a second. A client sends one per tick.
    static final int FLOOD_LIMIT = Match.TICK_HZ + 12;
    /// A turn larger than this in one tick is a mouse flick at best; many of them
    /// in a match is an aimbot.
    static final int SNAP_TURN = Trig.FULL / 3;

    final String id;
    final String level;
    final Mode mode;
    final Seat[] seats;
    final Match match;
    final Replay replay;
    final long startedAt;
    final List<WebSocketSession> spectators = new ArrayList<WebSocketSession>();
    /// The inputs each seat has sent and the server has not used yet, oldest
    /// first, one per tick. A client simulates one tick per input it sends,
    /// so two that arrive within one server tick must both be played, or the
    /// client's prediction runs a tick ahead and a trigger pull in the first
    /// is never fired.
    static final int QUEUE = 8;
    private final Input[][] queued;
    private final int[][] queuedSeq;
    private final int[] queueHead;
    private final int[] queueCount;
    /// Wipes each seat got away with, for the achievement nobody should be proud of.
    private final int[] wipes;
    /// Events since the last snapshot, already encoded.
    private final StringBuilder events = new StringBuilder();

    MatchRoom(String id, String level, String arena, Mode mode, long seed, Seat[] seats, long startedAt) {
        this.id = id;
        this.level = level;
        this.mode = mode;
        this.seats = seats;
        List<Slot> slots = new ArrayList<Slot>();
        for (int i = 0; i < seats.length; i++) {
            Seat s = seats[i];
            // Bots of mixed skill, so a bot-filled match has someone to laugh at.
            int skill = s.isBot() ? 35 + 15 * (i % 4) : 0;
            slots.add(new Slot(s.name, s.team, s.marker, skill));
        }
        this.replay = new Replay(seed, arena, mode, slots);
        this.match = replay.newMatch();
        this.startedAt = startedAt;
        this.queued = new Input[seats.length][QUEUE];
        this.queuedSeq = new int[seats.length][QUEUE];
        this.queueHead = new int[seats.length];
        this.queueCount = new int[seats.length];
        this.wipes = new int[seats.length];
    }

    int seatOf(String username) {
        for (int i = 0; i < seats.length; i++) {
            if (seats[i].username.equals(username)) {
                return i;
            }
        }
        return -1;
```

```
    }

    /// A player's input with its sequence number. Answers false when it is
    /// dropped: a flood, an old or repeated sequence, or a seat that is not theirs.
    boolean input(int seat, int seq, Input in) {
        if (seat < 0 || match.over() || in == null) {
            return false;
        }
        Seat s = seats[seat];
        if (seq <= s.lastSeq) {
            return false;
        }
        int now = match.tick();
        int inWindow = 0;
        int n = Math.min(s.recentCount, s.recent.length);
        for (int i = 0; i < n; i++) {
            if (now - s.recent[i] < Match.TICK_HZ) {

        return out;
```

```
    }
}
```

56.6.1. Making up for lag

Every input carries the tick the player was looking at. When it reaches the server a few ticks later, the ball is flown forward the ticks it lost on the way:

```
// The shooter aimed at the world as it was `viewTick`; the ball is flown
// forward the ticks it lost on the way here, at most MAX_LAG_TICKS, so a
// shot on a phone with a slow connection still lands where it was aimed.
int lag = in.viewTick < 0 ? 0 : FixedMath.clamp(t - in.viewTick, 0, MAX_LAG_TICKS);
boolean alive = true;
for (int i = 0; i < lag && alive; i++) {
    alive = fly(b, t);
}
if (alive) {
    balls.add(b);
}
```

The cap keeps a player with a slow connection from painting people around corners. The match test plays a full party match and checks that the server's result replays to the same paints:

```
@Test
void aPartyMatchIsRecordedAndReplaysToTheSamePaints() throws Exception {
    String host = Api.player(accounts, "host");
    String guest = Api.player(accounts, "guest");
    rooms.host(profile(host), null, "cul-de-sac:SNACK_BAR", null);
    String code = rooms.partyCode(host);
    assertFalse(code.isEmpty());
    rooms.join(profile(guest), null, code);
    assertEquals("", rooms.raceOf(host));
    // Only the host starts the match.
    rooms.go(guest, null);
    assertEquals("", rooms.raceOf(host));
    rooms.go(host, null);
    String id = rooms.raceOf(host);
    assertFalse(id.isEmpty());
    assertEquals(id, rooms.raceOf(guest));

    // Past the countdown, the host walks forward with the trigger held.
    rooms.tick(System.currentTimeMillis() + GameProtocol.COUNTDOWN_MILLIS + 100);
    rooms.input(host, 1, new Input(0, 100, 0, 0, Input.FIRE, -1));
    rooms.fastForward(id);
    assertEquals("", rooms.raceOf(host));

    List mine = Api.list(mvc, Api.as(get("/api/races"), host));
    assertEquals(1, mine.size());
    assertEquals(id, ((Map) mine.get(0)).get("id"));
```

```
    // The record is the field, the seed and every input. Played again
    // here, with the same rules, every player paints exactly as many.
    Map stored = Api.json(mvc, Api.as(get("/api/races/" + id), guest));
    Replay replay = Replay.decode((String) stored.get("replay"));
    Match again = replay.play();
    assertTrue(again.over());
    List scores = (List) stored.get("scores");
    for (int i = 0; i < scores.size(); i++) {
        assertEquals(((Number) scores.get(i)).intValue(), again.player(i).paints());
    }
}
```

56.7. Parties, voice and replays

The lobby is a socket to the server, shared by the party code, the chat and the start of the match:

```
public final class MatchLobby implements GameLink.Listener, Voice.Listener {

```

A replay is the seed and the human inputs, nothing more. The bots aren't in the file: they think inside the rules, so they make the same choices again. The replay screen follows any player, pauses, plays at double speed and skips ahead.

56.8. The Mission Builder

Players build fields of their own. The editor shows one half of the field from above; the other half is that half turned around, built by the same `Arena.Builder.mirror` the built-in yards use, so a player-made field is fair by construction. A `Mission` in the rules module holds the props, spawns, flag, mode and briefing, travels as JSON, and is checked by `Mission.problem()` on the phone and again on the server before it's stored:

```
public final class MissionEditor {
    static final String DRAFT = "splat-mission-draft.json";
    /// The arena code a play-test runs under; publishing gives the real one.
    static final String TEST_CODE = "draft";

    private MissionEditor() {
    }

    public static void show() {
        open(loadDraft());
    }

    static void open(final Mission mission) {
        final Form f = Ui.form("MISSION EDITOR", "missionEditor");
        f.setLayout(new BorderLayout());
        f.setScrollableY(false);
        Ui.back(f, MissionsForm::show);
        final Label status = new Label(" ", "EditorStatus");
        status.setName("editorStatus");
        final MissionCanvas[] canvas = new MissionCanvas[1];
        canvas[0] = new MissionCanvas(mission, () -> {
            saveDraft(mission);
            String p = mission.problem();
            status.setText(p == null ? mission.props.size() + " PROPS  //  " + mission.spawns.size()
                    + " SPAWNS  //  READY" : Ui.caps(p));
        });

        TextField name = new TextField(mission.name, "Operation name", 20, TextArea.ANY);
        name.setName("missionName");
        name.setUIID("EditorField");
        name.addDataChangedListener((t, i) -> {
            mission.name = name.getText();
            saveDraft(mission);
        });
        Container modes = new Container(new GridLayout(1, 3));
        final Button[] modeButtons = new Button[Mode.values().length];
        for (int i = 0; i < modeButtons.length; i++) {
            final Mode m = Mode.values()[i];
            String label = m == Mode.TEAM_PAINT ? "TEAM" : m == Mode.CAPTURE_THE_FLAG ? "FLAG" : "SNACK BAR";
            modeButtons[i] = Ui.button(label, mission.mode == m ? "EditorChipOn" : "EditorChip",

            }
        } catch (IOException e) {
            // the draft is a convenience; the editor still has the mission
        }
    }
}
```

Play-testing registers the draft as an arena and starts a practice match on it, so the bots, the briefing and the camera see it as any other yard. Publishing stores it under a code the server assigns, and the published list shows your missions and your friends'. A mission is played online as the level `m-`

<code>:<MODE>: before the server opens a lobby for such a level it loads the mission and registers it, and from there the match, the replay and the results are the same as for a built-in yard.

56.9. Engagement, moderation and the console

Results, trophies, coins and the season are settled on the server:

```
@Component
public class Results {
    /// Trophies for a win, and lost for a loss; a draw moves nothing.
    public static final int WIN_TROPHIES = 20;
    public static final int LOSS_TROPHIES = 15;
    /// Coins per paint, and the most a match can pay.
    public static final int COINS_PER_PAINT = 3;
    public static final int MAX_MATCH_COINS = 60;

    /// What one runner got out of a race.
    public static final class Outcome {
        public final int trophies;
        public final int coins;

        public Outcome(int trophies, int coins) {
            this.trophies = trophies;
            this.coins = coins;
        }
    }

    private final RaceRecordRepository races;
    private final RaceEntryRepository entries;
    private final ProfileRepository profiles;
    private final Progression progression;
    private final Referrals referrals;

    public Results(RaceRecordRepository races, RaceEntryRepository entries, ProfileRepository profiles,
            Progression progression, Referrals referrals) {

The engagement tools (campaign links, invitations, the home screen spotlight, pushes to an audience and scheduled pipelines) are the ones the Skirmish chapter walks through step by step, and they work in Splat unchanged.

56.10. Making it yours

- **Fields**: add an `Arena.Builder` to `Catalog.ARENAS`. The mission list, the server's playlist and the bots pick it up at once. Give a new box kind a color in `ArenaView`.
- **Markers**: add a `MarkerDef`, then sell it in the backend's shop `Catalog`. The shipped markers are side-grades, not upgrades: the pump hits harder at range and the ramping marker sprays.
- **Characters**: every operator is a rigged glTF model, `model_op-*.glb` in `common/src/main/resources`, listed by team in `Models`. `tools/pack-art.py` packs them from the CC0 sources in `ART.md`, keeps the clips the game plays, and smooths their normals so a low-poly body shades as a round one; `tools/pack-art.py --smooth` re-shades models already packed. Swap a model by packing your own under the same name.
- **The jokes**: the briefings are in `Mode`, the killfeed's excuses in `Hud`, and the emotes in `MatchForm`.
- **The look**: every color is a variable at the top of `theme.css`:

```
--bg: #0b0d10;
--surface: #161a1f;
--surface-light: #20262d;
--edge: #2e353d;
--edge-light: #4f5862;
--coral: #f2b632;
--coral-light: #ffd166;
--coral-dark: #a8770f;
--volt: #f2b632;
```

```
--volt-dark: #a8770f;
--cyan: #4aa8ff;
--violet: #5c6670;
--violet-glow: #aab3bd;
--ice: #e8ecef;
--ink: #0b0d10;
--text: #f2f4f5;
--text-muted: #8a949e;
--danger: #f0443a;
```

- **Store, ads and push**: the product ids are in `AppConfig`, and the receipt validator is chosen in `Services`:

```
/// Google's published test ad units. They always fill, never pay, and are
/// safe to click; replace them with your own AdMob units before release.
public static final String REWARDED_AD_UNIT = "ca-app-pub-3940256099942544/5224354917";

                    + "' profile; set it to store");
        }
        return new SimulatedReceipts();
    }
    if (!"store".equalsIgnoreCase(kind)) {
        return new MisconfiguredReceipts("splat.iap.provider is '" + kind
                + "', which is neither store nor simulated");
    }
    if (appleSecret.trim().length() == 0 && (googlePackage.trim().length() == 0
            || googleToken.trim().length() == 0)) {
```

```
        return new MisconfiguredReceipts("in-app purchases are not configured; set "
                + "splat.iap.apple.secret, or splat.iap.google.package and "
                + "splat.iap.google.token");
    }
    if (appleSecret.trim().length() > 0 && appleBundle.trim().length() == 0) {
        // Without it, a genuine receipt from any other app could buy gems.
        return new MisconfiguredReceipts("splat.iap.apple.secret is set without "
                + "splat.iap.apple.bundle, the bundle id receipts must belong to");
    }
    return new StoreReceipts(appleSecret.trim(), appleBundle.trim(), googlePackage.trim(), googleToken.trim());
}
```

Chapter 57. Parley: A private messenger from three sides

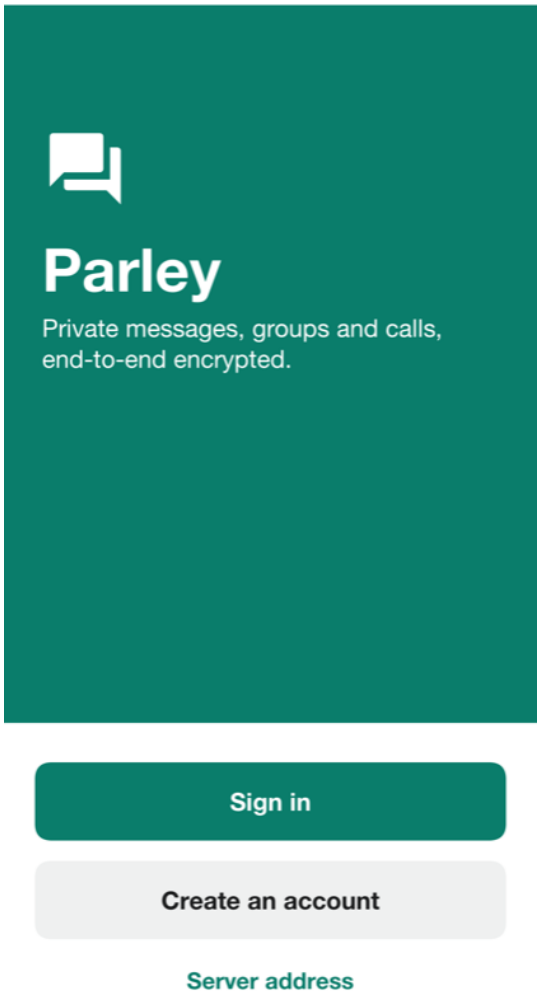
Parley is a sample app with a server behind it. People chat one to one and in groups, send photos, video and voice notes, and call each other with voice or video. Everything they write, and every call, is end-to-end encrypted: the server relays what it can't read. An administrator looks after the service without ever seeing a message. The app and the server are one Maven project, written in Java on both sides.

This chapter is the user's guide: what a person sees and can do, and what an administrator sees. Chapter 58, *Parley: Building on the sample* is the other half. It explains how the project is built, how the encryption works and what to change to make the app yours. Parley shares its accounts, sign-in, text messages, push notifications, live channel and operations console with Wayline and Savor, the two sibling samples.

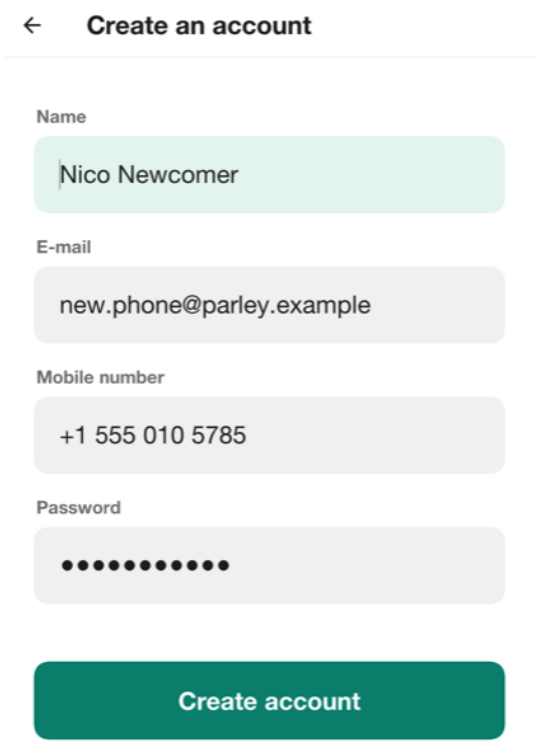
One app serves everyone. The server gives every account a set of roles, and the app opens on the screen that fits them: a person on their chats, an administrator on the admin console.

Role	What it adds
User	Every account is a user. Chat one to one, in groups and in channels, send photos, video and voice notes, call, link more devices, and decide what others can see about you.
Admin	Granted by another administrator. See the service in numbers and charts, read and resolve the reports people make, find and moderate accounts, and link conversations to Telegram and WhatsApp.

57.1. Trying it



Start the server on its development profile and it creates a set of accounts, all with the password `parley-demo`, a few conversations between them and a bot that answers. Section 58.1, "Running it" has the commands.

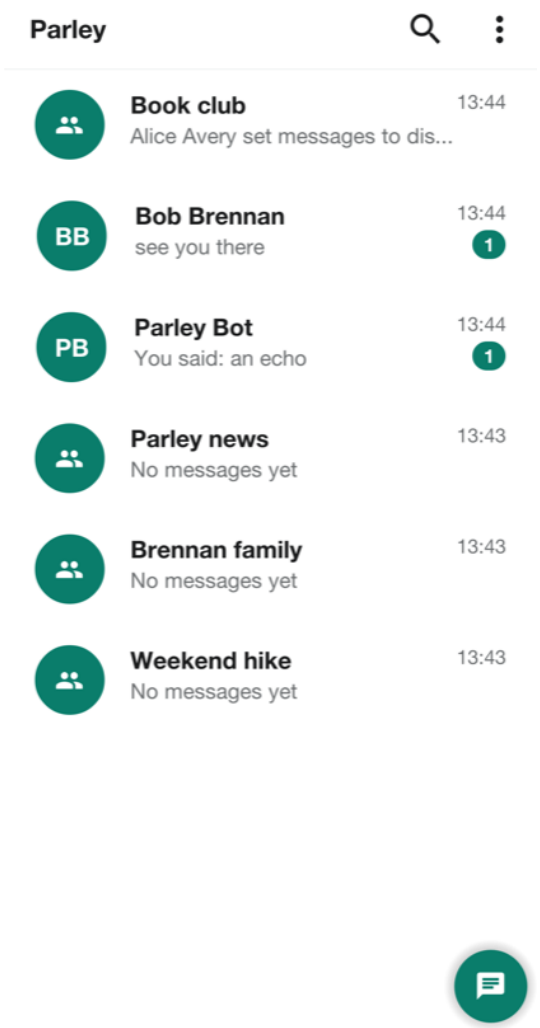


Account	Role
`alice@parley.example`, `bob@parley.example`, `carol@parley.example`, `dan@parley.example`	Users who share a group, **Weekend hike**, a family group and a channel, **Parley news**.
`mallory@parley.example`	A user an administrator has flagged, with a report about them still open.
`admin@parley.example`	Runs the service.
The Parley bot	Answers whoever writes to it, so that one person trying the app alone has someone to talk to. It's the server, so its chats are marked as not end-to-end encrypted.

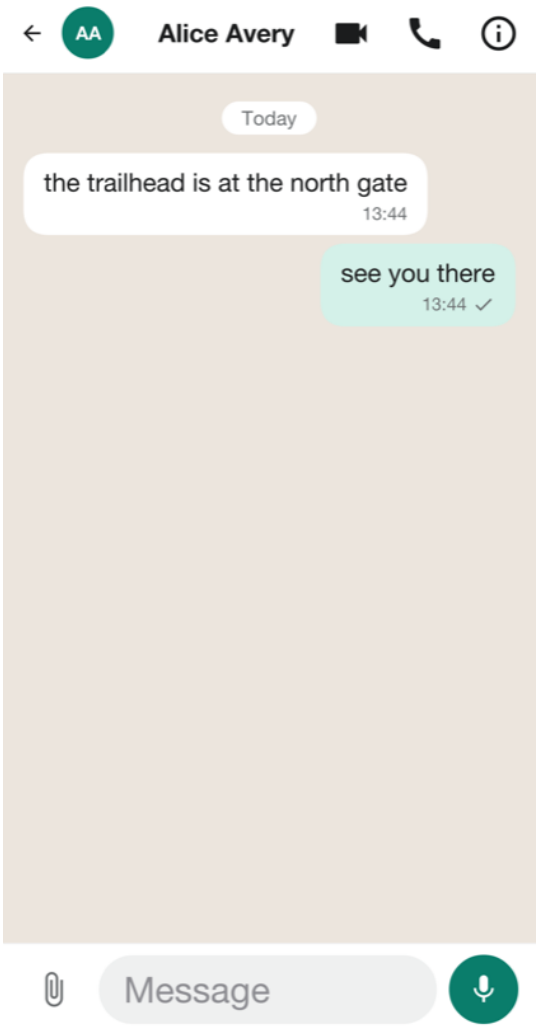
To see a conversation from both ends, sign in as one account in the simulator and as another in a second simulator, or in a browser.

57.2. Getting in

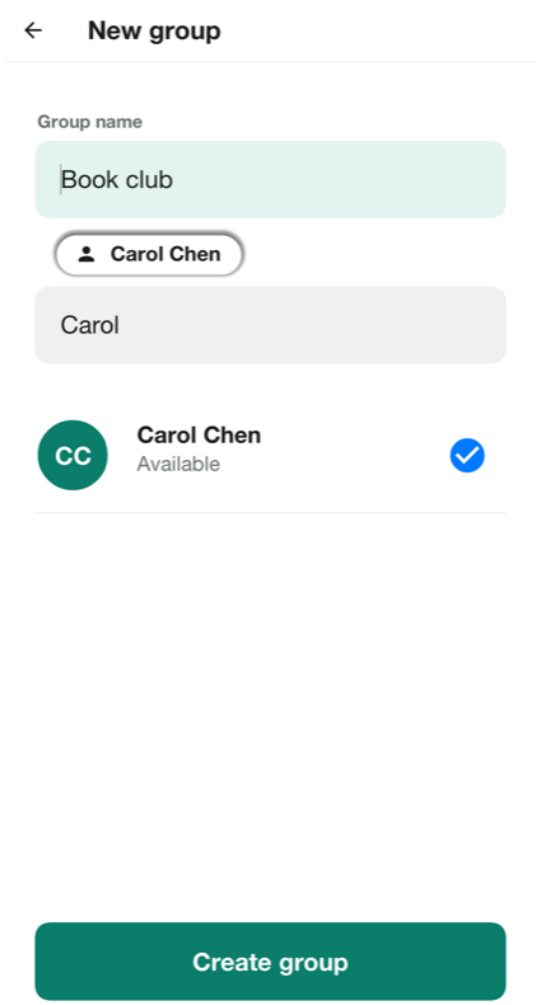
The welcome screen offers to sign in or to create an account. **Server address** is there for a phone on the same network as a development server: `localhost` on a phone is the phone, so the app has to be told where the server is. The app in a browser has no such entry: it always talks to the server that hosts it.



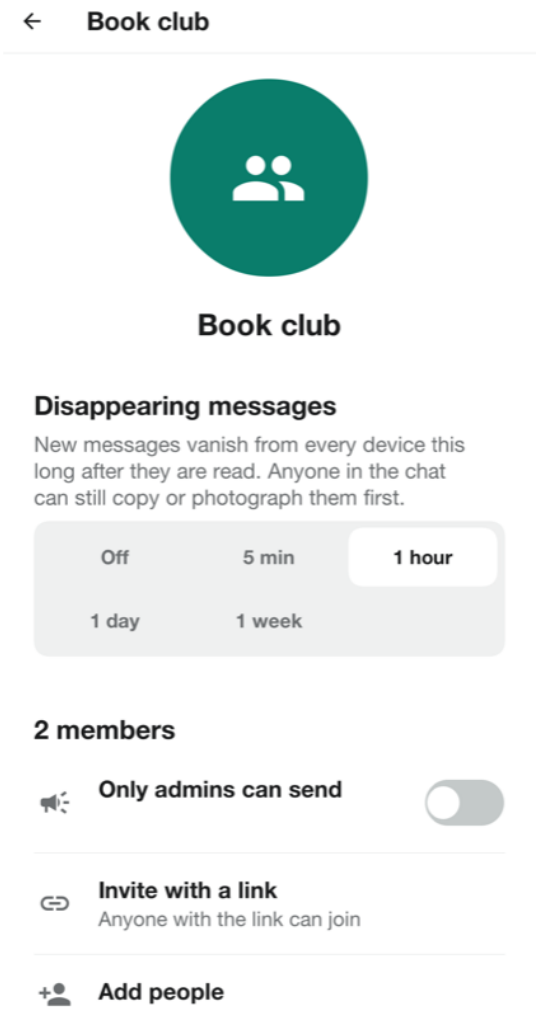
A new account asks for a name, an e-mail address, a mobile number and a password. The mobile number is verified with a code sent as a text message, and a development server prints the code on its console and the app shows it. The number is used to find people you know, and only if you leave that on.



The first sign-in on a device asks whether the app may share usage statistics. The answer can be changed in the settings at any time. What's shared never includes a name, a contact, a number or anything that was written.



On first sign-in the app also makes this device's encryption keys. They're made on the device and never leave it, which is why a message sent before the account existed on this device can't be read here.



57.3. Chats

The chat list starts with every conversation, the newest first, with an unread count and the start of the last message. Pressing and holding a conversation pins it to the top, mutes it or archives it. A notification only says that something arrived: what it says is fetched and decrypted on the device.

Create group

There are three kinds of conversation:

Kind	Description
Chat	Two people.
Group	Up to 256 people. The person who made it owns it and can name administrators, who add and remove members and change the name, the description and the photo. A group can be joined with a link or a code.
Channel	A group in which only the administrators can send. Everyone else reads.

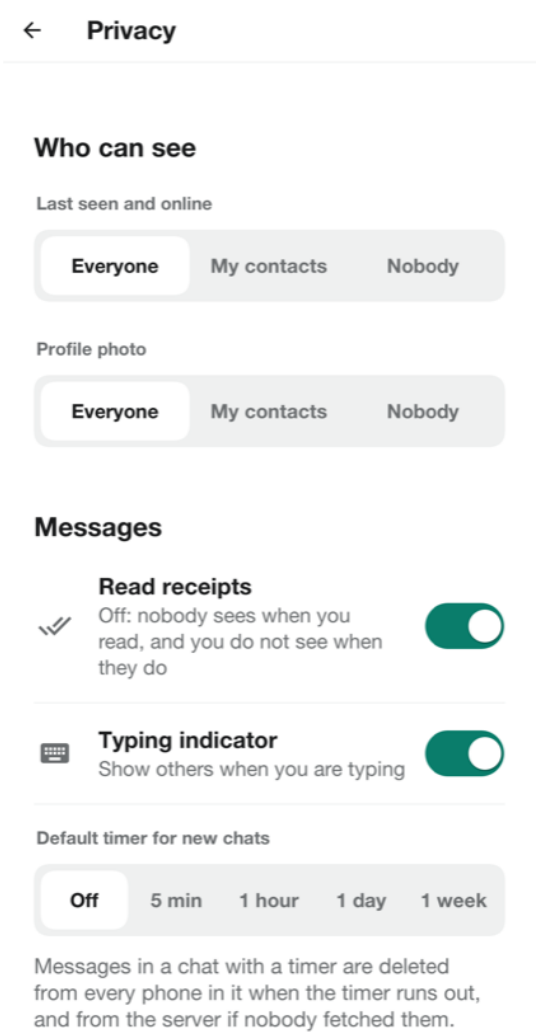
The button on the chat list starts a conversation: find a person by name, username or phone number, make a group, or join one with an invitation link.

A conversation shows its messages as they arrive, a typing indicator, and the state of each message you sent: sent, delivered, and read. A message can be replied to, copied, forwarded, edited, and deleted. **Delete for everyone** removes it from every phone in the conversation. Photos, video and voice notes are sent from the attachment button: a photo or a video from the gallery or the camera, and a voice note recorded with the microphone. Each is encrypted on your phone before it leaves, and an attachment is limited to 16 MB.

Pressing the name at the top opens the conversation's info: who is in it, a mute switch, the timer for disappearing messages, the safety numbers, and for a person, the choice to block or to report them.

57.4. Is anyone listening

Messages, photos, voice notes and calls are encrypted on your phone with keys that only the phones in the conversation hold. The server stores and relays what it can't read, which is the point: nobody outside the conversation, the server's administrators included, can read it.

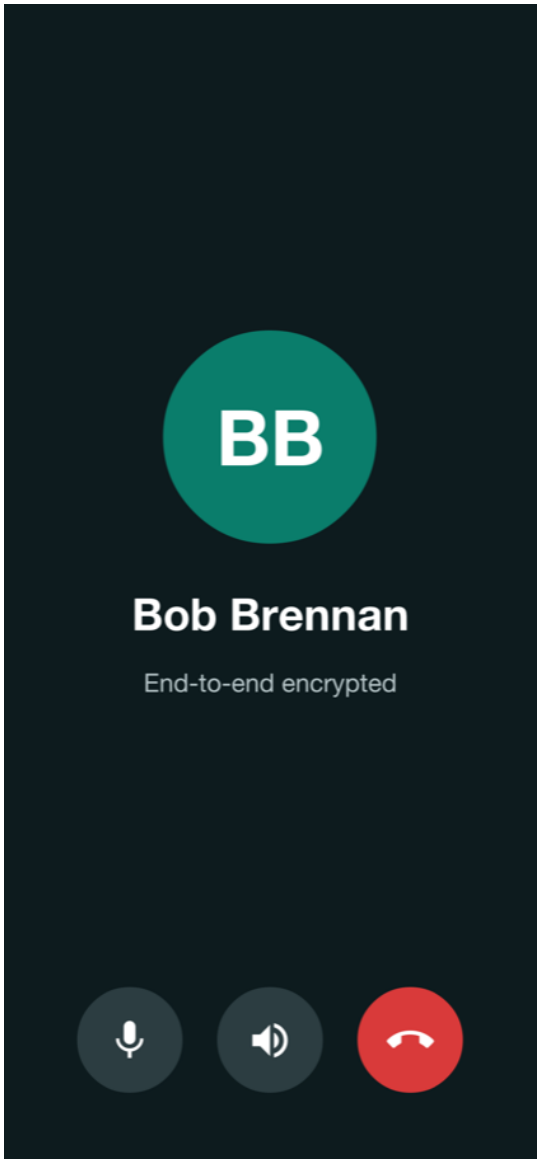


A message is only as private as the person you think you're talking to, so the info screen offers **Safety numbers**: sixty digits that both phones compute from their keys. Compare them with the other person's screen, in person or over a call. If they match, nobody is in the middle. They change when either person's keys do — a new phone, a reinstall — so a number that changed for a person who hasn't changed phones is worth a question.

A chat with the demo bot, and a conversation an administrator has linked to Telegram or WhatsApp, aren't end-to-end encrypted, because a bot or another network has to read what's written. The app marks those conversations, and anyone in a bridged conversation is told when it's linked. Section 58.6, "Bridges to Telegram and WhatsApp" explains the trade-off.

57.5. Privacy

Privacy and security in the settings holds what others can learn about you and what the phone shows:

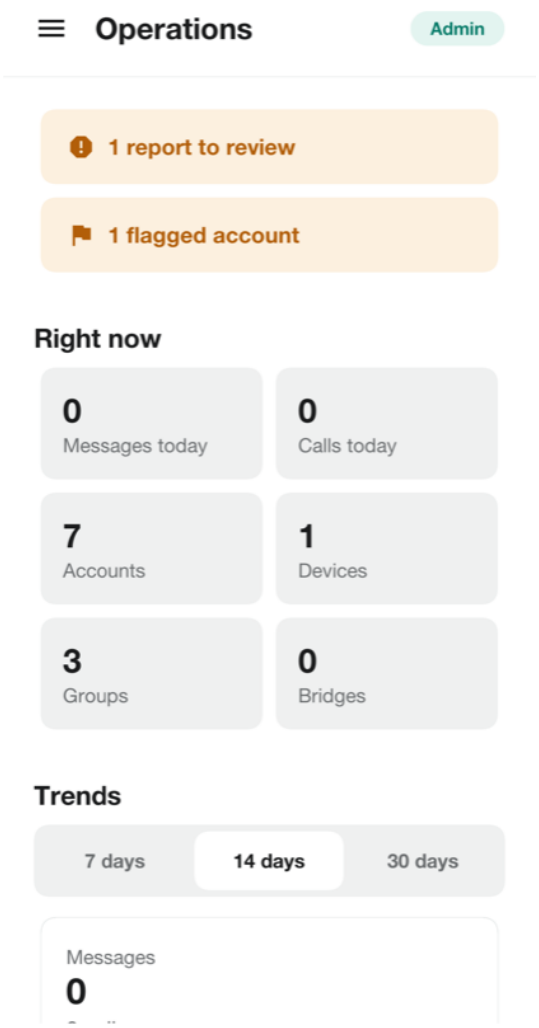


Setting	What it does
Last seen and online	Who sees when you were last online: everyone, your contacts or nobody. The server enforces it, because the server is what hands the information out.
Profile photo	Who sees your photo, in the same three choices.
Read receipts	Whether others see when you've read their message. Off, you don't see theirs either, so it isn't a way to watch without being watched.
Typing indicator	Whether others see when you're typing.
Disappearing messages	A default timer for new chats: off, 5 minutes, 1 hour, 1 day or 1 week. New messages in a chat with a timer vanish from every phone in it that long after they're read. Anyone in the chat can still copy what was said, so it limits what's kept, not what was seen.
Screen security	Keeps chats out of screenshots and the app switcher.
App lock	Asks for a fingerprint, face or passcode to open Parley, after the app has been away.
Blocked	People who can't message or call you. A person is blocked from their chat's info screen.

Report on a person or a conversation sends the administrators a reason and the last few messages as the reporter's phone shows them, and nothing else: they can't read anything the reporter didn't choose to send.

57.6. Calls

A call is one to one, voice or video, from the buttons at the top of a chat. The other person's phone rings, with a notification and the phone's own call screen — the lock screen on iOS, the system call UI on Android — even when Parley isn't running. Answering opens the call screen, which has a mute switch, a speaker switch, for video a camera switch and a button to turn the camera off, and **End**. A call you don't answer shows in **Calls** as missed, and a call to someone who's already in one is told they're busy.



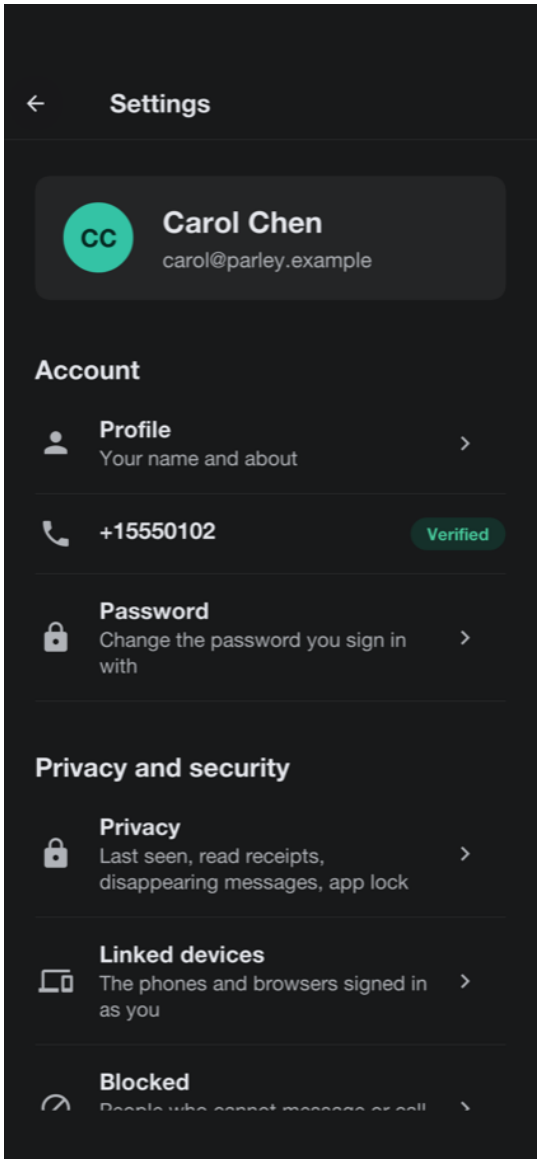
The audio and video go straight between the two phones, or through a relay when a direct path doesn't exist, which on mobile networks is often. Either way they're encrypted between the two phones. Calls need the camera and the microphone, which the app asks for the first time.

57.7. Linked devices

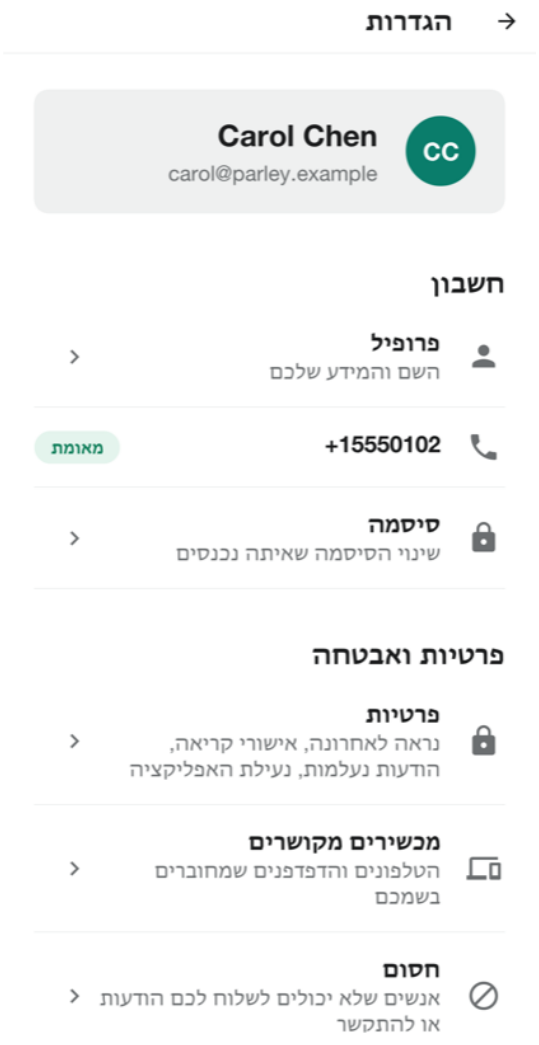
The same account can be signed in on up to six phones, tablets, and browsers. **Linked devices** in the settings lists them. Each is its own end of every conversation, with its own keys, and a message to you is encrypted for each. Unlinking one is final: the server stops sending it anything, and what it held opens nothing sent afterward.

57.8. The administrator

The admin console starts on a dashboard: how many people are active, how many messages were sent and how many accounts are new, with charts of the last two weeks, of the busiest hours and of the kinds of chat. Message counts are all the server knows: what was said is encrypted on the devices and never reached it.



Reports lists what people reported, with the reason, the messages the reporter attached and a button to resolve it with a note of what was done. **People** finds any account. An account can be flagged, which marks it for the admins and changes nothing for its owner, or blocked with a reason that's kept in its history: a blocked account is signed out everywhere and can't sign in. Another administrator can be named from the same screen.



Bridges lists the conversations linked to Telegram or WhatsApp, and says when a network isn't set up on this server.

On a tablet or a desktop the console lays its sections down the left side and opens what's picked beside its list.

57.9. Settings

The settings hold the account — its name, about line, photo, phone number and password — the privacy choices, the linked devices, the language, the theme, notifications and the usage statistics. Deleting the account removes the sign-in, the profile and the settings for good. The app is in English, Spanish, French, German and Hebrew, and in Hebrew it's laid out from right to left.

The translations are machine-generated samples, and no native speaker has reviewed them. Have them checked before you ship the app in those languages.

57.10. In a browser

The server can host the app itself: open the server's address in a browser and the same app loads there, signs in against that server, links itself as a device and opens its live channel. A browser gives a page less than a phone gives an app, and the app says so where it matters: the system call screen and the call push are for phones.

Chapter 58. Parley: Building on the sample

Parley is a messenger, and most of what makes one isn't in the server. The server stores and relays ciphertext it can't open; the keys, the sessions, the encryption and the history are in the app. Parley kept what it shares with Wayline and Savor: the module layout, the accounts and sign-in, text messages, push notifications, the live channel, the operations console and hosting the app in a browser. This chapter covers what a messenger changes. For the parts the samples share, it points at the Wayline chapter, which is true of Parley with the names swapped.

58.1. Running it

The project is in `scripts/parley`, and the Initializr generates it under your own package and name. Start the server on the development profile, which seeds the demo accounts and conversations and prints text messages on the console:

```
CN1_PROFILE=dev backend/server.sh run
```

Then run the app in the simulator, from the project's directory:

```
mvn verify -Psimulator -DskipTests -Dcodename1.platform=javase
```

`backend/server.sh run --web` builds the app for a browser as well and serves it at `http://localhost:8080/`. Running on a device, and the compiled server, work as Section 51.1, "Running it" describes.

58.2. The modules

The three modules are Wayline's: `shared` holds the contract, the data transfer objects and the `@RestClient` interfaces both sides compile against; `common` is the app; `backend` is the server. The app's packages are `crypto` (keys, sessions and the encrypted vault on the device), `chat` (sending, receiving and calls), `store` (the history), `live`, `net`, `notify`, `admin` and `ui`. The backend's follow the domain:

Package	What it holds
`device`	The devices of each account and the public keys they publish: identity keys, signed prekeys and one-time prekeys.
`chat`	Conversations and their members, the envelopes that carry messages, their fan-out to devices, encrypted attachments and the demo bot.
`call`	Calls: who is calling whom, the signalling relay and the TURN credentials.
`contact`	Finding people, blocks and reports.
`bridge`	The links to Telegram and WhatsApp.
`account`, `admin`, `sms`, `push`, `live`	Taken from Wayline and adapted: roles, moderation and the privacy preferences, the statistics, text messages, push, and the live channel.

The server's rules are in one table, with the admin console behind the `admin` role and everything else behind a signed-in account:

```
.authorizeHttpRequests(auth -> auth
        .requestMatchers(AntPathRequestMatcher.antMatcher("POST",
                "/api/account/register")).permitAll()
        .requestMatchers("/api/admin/**").hasRole(Roles.ADMIN)
        .anyRequest().authenticated())
```

58.3. The protocol

Parley follows Signal's two published specifications, X3DH to start a session and the Double Ratchet to carry it, over the primitives Codename One has on every port. Where Signal uses X25519 for the Diffie-Hellman steps, Parley uses P-256, which the platforms provide natively; it derives keys with HKDF-SHA-256 and encrypts messages with AES-256-GCM. The pieces are in the crypto API: `KeyGenerator.ec(256)`, `KeyAgreement.ecdh`, `Hkdf.derive`, `Cipher` and `Hmac`, and `Signature` for the prekey's signature.

Each device is its own identity. It makes three kinds of key, once, and keeps the private halves in the `Vault`:

- An **identity key**, long term.
- A **signed prekey**, which the identity key signs and which is rotated.
- A supply of **one-time prekeys**, each of which opens one session and is then gone.

The device publishes the public halves to `device/Devices`, which checks the signature. That check doesn't make the server trusted: a server that wanted to lie would swap the identity key too, which is what the safety numbers catch.

To write to a device it hasn't talked to, the sender fetches that device's prekey bundle. The server hands out, and so deletes, one of the one-time prekeys. The sender combines its identity key and a fresh ephemeral key with the bundle's identity key, signed prekey and one-time prekey — three or four ECDH results, joined and run through HKDF — into a root key, and the first message carries what the receiver needs to repeat the computation. The receiver can be offline, and the first message is still forward secret. After that the Double Ratchet takes over: every message moves a symmetric chain forward, every reply a Diffie-Hellman step, so a key that leaks opens neither the past nor, once a reply has been exchanged, the future. Messages that arrive out of order open from skipped keys the ratchet keeps, and a header that claims an absurd number of lost messages is refused.

`crypto/Sessions` keeps one session per remote device, plus the one before it. Two devices that start a session with each other at the same moment each end up with two; the earlier one opens whatever the other side sent on it. The same happens when a contact reinstalls: the new device's first message starts a new session, and messages still in flight on the old one still open.

A message is a JSON payload — kind, text and a media reference — that's encrypted for each recipient device. The server sees an envelope: who sent it, which device it's for, a header, a

ciphertext and a time. It never sees a payload. The ciphertext is limited to 64 KB, which is why attachments travel apart from it.

58.3.1. Groups, devices and delivery

There is no group key. A message to a group is encrypted once for every device of every member, and once for each of the sender's other devices, so that they show what was sent. The client sends all the copies in one request, and the server checks that they cover exactly the devices it knows, so that a message can't skip a device. A group of 256 people on up to six devices each is a lot of copies, which is the price of having no state to keep in step: adding a member needs no rekey, and a removed member simply stops being addressed.

`chat/Fanout` stores each envelope and sends it over the live channel to the device it's for. An account with no device connected gets a push that carries nothing: it only wakes the app, which fetches what's waiting over its own connection. An envelope is deleted when its device acknowledges it, and one nobody fetches is kept for 30 days. Delivery is at least once: an envelope is stored before it's sent live, so a device can see it twice, and the app remembers the ids it has seen. Typing indicators and call signals go live only and are never stored.

Linking a device is signing in on it. The server lists the account's devices, up to six, and the app on every one of them encrypts for the others. Unlinking one deletes its keys and the envelopes waiting for it, which nobody else could read. A safety number is computed from the two identity keys and usernames, hashed a thousand times, and is shown as sixty digits. It follows the shape of Signal's but its iteration count and version byte are the app's own, so the numbers don't match Signal's.

58.3.2. Media

A photo, a video or a voice note is encrypted on the device with a fresh AES key, and the ciphertext is uploaded to `chat/Media`. The upload answers an id of 128 random bits. The id, the key and a digest of the ciphertext go inside the message, so only the message's recipients have the key. The server stores bytes it can't read for anyone who presents the id, up to 16 MB, and the receiver checks the digest before it opens anything: an attachment changed on the way isn't opened. Profile and conversation photos are the one exception, because the server has to hand them to people who haven't been sent a message.

58.3.3. At rest on the device

Keys, sessions and message history are JSON documents in `Storage`, each sealed with AES-GCM under a vault key that lives in the platform keystore (`SecureStorage`: the Keychain, the Android Keystore). A copy of the app's files holds nothing readable without that key, and signing out deletes it, which turns the files into noise. Each account on a device has a vault of its own, named by a hash so that the file names don't say whose they are. App lock, screen security and the privacy settings that the app enforces itself — read receipts, typing — are in `ui/Privacy` and `Prefs`; last seen and the profile photo are enforced by the server, which is what hands them out.

58.4. Disappearing messages

The timer is a setting of the conversation, in seconds, that the server keeps and every member's

phone reads. A message in a conversation with a timer is stamped with the time it vanishes, counted from when it was sent: the server stamps the envelopes it stores, and each phone stamps its own copy and deletes it then. An envelope that's still waiting when its time comes is deleted on the server too (`EnvelopeRepository.expire`), so a phone that was offline for longer than the timer never receives it. A timer can't take back what a recipient already copied, and the user's guide says so.

58.5. Calls

A call is two apps and a relay. The server never touches the media: it rings the callee, relays the signalling, and hands out the addresses of the servers through which the apps reach each other. The media itself is WebRTC's, encrypted with DTLS-SRTP between the two devices.

The app owns the signalling, which is how `com.codename1.webrtc` is meant to be used (the WebRTC chapter). `call/Calls` starts and ends a call and passes along six signals as `call` frames on the live channel: `OFFER`, `ANSWER` and `ICE` carry WebRTC's own text, and `ACCEPT`, `DECLINE` and `END` move the call through its states:

State	How it gets there
`RINGING`	The caller started it. It rings the callee for 45 seconds.
`ACCEPTED`	The callee answered.
`ENDED`	Either side hung up.
`DECLINED`	The callee refused.
`MISSED`	The caller gave up, or nobody answered in time.
`BUSY`	The callee was already in a call.

The caller opens its camera and microphone and sends the offer at once, so the callee's phone already holds it when the person answers. A candidate that arrives before the description it belongs to waits for it. A call nobody ended is closed by a sweep after it has been ringing too long, or running for hours.

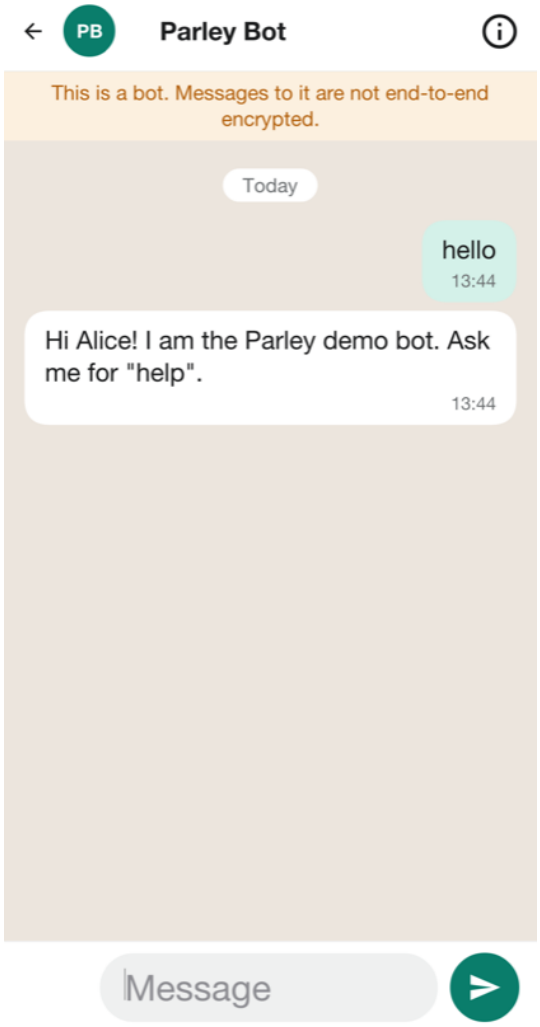
Where the platform has a system call screen the call is reported to it as well: CallKit on iOS and the ConnectionService on Android, through `com.codename1.call`. The call rings on the lock screen, shows in the phone's call log, and the system's answer and hang-up buttons drive the same steps as the app's. A VoIP push rings a phone the app isn't running on. The pieces are in `chat/Calls` in the app and `push/MessagePushes` on the server.

58.5.1. Reaching each other: STUN and TURN

Most calls find a direct path with only STUN. A call between two phones on mobile networks often doesn't, and needs a TURN server to relay the encrypted packets. The server doesn't run one. It hands each caller the addresses of yours, with a credential that expires, so nothing about the TURN server is kept in the app:

```
parley.ice.stun=stun:stun.example.org:3478
```

```
parley.ice.turn=turn:turn.example.org:3478,turns:turn.example.org:5349
parley.ice.secret=${PARLEY_ICE_SECRET}
parley.ice.ttl=86400
```



`parley.ice.secret` is the secret shared with the TURN server — coturn's `static-auth-secret`, with `use-auth-secret` on. `Calls.ice` builds the credential the way coturn checks it: the username is the expiry time and the account, and the password is the HMAC-SHA1 of the username under the secret. Nothing is stored, and a leaked credential stops working on its own after `parley.ice.ttl` seconds. With no TURN server set, only STUN is handed out, and calls between networks that block a direct path fail. The default STUN server is a public one; run your own for a service of your own.

58.6. Bridges to Telegram and WhatsApp

A group or a channel can be linked to a Telegram group or a WhatsApp number. What a Parley member writes goes out to the linked chat, and what's written there comes in and is posted into the conversation. Each bridge is off until the server has its credentials:

```
parley.telegram.token=${PARLEY_TELEGRAM_TOKEN}
parley.telegram.secret=${PARLEY_TELEGRAM_SECRET}
parley.telegram.bot=example_parley_bot
parley.whatsapp.token=${PARLEY_WHATSAPP_TOKEN}
parley.whatsapp.phone=${PARLEY_WHATSAPP_PHONE}
parley.whatsapp.secret=${PARLEY_WHATSAPP_SECRET}
parley.whatsapp.verify=${PARLEY_WHATSAPP_VERIFY}
```

- **Telegram:** a bot from BotFather. Its webhook is `/bridge/telegram/<secret>`, where the secret is a random string of 16 or more characters, and is also given to `setWebhook` as the `secret_token`. A group is linked by adding the bot to the Telegram group, sending it `/id` and typing the number it answers with.
- **WhatsApp:** a Cloud API access token and phone number. Meta calls `/bridge/whatsapp`, answers the verify token when subscribing, and signs every delivery with the app secret, which the server checks.

58.6.1. The privacy trade-off

To carry a message across, a bridge has to read it. A bridged conversation is therefore **not end-to-end encrypted**: its members' apps send it to the server in plain text, so that the server can pass it on. The sample doesn't hide this. Only a group's owner or one of its admins can link it, the link is announced in the group so that everyone learns, in a notice they can't miss, that from now on what they write there leaves Parley in plain text, and every member's app marks the conversation as not end-to-end encrypted. The chat with the demo bot is marked the same way, for the same reason. The administrator's **Bridges** screen lists every link.

Plain text on the server is also plain text in the other network, under that network's own rules about what it keeps. Decide whether your service wants bridges at all; leave them unconfigured and the feature isn't offered.

58.7. The admin console and what the server knows

The console is built on the operations console's `Console`, so it's a list beside a detail on a wide screen and a list that opens a screen per item on a phone. The statistics count what the server can see — accounts, messages, kinds of conversation, the busy hours — and nothing it can't. A report is

the only way content reaches an administrator, and it carries only what the reporter's own phone chose to attach.

58.8. Hosting, accounts, text messages and push

These are Wayline's, with the names swapped: the accounts and the sign-in (Section 51.5, "Who may do what"), text messages (Section 51.14, "Text messages") with the providers `parley.sms.provider` names, push (Section 51.15, "Push notifications") with `parley.push.provider`, the database (Section 51.23, "The database") and hosting (Section 51.23.5, "Hosting it: A managed database and one binary"). One difference matters here: a Parley push never carries a message, it only wakes the app, which fetches and decrypts on the device, so the push provider never learns what anyone said.

58.9. Tests

```
mvn -pl shared,backend -Dcodename1.platform=backend test
mvn -pl shared,backend -Dcodename1.platform=backend test -Dcn1.backend.compiledTests=true
./run-e2e.sh
./run-web-e2e.sh
```

The backend tests run the server on the JVM and then compiled, against the envelope and device rules, the calls' states, the bridges and who may call what. `run-e2e.sh` starts a server on the test profile and drives the app in the simulator against it. `run-web-e2e.sh` does the same for the app in a browser, linked as a device.

58.10. Making it yours

The ways to make Wayline your own apply here too: the name, icon and colors, the languages, the text-message and push providers, the database, hosting. A few apply to a messenger in particular:

- **Your own relay.** Point `parley.ice.turn` at a TURN server you run.
- **No bridges.** Leave the Telegram and WhatsApp settings out.
- **A different curve or cipher.** The primitives are in `crypto/Ratchet`, and the server never sees them, so changing them is an app-side change with a migration for existing sessions.
- **Before it's a product.** A real service needs an independent review of the protocol code, a way to back up and restore history, key transparency or another answer to a server that lies about keys, abuse handling at scale, calls with more than two people and retention rules for the places it operates in. None of them are in the sample.

Chapter 59. Reel: A streaming service from four sides

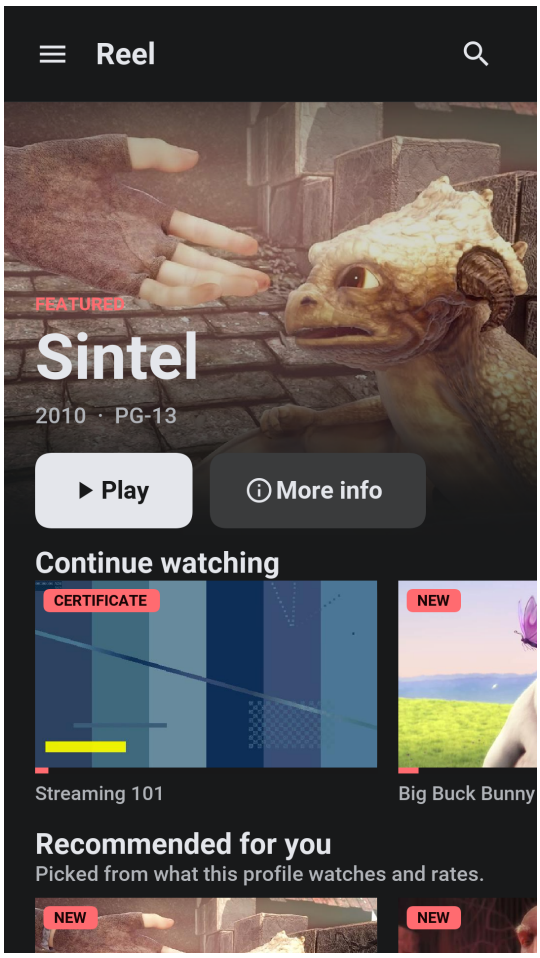
Reel is a sample app with a server behind it. Viewers watch films, series and courses on a phone, a tablet, a desktop or in a browser, and pick up on one screen where they left off on another. Creators upload video and publish it. Moderators decide what gets published. An administrator runs the service. The app and the server are one Maven project, written in Java on both sides.

This chapter is the user's guide: what each of them sees and can do. Chapter 60, *Reel: Building on the sample* is the other half. It explains how the project is built, how playback is protected and what to change to make the service yours.

One app serves everyone. The server gives every account a set of roles, and the app opens on the screen that fits them.

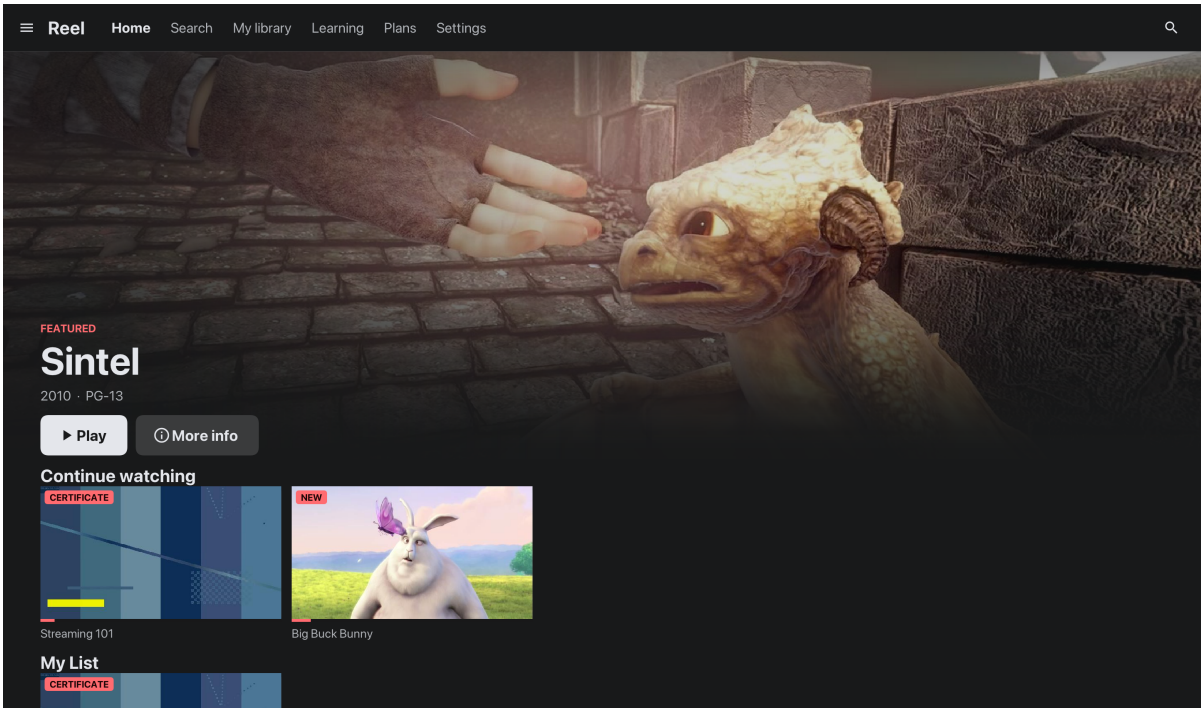
Role	What it adds
Viewer	Every account is a viewer. Browse and search the catalog, watch with ads or without, keep a list, download for offline viewing, take courses, and manage the household's profiles and the plan.
Creator	Upload video, describe it, add chapters, quizzes and polls, submit a title for review and follow how it's watched.
Moderator	Approve or reject what creators submit, take down what was published, and keep the blocklists that check every upload.
Admin	See the service in numbers and charts, manage accounts, plans, coupons and ad campaigns, switch features on and off, and deal with account sharing.

59.1. Trying it



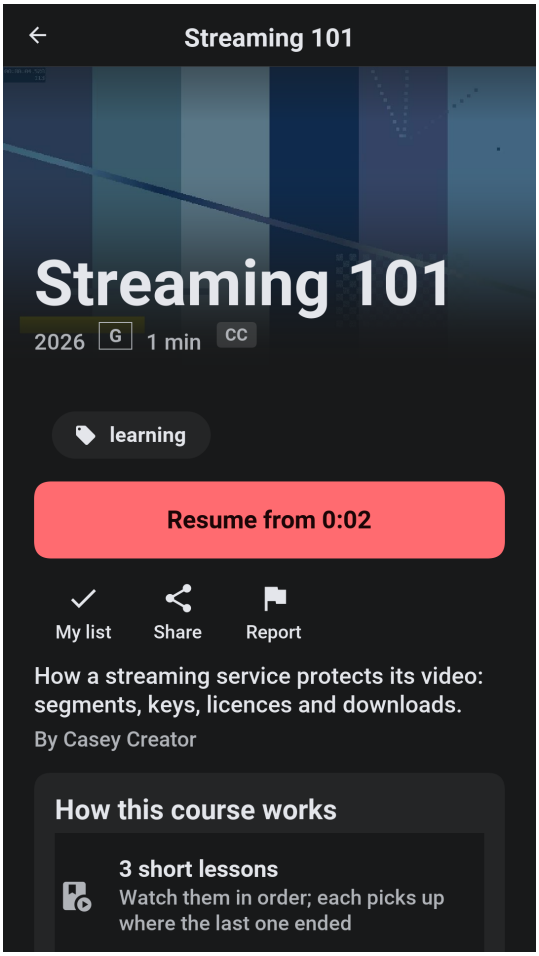
Start the server on its development profile and it creates a set of accounts, all with the password `reel-demo`, the plans, two ad campaigns and a catalog of the Blender open movies and a short course:

`viewer@reel.example`, `viewer2@reel.example`	viewers
`viewer3@reel.example`	a viewer with an open account-sharing alert
`creator@reel.example`	owns the uploaded titles
`moderator@reel.example`	reviews what creators submit
`admin@reel.example`	runs the service



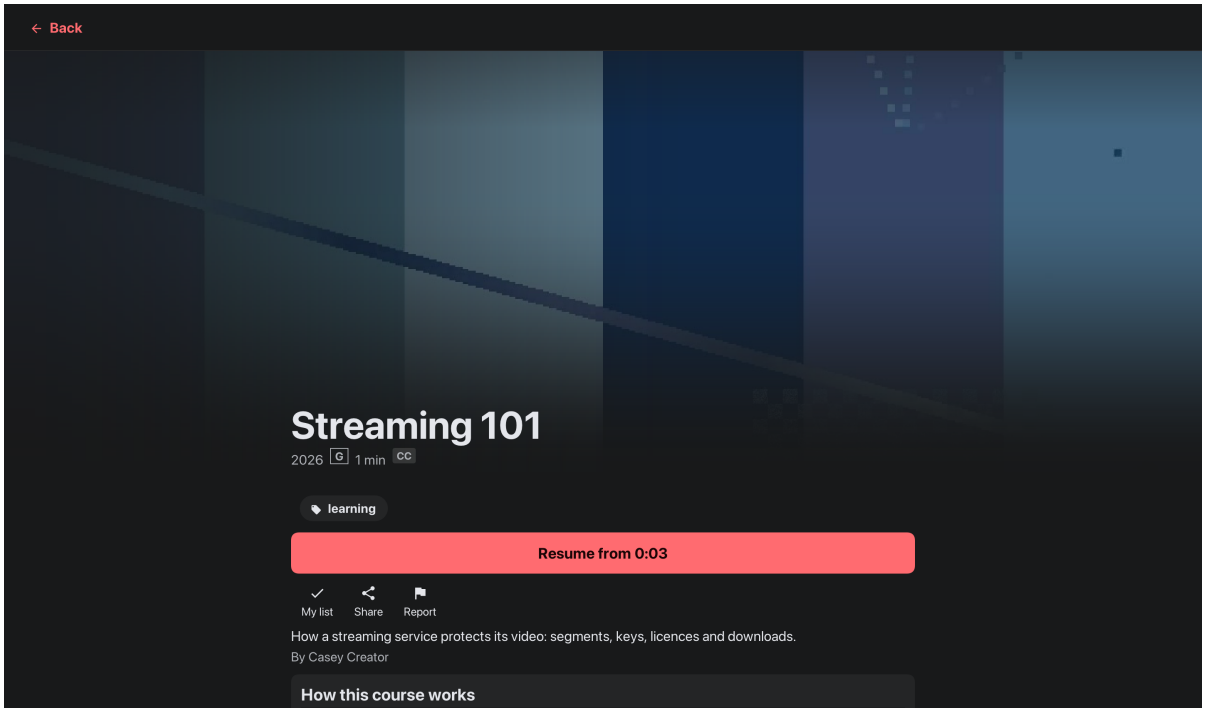
`scripts/reel/README.adoc` has the two commands that start the server and the app, and the one that fetches the films. Without the films every screen works; the artwork and the picture are missing.

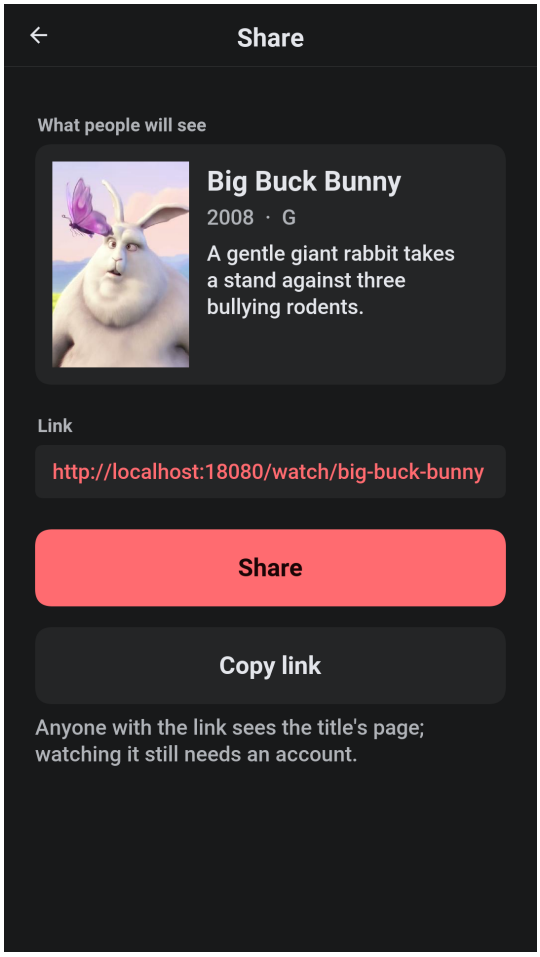
59.2. Watching



A viewer with more than one profile in the household is asked who is watching. A kids profile sees only titles rated for children, and a profile can be locked with a PIN.

The home screen leads with one title and then rows: continue watching, recommendations based on what the profile watched, the list, and the catalog by genre. Search finds titles by name, synopsis, genre, and creator.

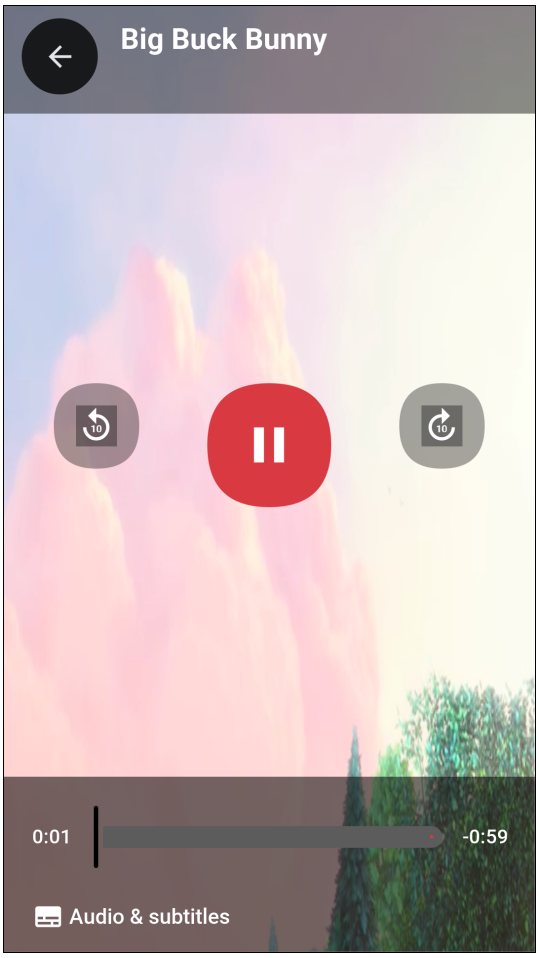


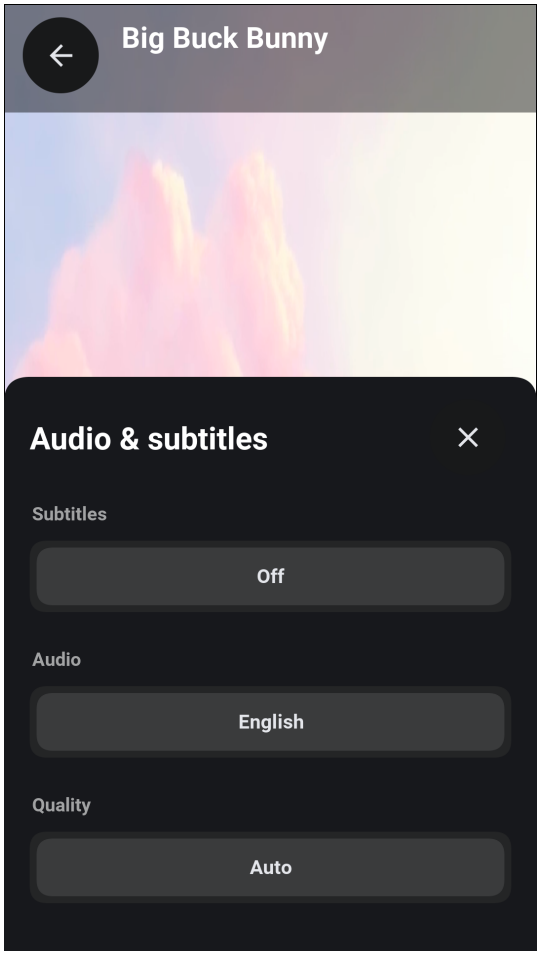


On a desktop or a tablet the sections of the app sit along the top bar, the featured title's text moves to the left of its artwork, and the rows show as many titles as the window has room for.

A title's page shows its episodes or lessons, plays it from where the profile stopped, adds it to the list, rates it, downloads it, shares it and reports it. Under the name are the year, the age rating in its box, the length, the best quality the title was packaged in and a CC mark when it has subtitles. The content advisories say what the rating is for: violence, frightening scenes, strong language, sexual

content, drugs or alcohol, flashing lights. Further down the page lists the audio and subtitle languages. A title that's not in the plan offers the plan that has it, or a rental.



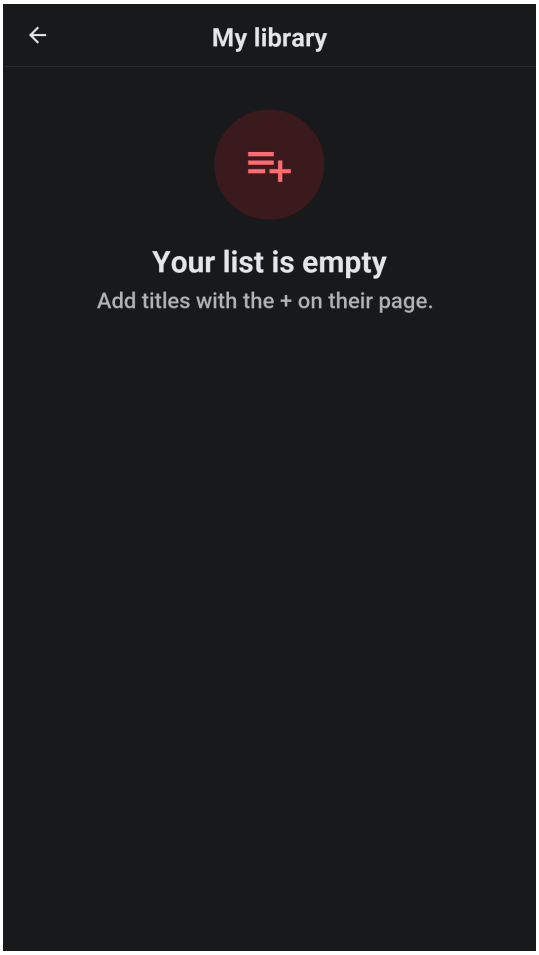


Share shows how the link will look where it's pasted and offers the device's share sheet or a copy of the link. The link opens a public page on the server with the poster, the rating, the advisories and the synopsis, which is what a chat app or a social network shows in its preview. Its Watch button opens the app on that title, after signing in where needed. A draft or a removed title has no public

page.

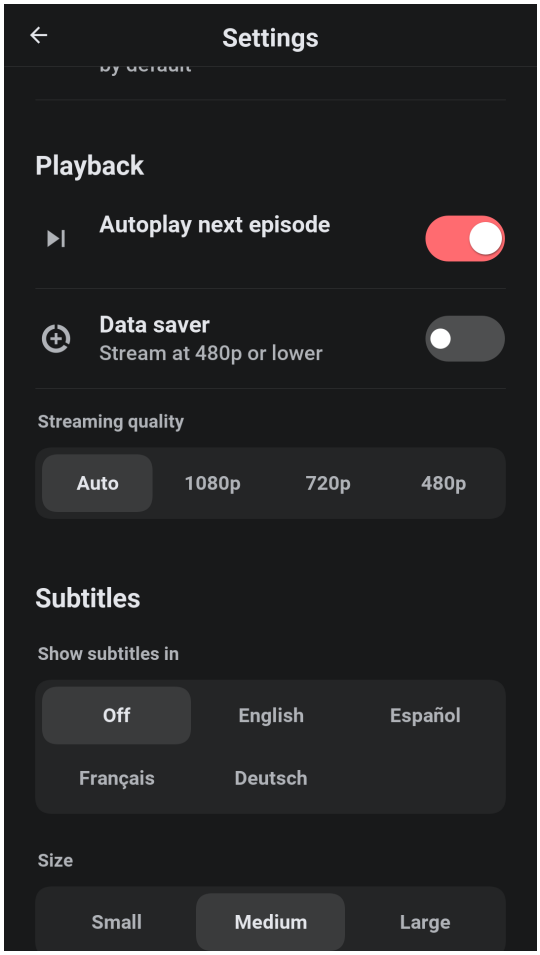
59.2.1. The player

The player draws its own controls over the picture: back and forward ten seconds, play and pause, a scrub bar with the time played and the time left, chapters, Audio & subtitles and, in a series or a course, the next episode. The controls fade after a few seconds of playback and come back on a tap. When an episode ends and autoplay is on, the next one starts.



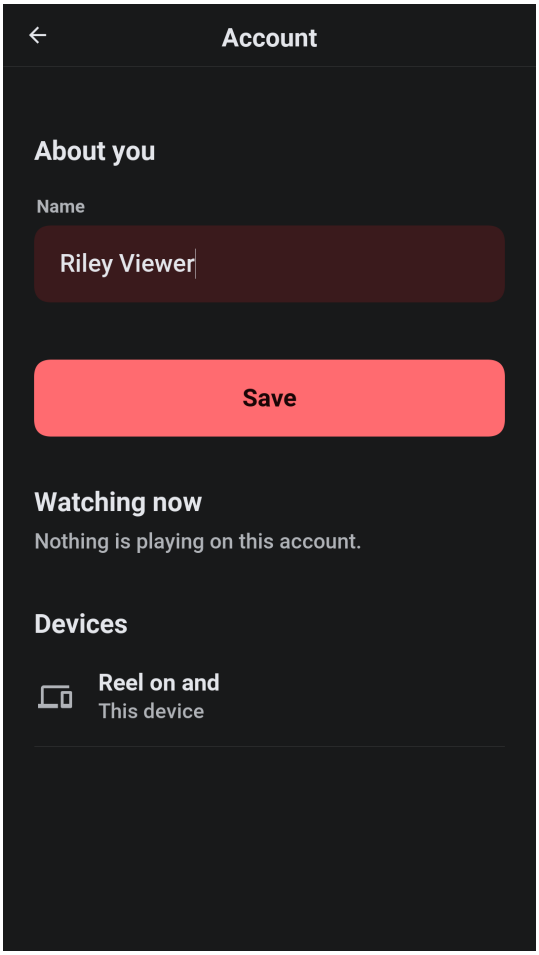
Audio & subtitles picks the subtitles (or none), the audio track and the quality: Auto, or one of the heights the title was packaged in, up to what the plan allows. Subtitles change at once. A different audio track or quality reopens the stream where it was.

Subtitles are WebVTT files kept beside the video and drawn by the app, so they look the same on every device and work with every kind of protection. The audio track is chosen by the server, which marks it as the default in the playlist the player reads.



On a plan with ads, short ad breaks play before and during the title, and some can be skipped after a few seconds. A course pauses for a quiz or a poll and, where the course branches, moves on to the lesson the answer leads to. While a protected title plays, screenshots and screen recording are blocked where the device allows it, and a faint mark naming the account sits over the picture.

A plan allows a number of screens at once. Starting one more ends with a message saying so, and an administrator, a suspension or a sign-out on another device can end a stream that’s playing.

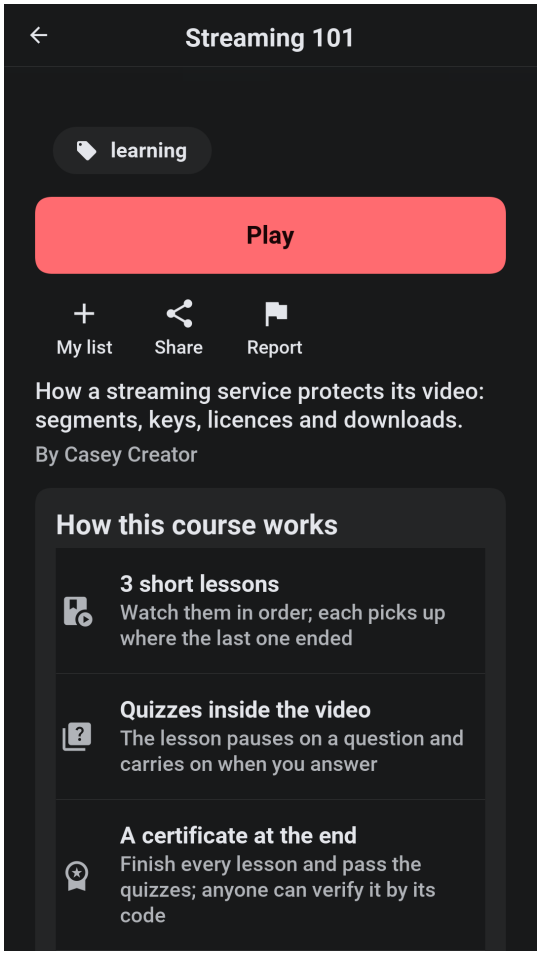


59.2.2. Your library, settings and account

The library holds the profile’s list, its downloads and what it watched. A title can be taken out of the history, which also takes it out of what the recommendations learn from.

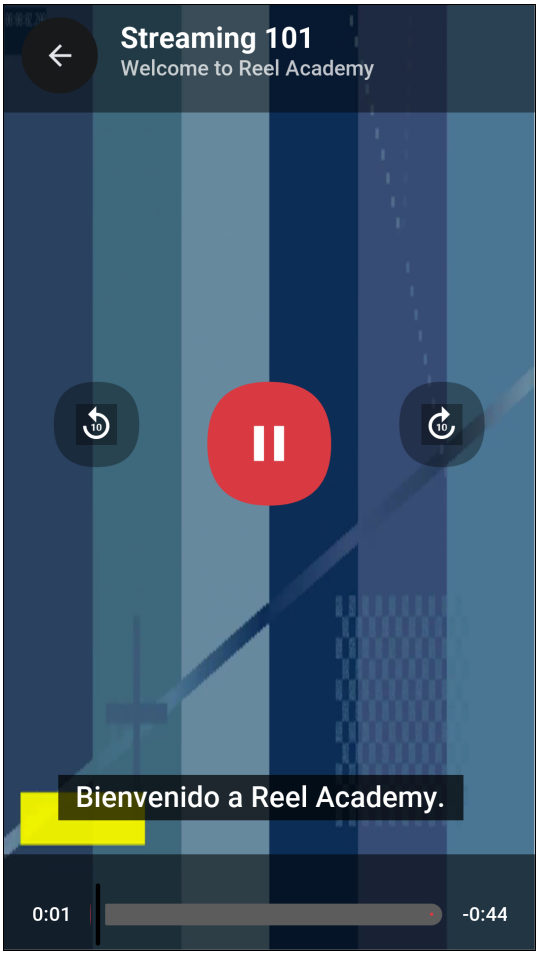
Settings hold the playback preferences (autoplay, data saver, the streaming quality), the subtitle language and size used whenever a title has a track in that language, notifications, the language and the theme of the app, and privacy. The account screen shows the devices signed in and what's playing on each, and signs any of them out.

59.3. Downloads



On a plan with downloads, a title can be kept on the device. The file stays encrypted, and playing it asks the server for the key, so a download stops playing when its license runs out, when the device is signed out or when the account is suspended. The library lists downloads without a connection. Signing out removes them from the device.

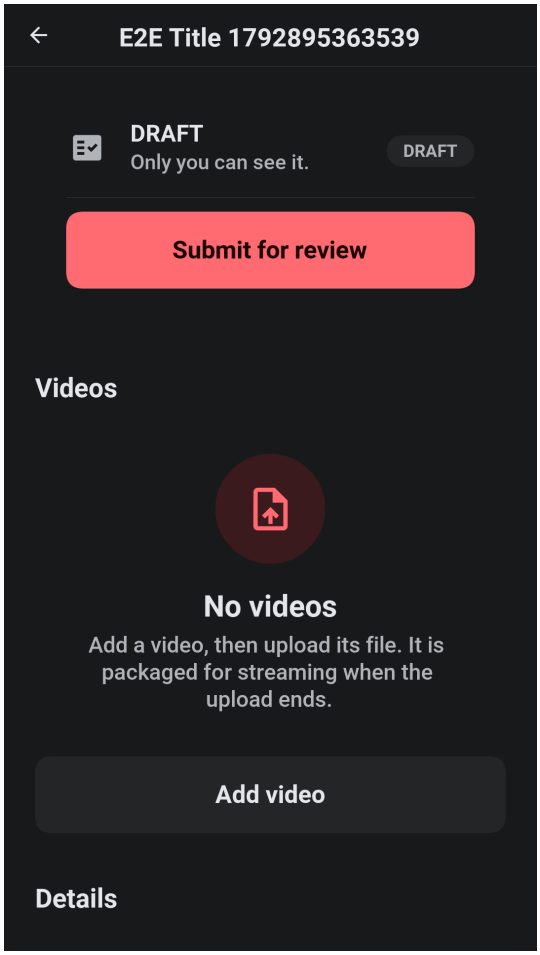
59.4. Plans, rentals and the wallet



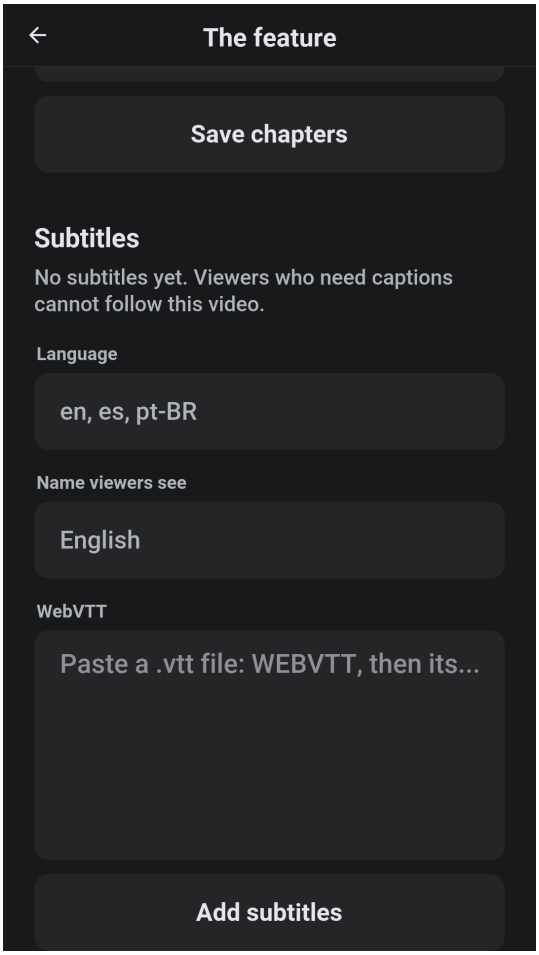
The development profile offers three plans: Basic with ads (one screen, HD), Standard (two screens in Full HD, downloads) and Premium (four screens, the best quality there is, downloads). A plan starts with a trial where the administrator gives one, a coupon takes money off, and the plan can be changed or cancelled at any time; a cancelled plan runs to the end of what was paid. Invoices are listed in the account.

Cards are added in the wallet. On the development profile `4242 4242 4242 4242` is accepted, `4000 0000 0000 0002` is declined and nothing is charged. On a phone the plan can also be bought through the app store.

59.5. Learning

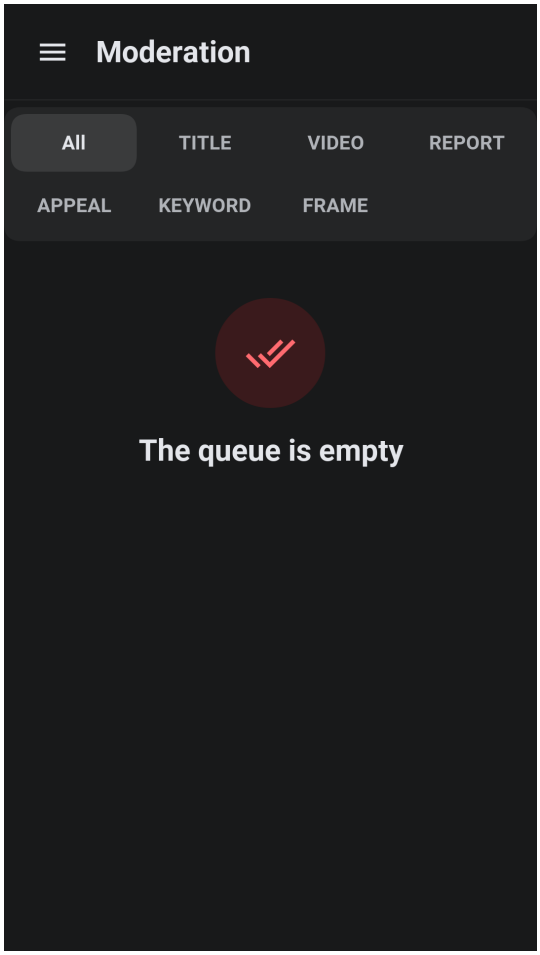


On a service with courses, a course is a title whose episodes are short lessons. The Courses row on the home screen says so, and a course's page explains how it works: the lessons are watched in order, the video pauses on a quiz and carries on when it's answered, and finishing every lesson and passing the quizzes earns a certificate. The page shows how far the profile got. Progress is kept per lesson, and a certificate opens from the learning screen, where anyone can verify it by its code.



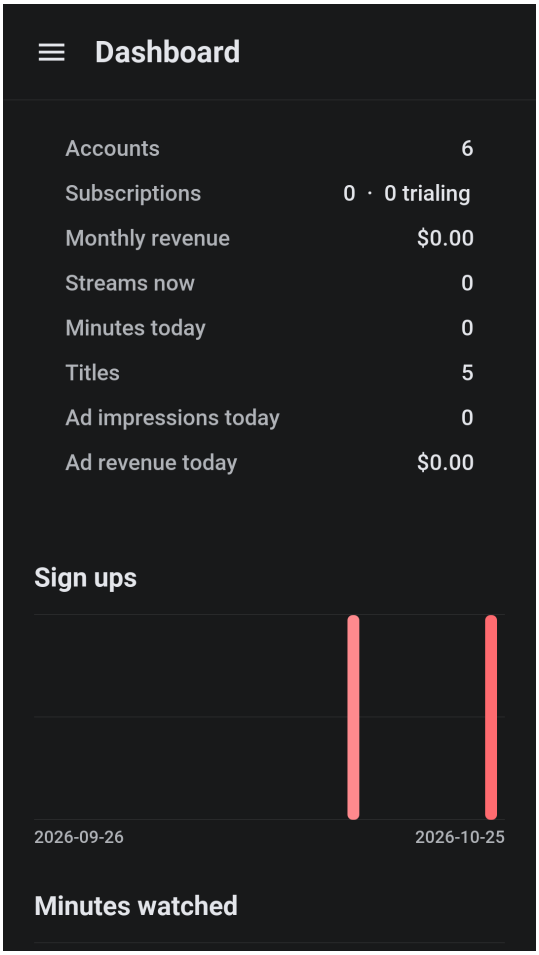
The demo course has subtitles in English, Spanish, French, and German.

59.6. Creating



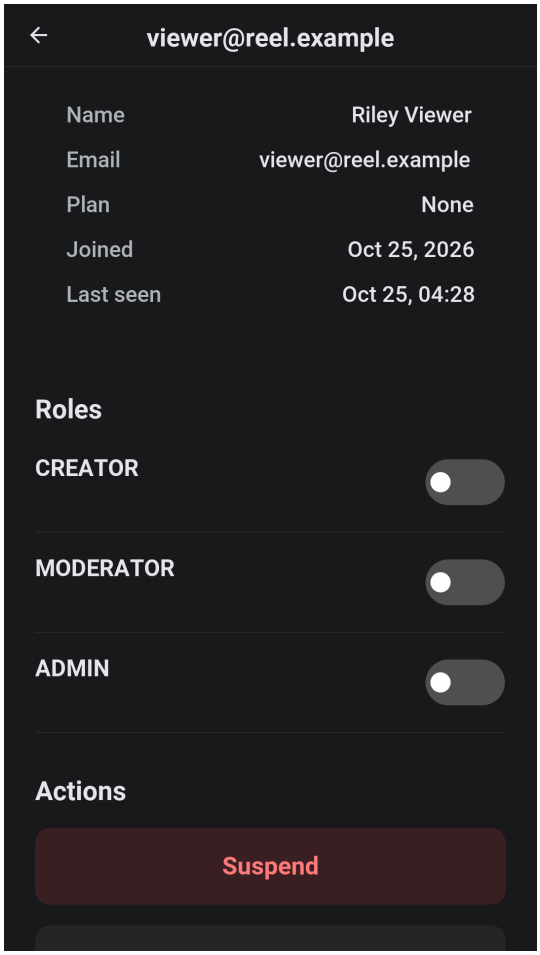
The studio lists the creator’s titles with their status: draft, in review, published, changes needed or removed. A title has a name, a synopsis, genres, a rating and its videos. A video is uploaded in pieces, so a dropped connection costs one piece and not the file, and the server packages it into the protected formats the players need. Its chapters are lines of `m:ss Title`, and its quizzes, polls and branches are added at a time in the video.

A video’s subtitles are added one language at a time, as WebVTT: a language such as `en` or `pt-BR`, the name viewers see, and the text. A title’s age rating comes with its content advisories, which the creator ticks when making or editing the title.



A finished title is submitted for review. A rejected one comes back with the moderator’s note, and the creator can correct it and submit it again, or appeal. The analytics show views, minutes watched and where viewers stop, over the last thirty days.

59.7. Moderating



The queue holds submitted titles, reports from viewers and appeals. Every upload is checked on arrival against the keyword blocklist and against the frames of video that were taken down before, and what matches is marked in the queue. A moderator approves a title, which publishes it and tells whoever follows the series, or rejects or removes it with a note the creator sees. Every decision is kept on the account’s record.

59.8. Administering

The dashboard shows the service at a glance: accounts, subscriptions and trials, monthly revenue, streams now, minutes watched today, titles, ad impressions and ad revenue, with thirty days of sign-ups, minutes, revenue and cancellations drawn as charts.

An account's page grants and removes roles, suspends and reinstates the account with a reason, flags it, and lists its devices, its sessions, its sharing alerts and its invoices. **Watching now** lists every stream that's playing and ends one. Account sharing raises an alert when an account streams from more places than a household plausibly does; the administrator dismisses it or signs the account out everywhere.

Features switches the service between three presets, a streaming service, a video platform and a training academy, and then turns single features on and off: subscriptions, rentals, ads, open uploads, interactive video, certificates, profiles, downloads, sharing detection, hardware DRM, the watermark and reports. The app follows on its next start, with no new build. **Branding** sets the name, the tagline, the logo and the colors.

59.9. In a browser

The server can host the app itself, so a browser opening the server's address gets Reel with nothing installed. A browser plays the protected video through its own media player, and offers neither downloads nor app-store purchases.

Chapter 60. Reel: Building on the sample

Reel is a streaming service, and most of what makes one is deciding who may play what, on which device, for how long, and then making it hard to play anywhere else. Reel keeps what it shares with Wayline, Savor and Parley: the module layout, the accounts and sign-in, push notifications, the admin console and hosting the app in a browser. This chapter covers what streaming changes. For the parts the samples share, the Wayline chapter is true of Reel with the names swapped.

60.1. Running it

```
cd scripts/reel
tools/fetch-demo-media.sh --small      # once: download and package the films
CN1_PROFILE=dev backend/server.sh run
mvn verify -Psimulator -DskipTests -Dcodename1.platform=javase
```

`fetch-demo-media.sh` needs `ffmpeg`. It downloads the Blender open movies into `scripts/reel/sources`, packages each with fresh random keys into `scripts/reel/media` and writes `media/seed.json`, which a development server reads at start-up for every video's keys, length, and renditions. Neither directory is committed. Without them the server writes the catalog anyway, with keys of its own, so every screen works and only the picture is missing.

60.2. The modules

`shared`	The transfer objects and the `@RestClient` interfaces, one per area: `AccountApi`, `CatalogApi`, `PlaybackApi`, `LibraryApi`, `BillingApi`, `PaymentApi`, `StudioApi`, `ModerationApi`, `LearningApi`, `AdminApi`. The app gets a generated client and the server a generated interface to implement, so the two can't drift apart.
`common`	The app. `viewer` is the catalog, the title pages, the library and the plans; `player` is playback, the ad breaks and the interactive overlays; `studio`, `moderation` and `admin` are the other roles' screens; `net` holds the session and the device identity; `notify` registers for push.
`backend`	The server. Each area is a package with its service, its controller and the repositories beside it; the schema is the migrations in `src/main/resources/db/migration`, and the server runs on SQLite, PostgreSQL, MySQL and MariaDB.
`tools/packager`	A command line tool with no dependencies beyond `ffmpeg`: it packages a video, seeds the demo catalog, and runs as the worker that packages uploads.

60.3. Playback

The app asks for a playback session with the title, the profile, the device and the DRM schemes the device supports, strongest first:

```
List<String> out = new ArrayList<String>();
DrmScheme[] order = {DrmScheme.WIDEVINE, DrmScheme.FAIRPLAY, DrmScheme.CLEARKEY, DrmScheme.AES_128};
for (int iter = 0; iter < order.length; iter++) {
    if (MediaManager.isDrmSupported(order[iter])) {
        out.add(order[iter].name());
    }
}
```

The server (`Playbacks.start`) checks everything that decides whether the title may play: the profile's rating, the plan or a rental, the device, and how many streams the plan allows at once. It then answers a manifest URL and a license URL, each carrying a token signed for this session alone, the scheme it chose, the ad breaks, the chapters and the interactions. The app hands that to the framework's streaming API, with a `DrmConfig` that sends the license token in an `X-Reel-License` header (`PlayerForm.startMain` in the sample):

```
String manifestUrl = "https://reel.example.com/media/42/master.m3u8";
String licenseUrl = "https://reel.example.com/api/license/clearkey";
String licenseToken = "token-from-playback-start";
int resumeSeconds = 90;
Form player = new Form("Player", new BorderLayout());
StreamRequest req = new StreamRequest(manifestUrl)
        .setStartPosition(resumeSeconds * 1000)
        .setDrm(new DrmConfig(DrmScheme.CLEARKEY, licenseUrl)
                .addLicenseHeader("X-Reel-License", licenseToken));
req.createAsync().ready(media -> {
    player.add(BorderLayout.CENTER, media.getVideoComponent());
    player.revalidate();
});
player.show();
```

While the title plays, the app reports a heartbeat. A session whose heartbeats stop is swept, so a crashed app doesn't hold one of the plan's streams, and a session ended elsewhere (an admin, a suspension, a device signed out) is answered `ok=false` at the next heartbeat and the player closes. Each heartbeat also checks again that the title is published and that the plan or a rental still covers it, so a rental that runs out or a title that's taken down stops within one heartbeat. A download's license is held to the same checks. The heartbeat runs on its own timer rather than the form's, because the chapters list and the quiz dialogs are other forms and a form's timer stops while it's hidden.

60.4. What protects the video, and from what

Every video is packaged twice with one content key: an HLS AES-128 ladder and a CENC MP4 for ClearKey. The origin (`MediaOrigin`) checks the media token on every playlist, segment and key: a token names the session, the video and the tallest rendition the plan allows, and expires, so a URL copied out of the player is good for one video for a few hours. The license endpoints answer ClearKey and AES-128 from the key table, only for a valid license token.

That stops casual copying of links and files. It doesn't stop a determined person with a debugger:

AES-128 and ClearKey keys reach the device in the clear over TLS. That's what Widevine and FairPlay are for. Reel offers them when a license vendor is configured and the **hardware DRM** feature is on; the server forwards the device's challenge to the vendor and passes the answer back:

```
reel.drm.widevine.url=https://license.example.com/widevine
reel.drm.widevine.header=Authorization: Bearer ...
reel.drm.fairplay.url=https://license.example.com/fairplay
reel.drm.fairplay.certificate=https://license.example.com/fairplay.cer
```

The FairPlay certificate is a URL the device downloads, not a file on the server. A device then gets the strongest scheme it supports that the server can license, and a device that can play none is told so before playback starts. The app also blocks screenshots while protected video is on the screen, and draws the account's name over the picture when the **watermark** feature is on.

60.5. Uploads and packaging

An upload starts with `POST /api/studio/uploads`, which answers the piece size, and continues with `PUT /api/studio/uploads/{id}?offset=N`, one piece at a time. A piece sent at the wrong offset is refused with 409 and the app asks where the server is; a dropped connection is retried. When the last byte arrives the server queues a packaging job.

Packaging is a separate process so that the server never runs `ffmpeg`:

```
java -jar tools/packager/target/reel-packager-1.0-SNAPSHOT.jar \
    worker --server https://reel.example.com --token "$REEL_WORKER_TOKEN"
```

The worker claims a job and is handed the source and the content key, which the server generated and keeps; it encodes the ladder and the CENC file with that key, uploads the outputs and reports. Run as many workers as there is video to package; each needs `reel.worker.token`.

60.6. Moderation

Every upload is checked as it's packaged. The keyword blocklist is matched against the title's words, and the frames of the new video, a perceptual hash every ten seconds, are compared with the frames of video that was taken down before, so a re-upload of removed content is marked in the queue even under a new name. `ContentClassifier` is the place to call an outside classifier. Nothing a creator submits is published until a moderator approves it; an administrator's own titles publish directly.

60.7. Billing and ads

Plans, trials, coupons, rentals and invoices are in `billing`. Payments go through `reel.payments.provider`: `simulated` on a development profile, or `stripe` with `REEL_PAYMENTS_STRIPE_SECRET` in the environment, where cards are added on Stripe's own page so a card number never reaches the app or the server. App-store purchases are refused unless

`reel.billing.trust-store-receipts=true`, which grants the plan on the product the app reports without asking the store; a real service verifies the receipt with Apple or Google in `Billing.storePurchase` before granting. A renewal that fails puts the subscription past due and tells the viewer by push.

`ads` decides where the breaks go and which campaign fills each when the break comes, so a campaign whose budget ran out meanwhile isn't shown. A campaign pays per thousand impressions, prefers titles in its genres and stops at its budget or its end date. The player reports impressions, skips, clicks and completions.

60.8. Features and presets

`settings.Settings` holds the feature switches the app reads at start-up, so an administrator reshapes the service without a release. The presets set them all at once:

Streaming service	Subscriptions, rentals, ads, profiles, downloads, courses, hardware DRM, sharing detection and reports; no uploads from strangers.
Video platform	Open uploads, ads, rentals, reports and interactive video.
Training academy	Subscriptions, interactive video, certificates, downloads, sharing detection and the watermark.

A feature that's off is hidden in the app and refused by the server, so switching one off is safe while apps are running.

60.9. Tests

```
mvn -pl shared,backend -Dcodename1.platform=backend test
mvn -pl shared,backend -Dcodename1.platform=backend test -Dcn1.backend.compiledTests=true
./run-e2e.sh
./run-web-e2e.sh
./check-template.sh
```

The server's tests run on the JVM and again compiled to a native binary, which is how the server ships. `run-e2e.sh` starts a server and drives the app through its screens in the simulator as each role; `run-web-e2e.sh` does the same for the browser build in a headless browser. `.github/workflows/reel.yml` runs them all, the server tests on each database, and the Android and iOS builds.

60.10. Making it yours

- **Your catalog.** Replace `DemoData` with an import from your own library, and run the packaging worker over your masters.
- **Real DRM.** Contract a Widevine and FairPlay license service and set the `reel.drm.*` settings; keep AES-128 for browsers and older devices.
- **A CDN.** The media origin checks a token on every request. Put a CDN in front of it with the

token in the cache key, or move the check to the CDN's edge with the same secret (`reel.media.secret`).

- **Store receipts.** Verify App Store and Google Play receipts on the server before turning on `reel.billing.trust-store-receipts`.
- **Billing.** Point `reel.payments.provider` at Stripe, or implement the payment provider interface for another processor.
- **The look.** `common/src/main/css/theme.css` starts with the colors and the corner radius; the admin console's **Branding** sets the name, the tagline and the logo at run time.

Chapter 61. Bastion: A bank that shows its locks

Bastion is a virtual bank written in Codename One from end to end: a phone and desktop app, and the server it talks to. It holds money in several currencies and coins, moves it between accounts and people, issues cards, and runs a small exchange where customers trade bitcoin and ether against dollars. It's built to show the security a financial app needs, and every protection it has is listed, with its real state, on one screen of the app.

The sample lives in `scripts/bastion`. This chapter is about using it: what a customer and an administrator see and do. The next chapter, Chapter 62, *Bastion: Building on the sample*, is about how it's built and what a real bank would still have to add.

Out of the box nothing in Bastion is real money. Deposits are a counter, cards spend nowhere, and the exchange trades against a simulated market. Ether can be made real: connected to an Ethereum node, the app shows a deposit address under **Receive crypto**, and deposits and withdrawals settle on the chain. The security mechanisms are the ones a production bank would use: the passwords, codes, passkeys and signatures work as they would there. The audit chain is hashed the same way, but its head isn't anchored anywhere outside the server's own database, so someone who controls that database could rewrite it and the chain along with it.

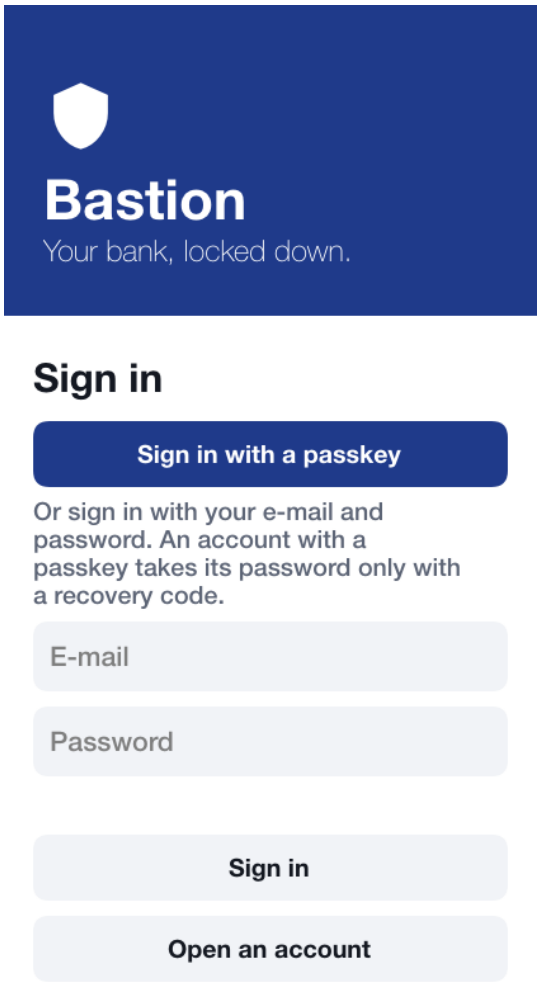
61.1. Trying it

The server runs on the JVM with an in-memory database and demo accounts, with nothing to install but a JDK 17:

```
cd scripts/bastion
CN1_PROFILE=dev backend/server.sh run
```

The app then runs in the simulator from another terminal:

```
cd scripts/bastion
mvn verify -Psimulator -DskipTests -Dcodename1.platform=javase
```

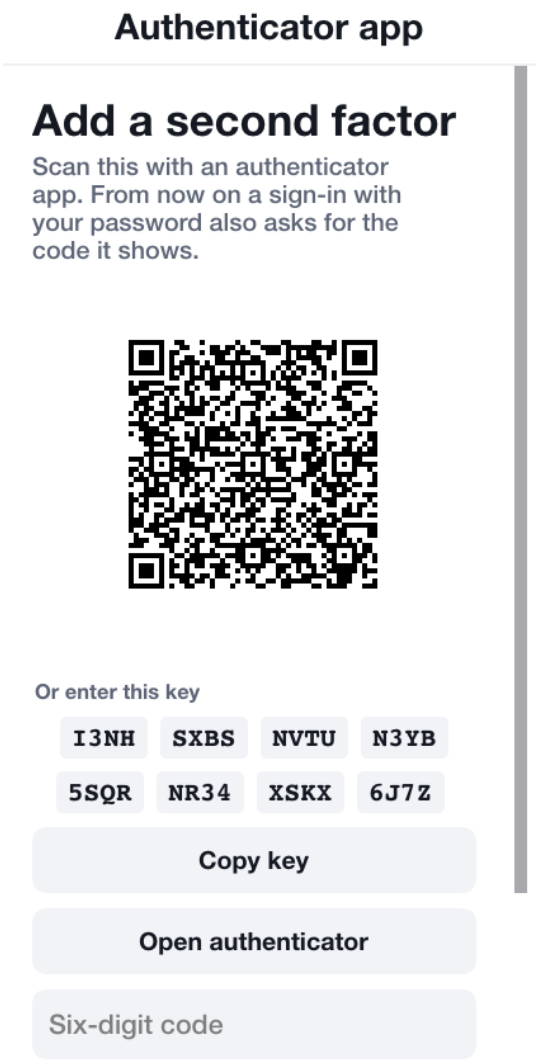


`CN1_PROFILE=dev backend/server.sh run --web` also builds the app for the browser and serves it at the server's own address, `http://localhost:8080/`. The screenshots in this chapter come from that browser build, at a phone's width.

The development profile creates three demo accounts, all with the password `bastion-demo-password`:

Account	What it's for
`customer@bastion.example`	A customer with $2,500.00 in a checking account
`customer2@bastion.example`	A second customer with $1,200.00, to pay and to trade with
`admin@bastion.example`	The administrator

On the development profile a small market maker also keeps the exchange's books moving, so that there is something to trade against.

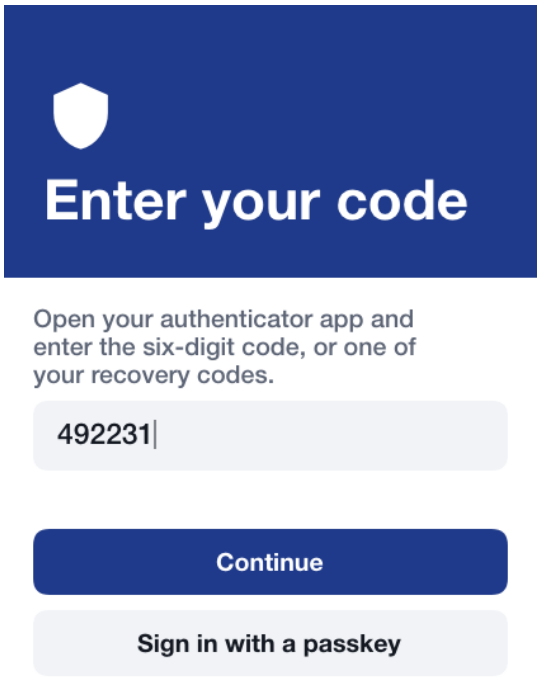


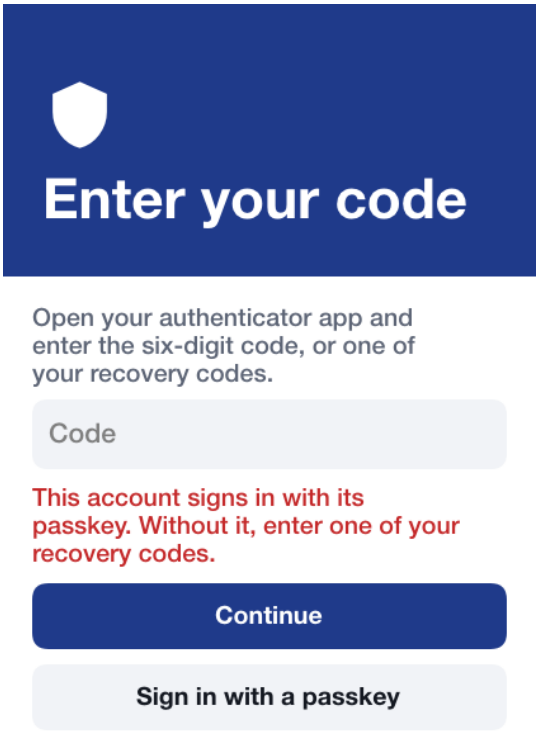
61.2. Opening an account

Open an account on the sign-in screen walks through the steps a new customer takes:

1. **Name, e-mail and password.** The password has to be at least twelve characters and can't be the e-mail address; the server checks it too, not only the app.
2. **Authenticator app.** The app shows a QR code and the same secret as text. Scanning the code with any authenticator app and typing the six digits it shows turns on the second factor. Adding the app asks for the password again after a sign-in made with the password alone, so a stolen session can't put somebody else's app on the account. The secret can be copied instead; the copy is marked sensitive, which keeps it out of the keyboard's suggestions on Android and off the user's other devices on iOS, and it's wiped from the clipboard after a minute, or at the next start if the app was closed before then. Bastion then shows ten recovery codes, once, to write down or copy into a password manager the same way. Each opens the account once if the phone is lost; keep them somewhere other than the phone.
3. **Passkey.** Where the device or browser supports passkeys, one can be added now, so that later sign-ins need no password at all.

4. **Unlock with biometrics.** An option on a phone with a fingerprint or face enrolled: the key that opens the stored sign-in and the payment key is released only by the biometric.
5. **Unlock PIN.** An option: six to twelve digits that open the lock when a biometric isn't available or isn't wanted. Five wrong PINs in a row erase the keys on the device, and the way back is signing in again.
6. **This device.** The app makes a signing key that never leaves the device and registers it with the bank. Payments to other people are signed with this key, so the device itself is a second proof of who is paying. The bank adds a device only after a sign-in made with an authenticator code or a passkey; after a sign-in with the password alone, the app asks for one of those to be set up first.

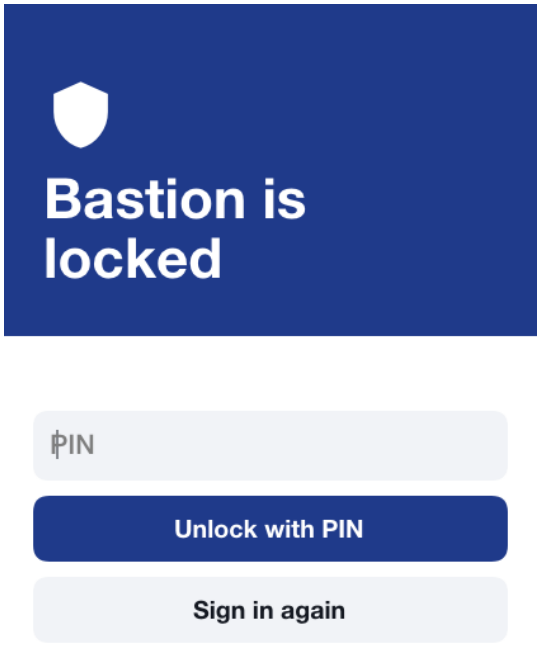




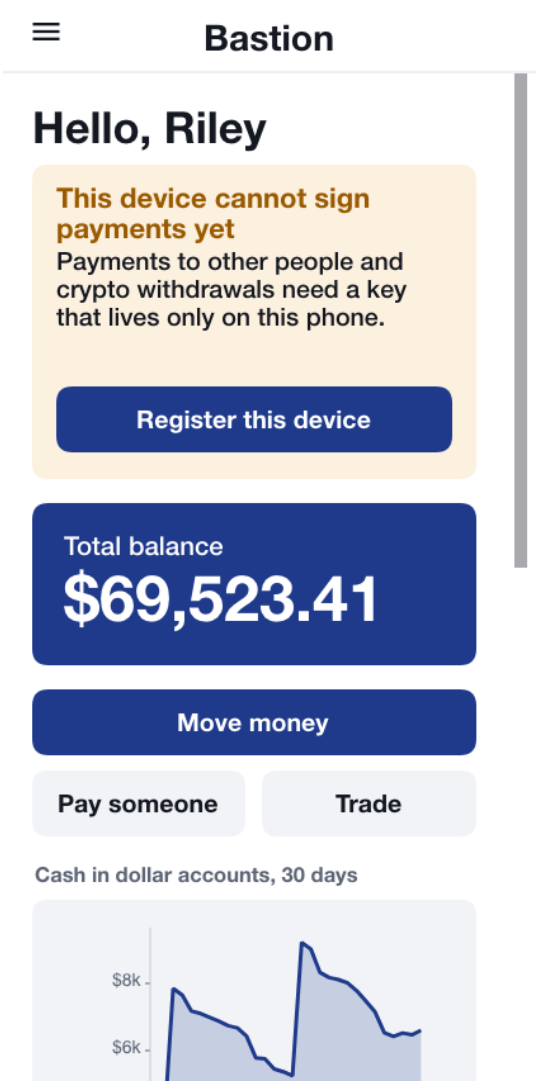
A new account starts with a dollar checking account. Others, in euros or as coin wallets, are opened from the dashboard.

61.3. Signing in

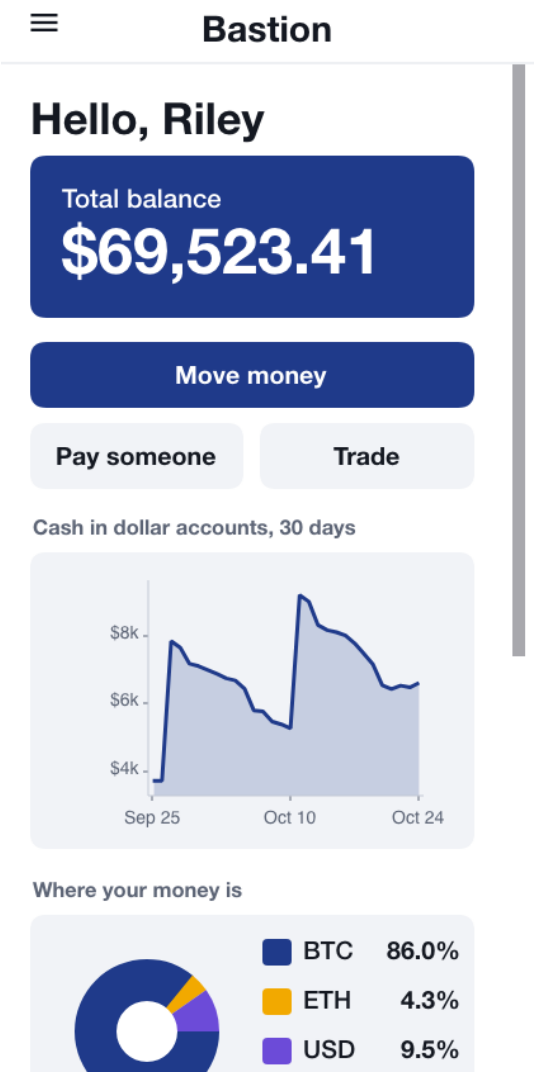
The sign-in screen offers the strongest way in the device has first. Where the device or browser supports passkeys, **Sign in with a passkey** is the main button: the passkey sheet asks for a fingerprint, a face or the device PIN, and that one step is both factors. On a phone that keeps a sign-in behind biometric unlock, **Unlock with fingerprint or face** comes next. The e-mail and password, then a code from the authenticator app when the account has one, are the last way in.



Once an account has a passkey, the server holds it to the passkey. The password is refused, and the code step after it takes a recovery code and nothing else; a six-digit code from the authenticator app no longer signs in. That’s the way back for a customer whose passkey is gone: the password and one of their recovery codes, each of which works once. An account with a passkey and no authenticator app has no recovery codes, so its way back is the bank. Five wrong passwords in a row lock the account for fifteen minutes; the lock is per account, so guessing from many places at once doesn’t help.

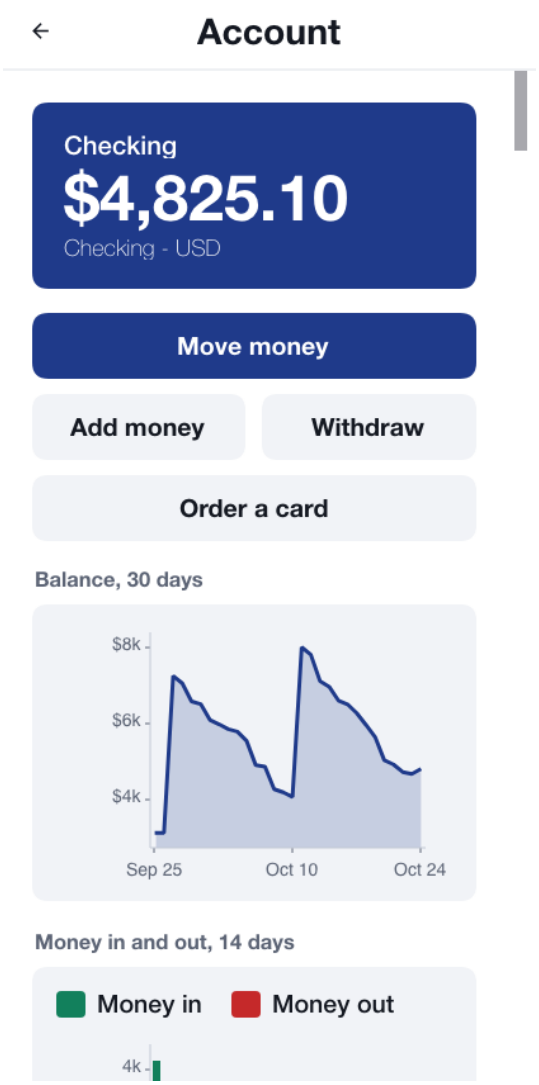


61.4. The lock



The app locks itself after half a minute in the background and after two minutes without a touch. Locked, it shows nothing of the account and can't sign a payment or read its stored sign-in until it's unlocked again: with biometrics when they're turned on, then with the unlock PIN when one is set, and otherwise by signing in again. Signing in again from the lock sets the device up from the start when a biometric or PIN was set up, so its payment key is registered again the next time a payment needs it. Signing out from the menu does the same, so whoever signs in next on the device starts with none of the previous account's keys.

61.5. The dashboard



The dashboard shows the total of every account in dollars, at the exchange’s current prices, the cash in dollar accounts over the last 30 days, how the money is spread across currencies and coins, and each account with its balance. Until the device has a payment key, a banner above says so and offers to register it; registering asks for the password again, because only a recent sign-in may add a key.

Bastion

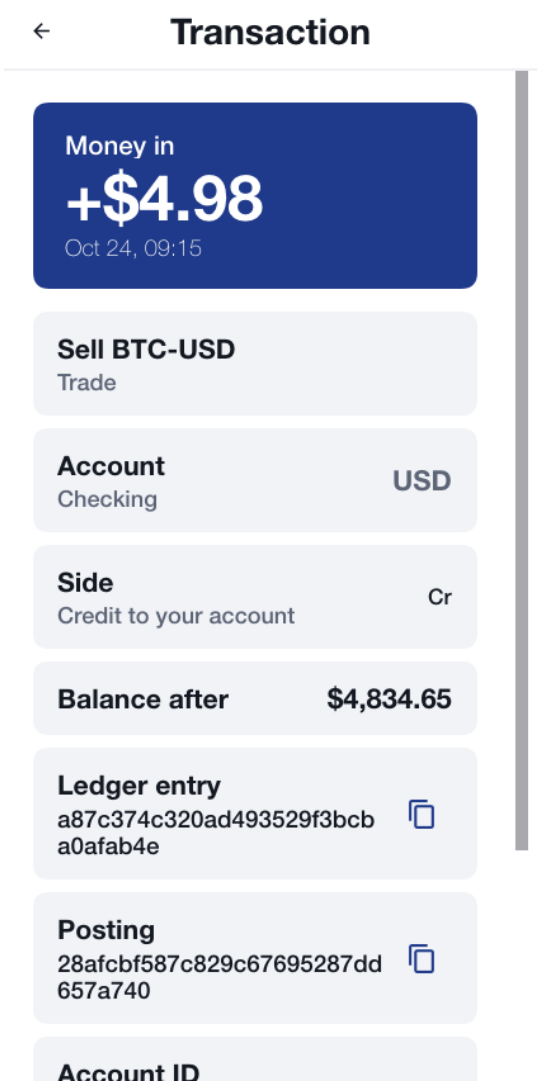
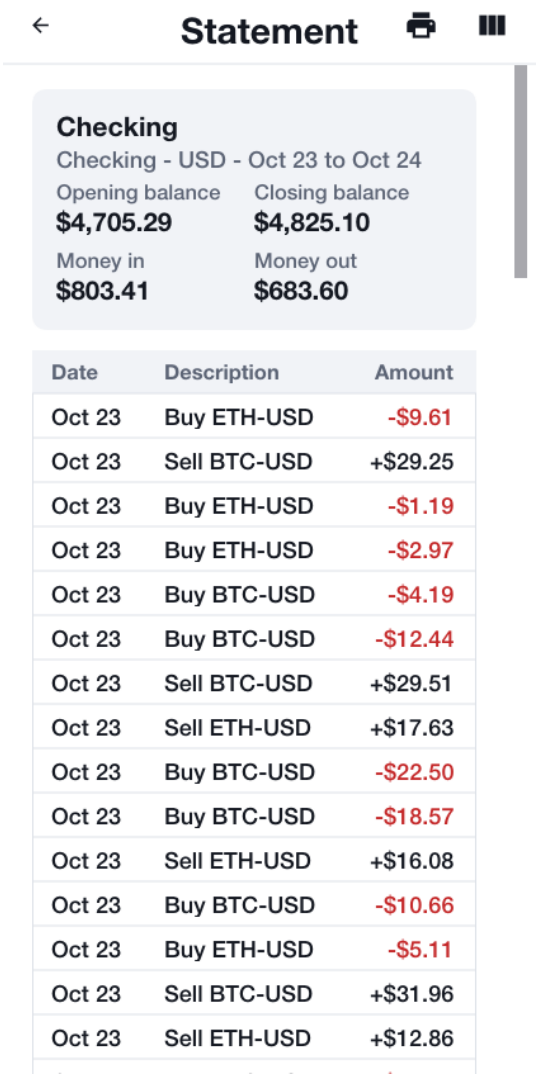
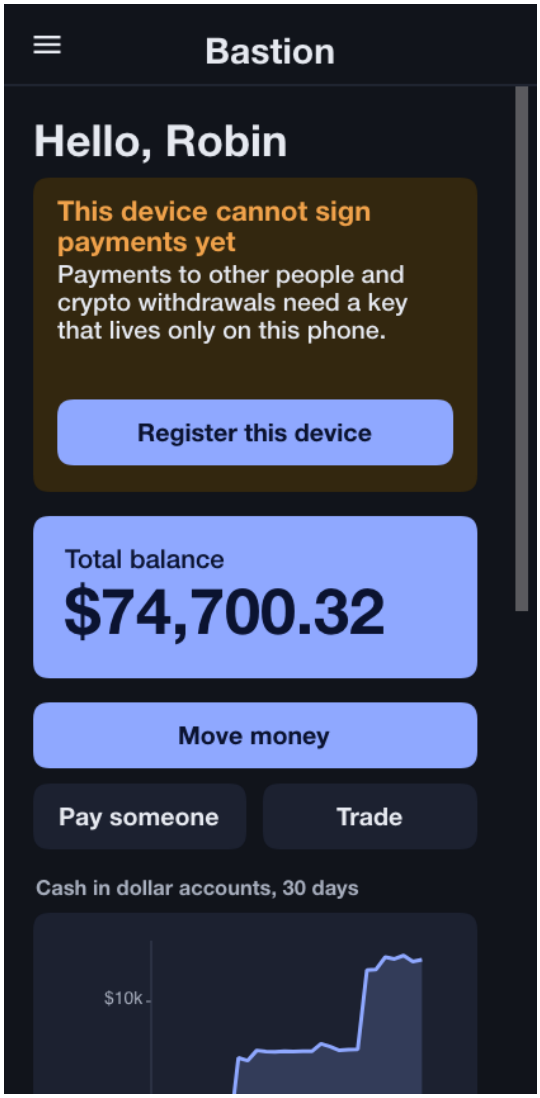
$6k





Screens reached from the menu are top-level and have the menu button; a screen opened from another one has a back arrow instead. No screen has both.

Tapping an account opens it: its balance, what can be done with it, a chart of the balance over 30 days, the money in and out each day, and its history, every posting newest first.



Tapping a line of the history shows that posting in full: the side of the entry it's (a credit to the account or a debit from it), the balance it left and the ledger entry it belongs to. **Statement** lists every posting oldest first with the running balance between an opening and a closing balance, the way a bank statement does.

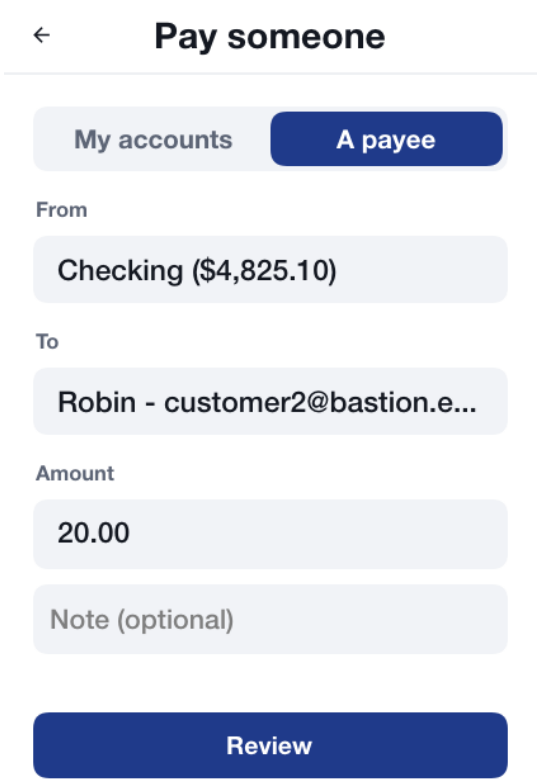
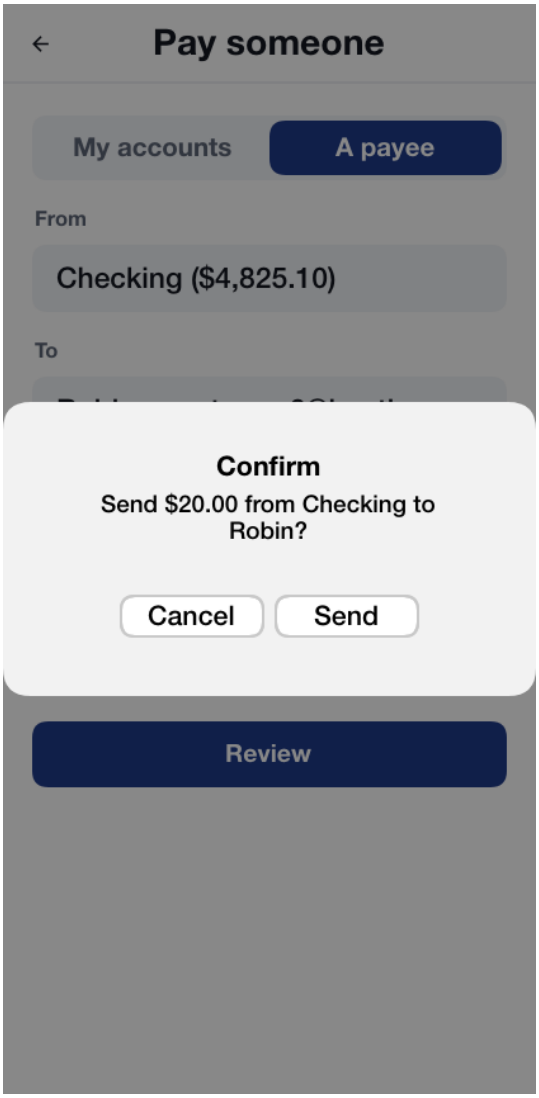
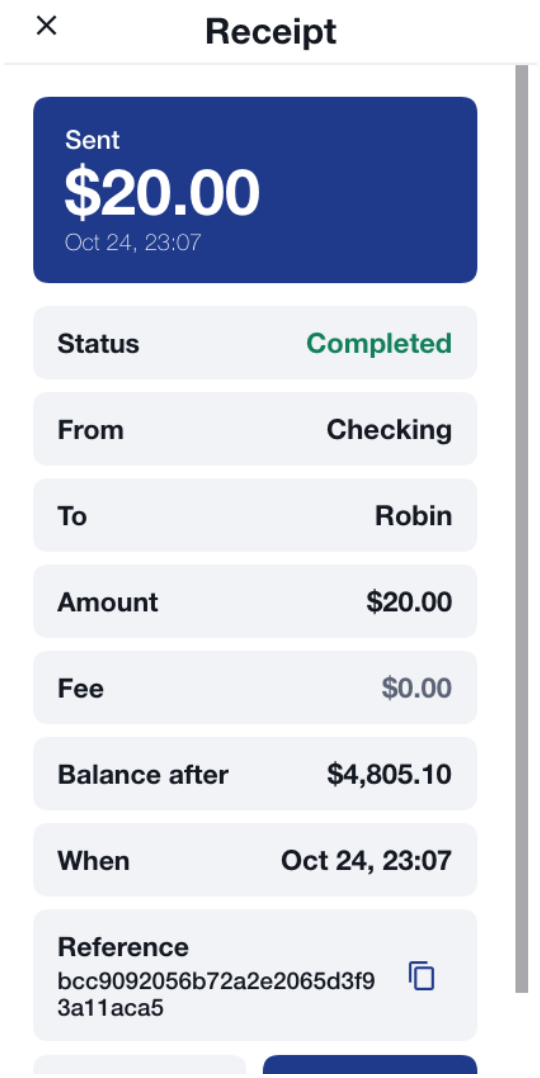
The app follows the device’s dark mode, charts included:



Balances, card numbers and codes are on **sensitive screens**. On Android those screens can't be captured or recorded, and the recent-apps list shows them blank; on iOS the app switcher shows a cover instead of the screen.



61.6. Moving money



Move money moves money between your own accounts in the same currency. **Pay someone** sends it to a payee: another Bastion customer, added by e-mail on the **Payees** screen.

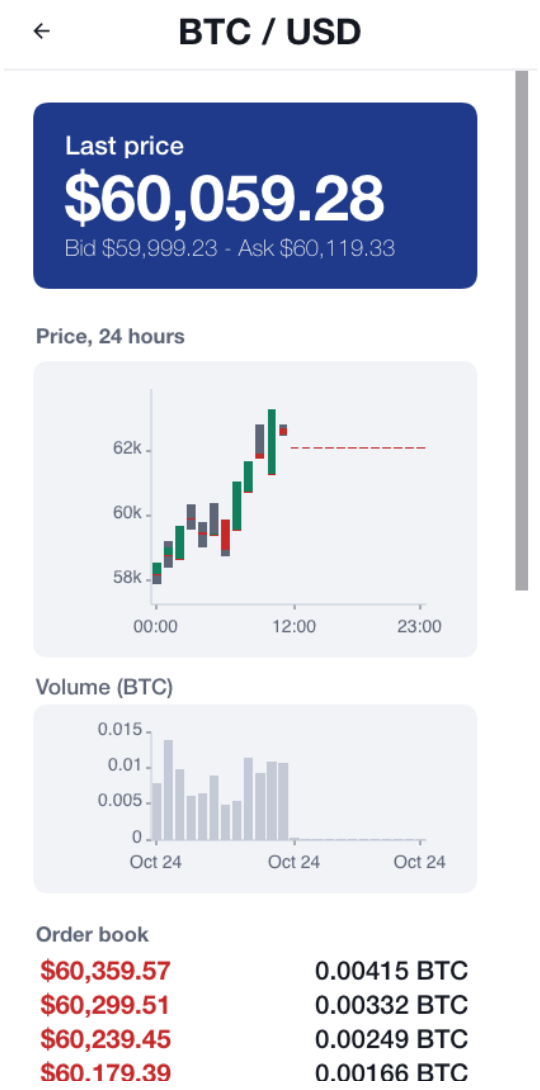
Every transfer carries a key that makes it happen once: a payment retried after a dropped connection isn't paid twice. Some transfers ask for more:

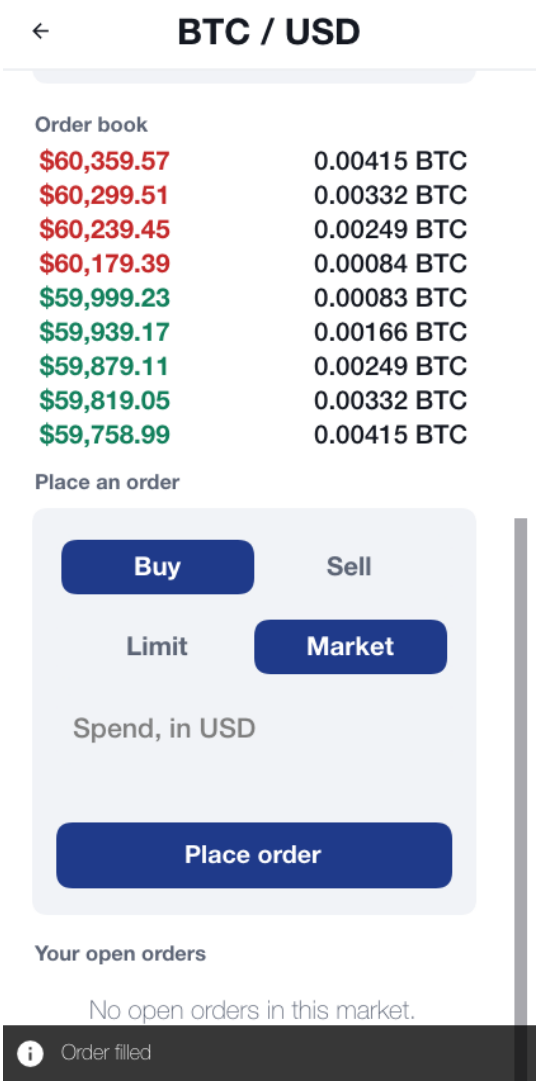
- A payment to someone else is signed with this device's key. On a device that has no key yet, the app offers to register one first, then sends the same payment.
- By default, money leaves your accounts only from a device the bank trusts: a phone that passed the platform's integrity check and doesn't look rooted or jailbroken. A browser or the simulator can't prove that, so there the server refuses the payment, explaining that the device can move money only between your own accounts. The screenshots above were taken with that policy turned off on the development server (Chapter 62, *Bastion: Building on the sample* has the setting).
- A new payee is in a cooling-off period for its first day, in which it can receive only $100.00. Someone who has taken over a session can't add an account of their own and empty yours into it.
- A move between your own accounts above $1,000.00 is signed with the device key too.
- Every transfer is held to a limit per transfer ($5,000.00) and per day ($10,000.00); one past either is refused.



61.7. Cards

Order a card on a checking account issues a card on it. **Cards** lists them, freezes and unfreezes each, and sets its daily spending limit. A frozen card is refused at once. Freezing works from any signed-in session; unfreezing a card or raising its limit needs this device’s approval, so somebody holding only your session can’t undo a freeze. The card number is on a sensitive screen.

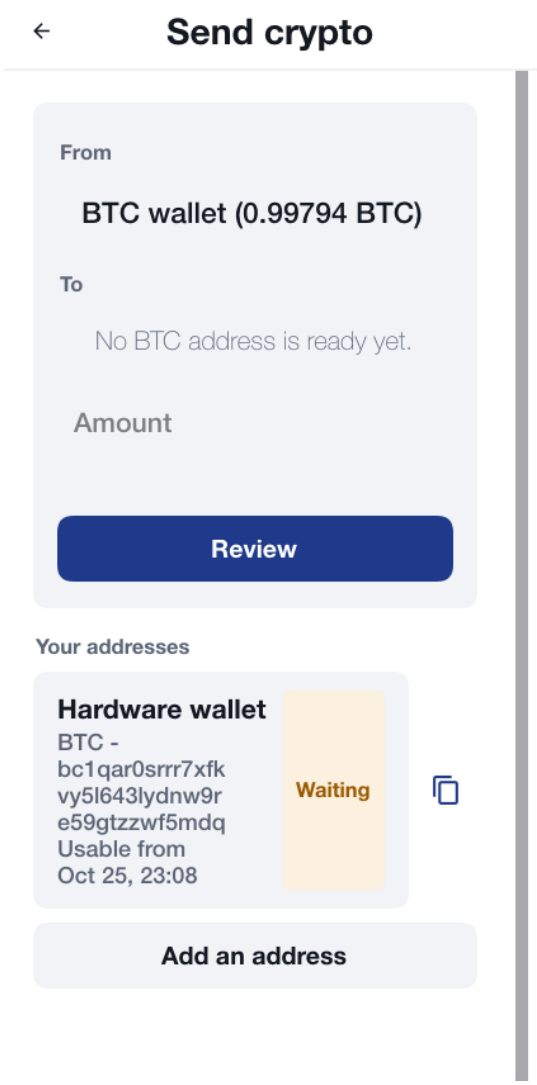
61.8. The exchange



Exchange lists the markets, BTC-USD and ETH-USD, with their last price and the index price the bank values coins at, and the customer’s recent trades.

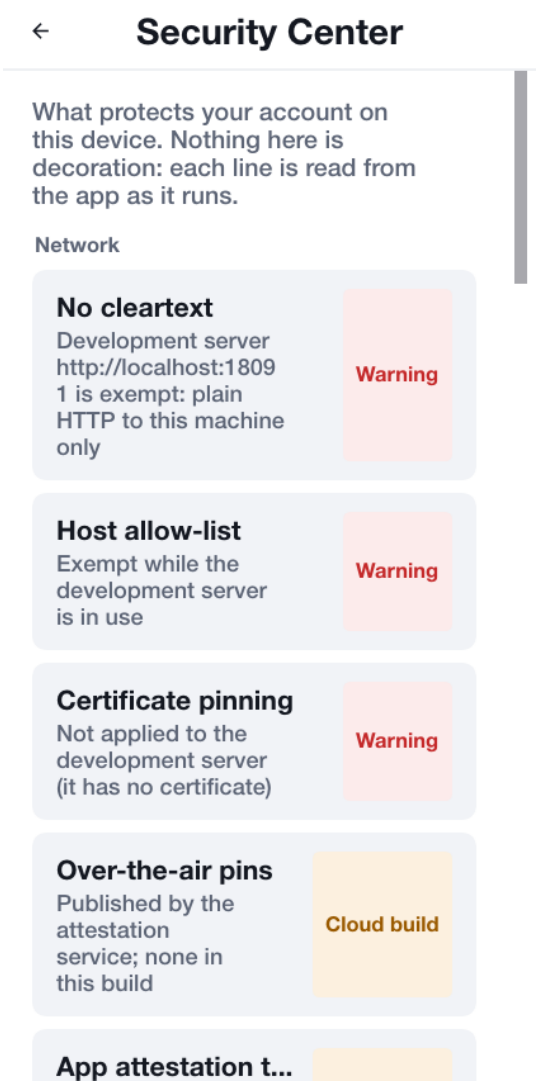
A market opens the last day in hourly candles, a rising hour in green and a falling one in red over its high-low range, the volume traded each hour, its order book and a ticket:

- A **limit order** names a price and a quantity, and rests on the book until another order meets it, or until it's cancelled.
- A **market order** takes what the book offers now, up to a budget for a buy or a quantity for a sell.



Placing an order sets aside what it could spend; the rest of the balance stays free. Fills move both sides and the fee in one ledger entry, so a trade is never half done. The **Open orders** list shows what's still resting, each with a cancel button, and a bought coin lands in a wallet account of its own.

61.9. Sending coins



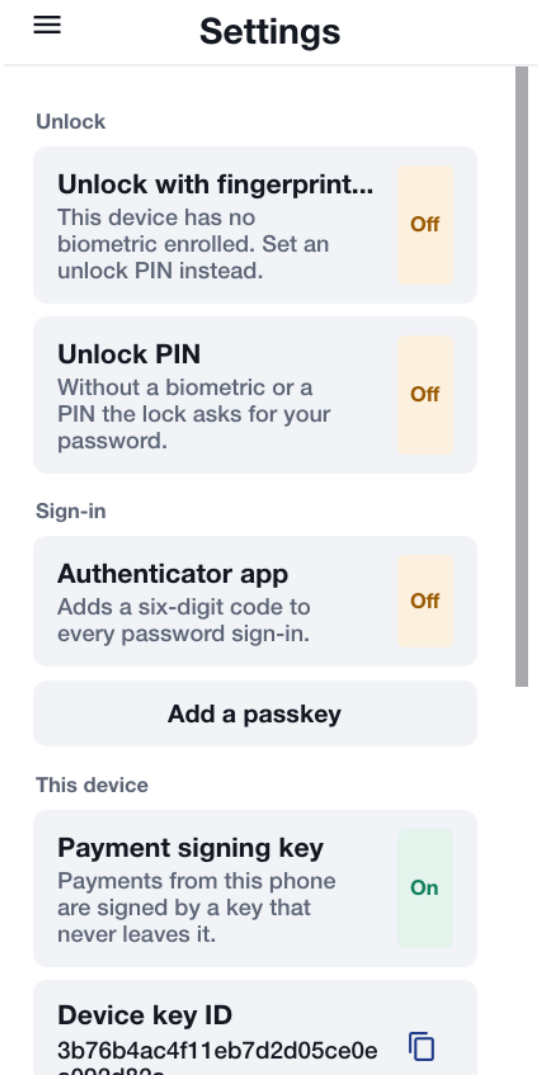
Coins leave the bank only to an address on the account's **allow-list**, and the list is guarded:

- Adding an address is signed by this device.
- A new address waits a day before anything can be sent to it.
- Every withdrawal is signed by this device, and is held to a limit per withdrawal and per day, counted in dollars.

61.10. Security Center

Security Center lists every protection the app has and whether it's in force on this device, in this build, now: the connection rules and certificate pins, where the keys and the sign-in are kept, the app lock, the screen protections, whether the device looks rooted or jailbroken, whether it passed the platform's integrity check, and the hardening the build applied.

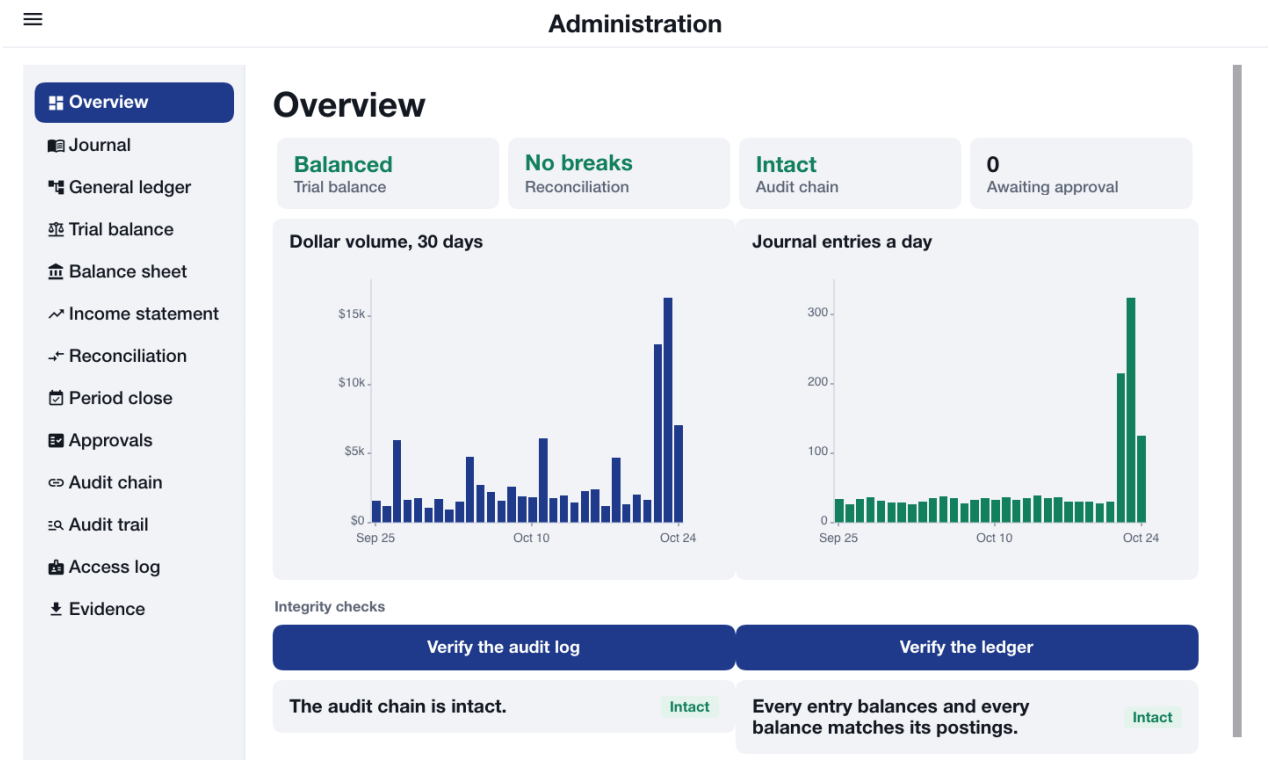
It’s honest by design. A protection the simulator or a browser can’t provide, such as a hardware keystore, says so. One that only a build from the Codename One build server applies, such as code hardening or Play Integrity, is marked **Cloud build** instead of claiming to be on. A development exemption in use, such as the unpinned connection to a server on this machine, is a **Warning**.



61.11. Settings

Every value a customer may need somewhere else has a copy button beside it, and the value itself can be selected: a receipt’s reference, a transaction’s ledger entry and posting, an account and a card identifier, a coin address, a passkey’s ID, this device’s key ID, the authenticator key, and on the console an entry’s ID and the audit and evidence hashes. Keys and account and card identifiers are copied as sensitive clips that clear themselves after a minute, the same as the authenticator key; a short message confirms each copy.

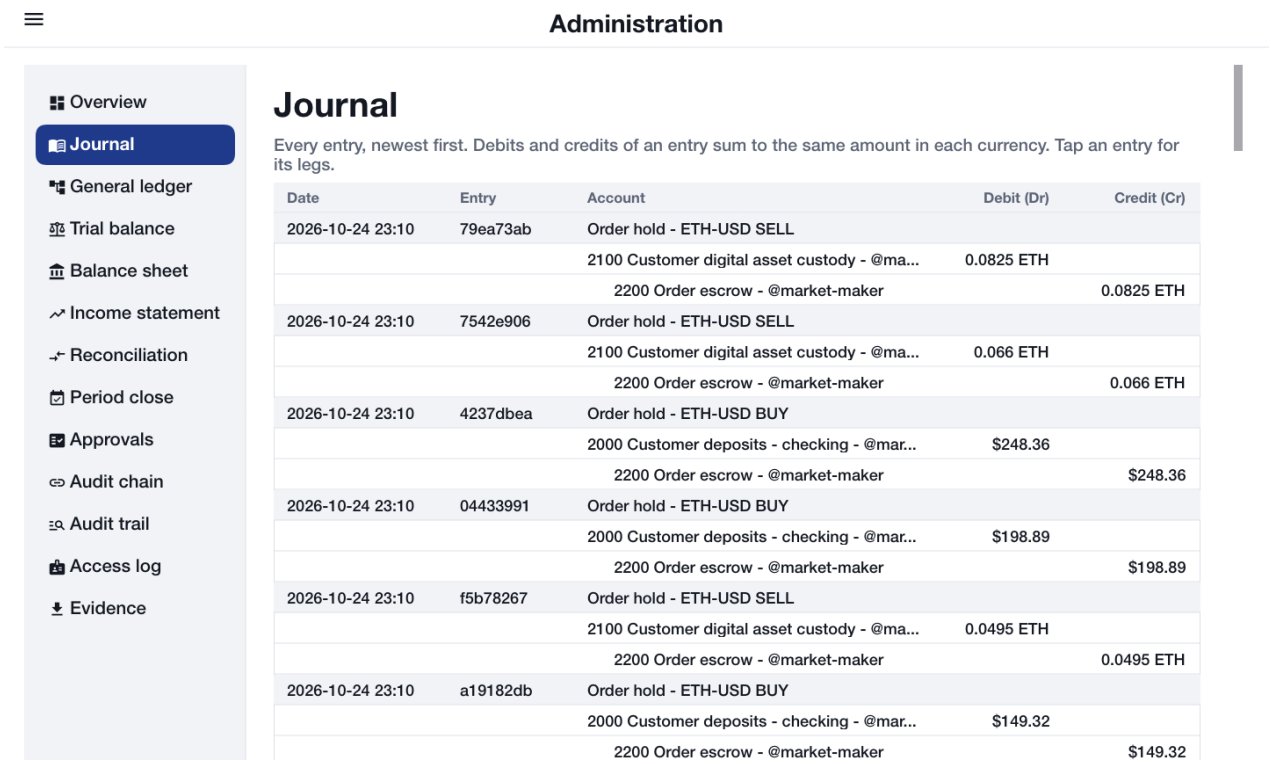
Statements, receipts and transactions have a **Print** button, as do the console’s reports: the general ledger, the trial balance, the balance sheet, the income statement, the audit chain, the audit trail, the access log and an evidence export. The printout has the bank’s name, the report, the account and period it covers and when it was made, then the table, then the totals, and goes to the platform’s print dialog. Where the platform can’t print, there is no button.



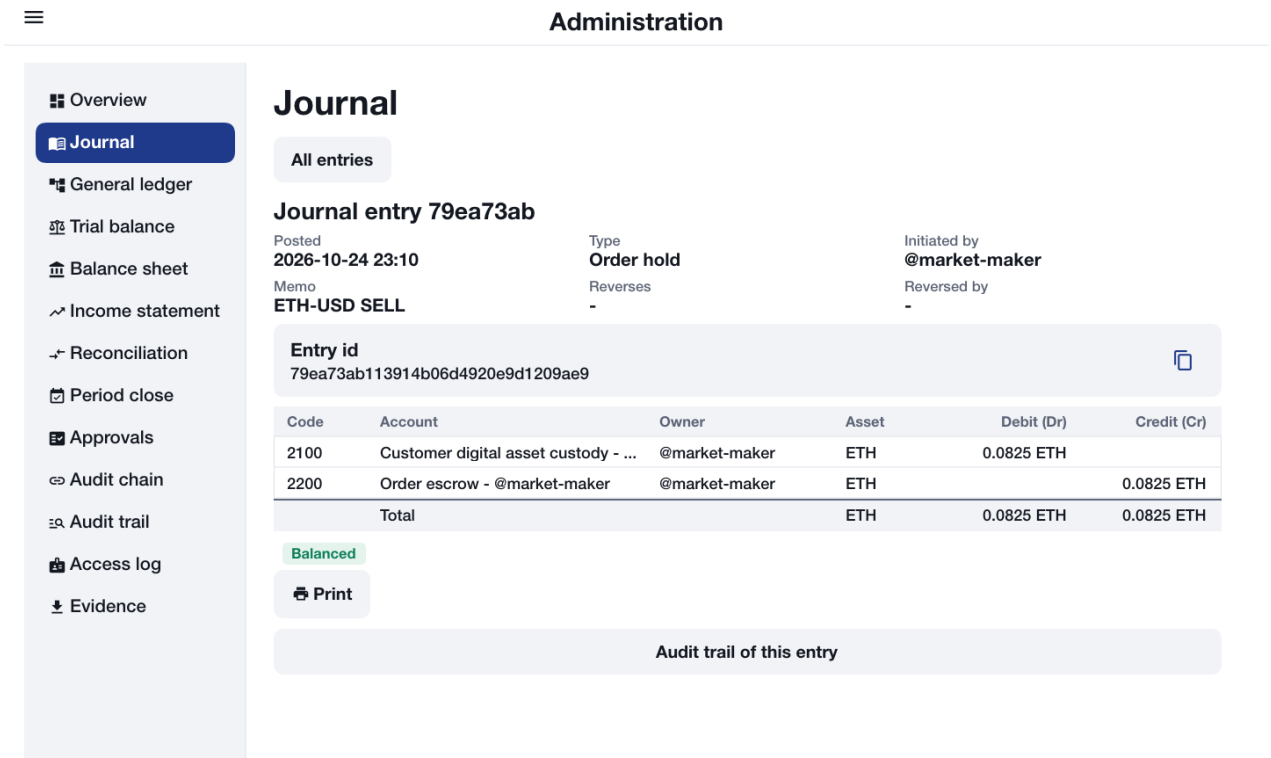
Settings turns biometric unlock on and off, sets, changes or removes the unlock PIN, turns on the

authenticator app and makes new recovery codes, lists and removes passkeys and adds new ones, shows this device's payment key, and chooses the language: English, Spanish, French, German or Hebrew, which lays the app out right to left. Tables mirror, so the debit side of a T-account is on the right as a Hebrew ledger writes it; charts keep time running left to right.

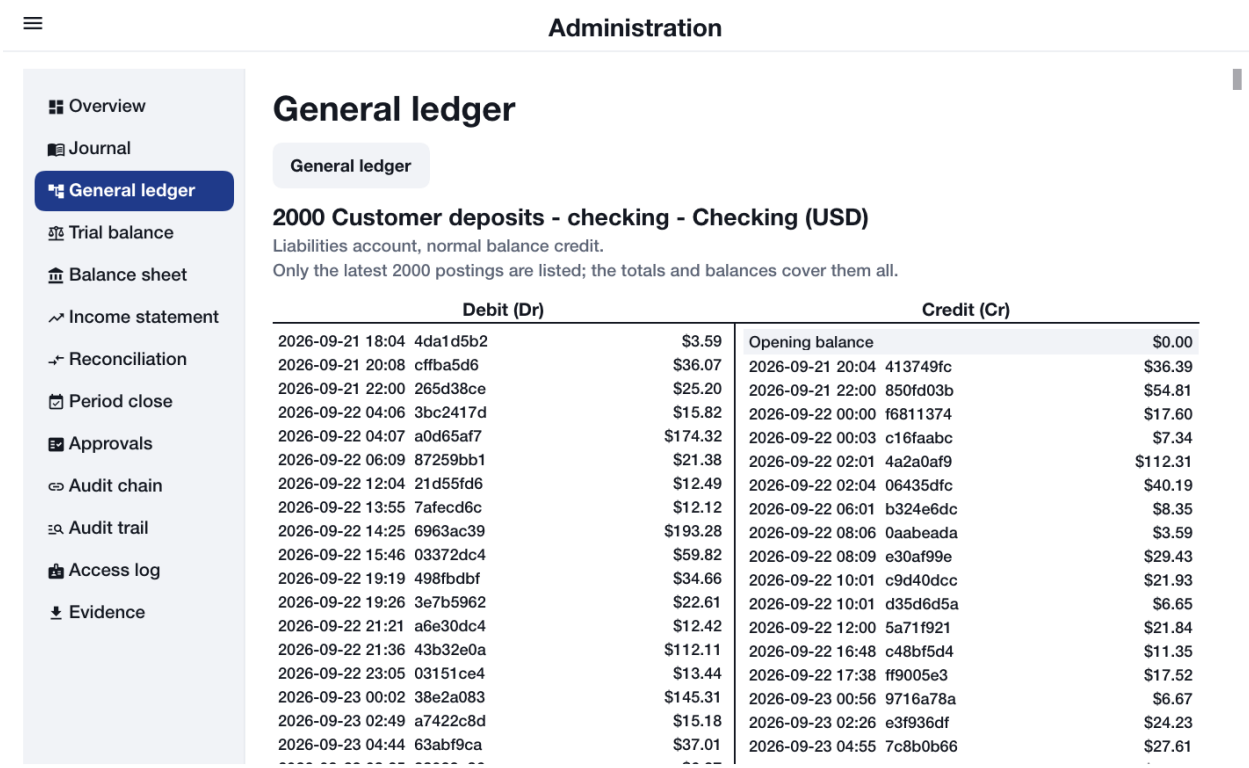
61.12. The back office



Staff sign in like customers and land on the console: **Administration** for an administrator, **Audit** for an auditor. On a wide window, a desktop or a tablet on its side, the sections are a sidebar beside the page and the tables use the width; on a phone the sections are a picker over one column, and a wide table scrolls sideways. A customer's statement on a phone keeps three columns instead: the date, the amount signed in or out, and the running balance.

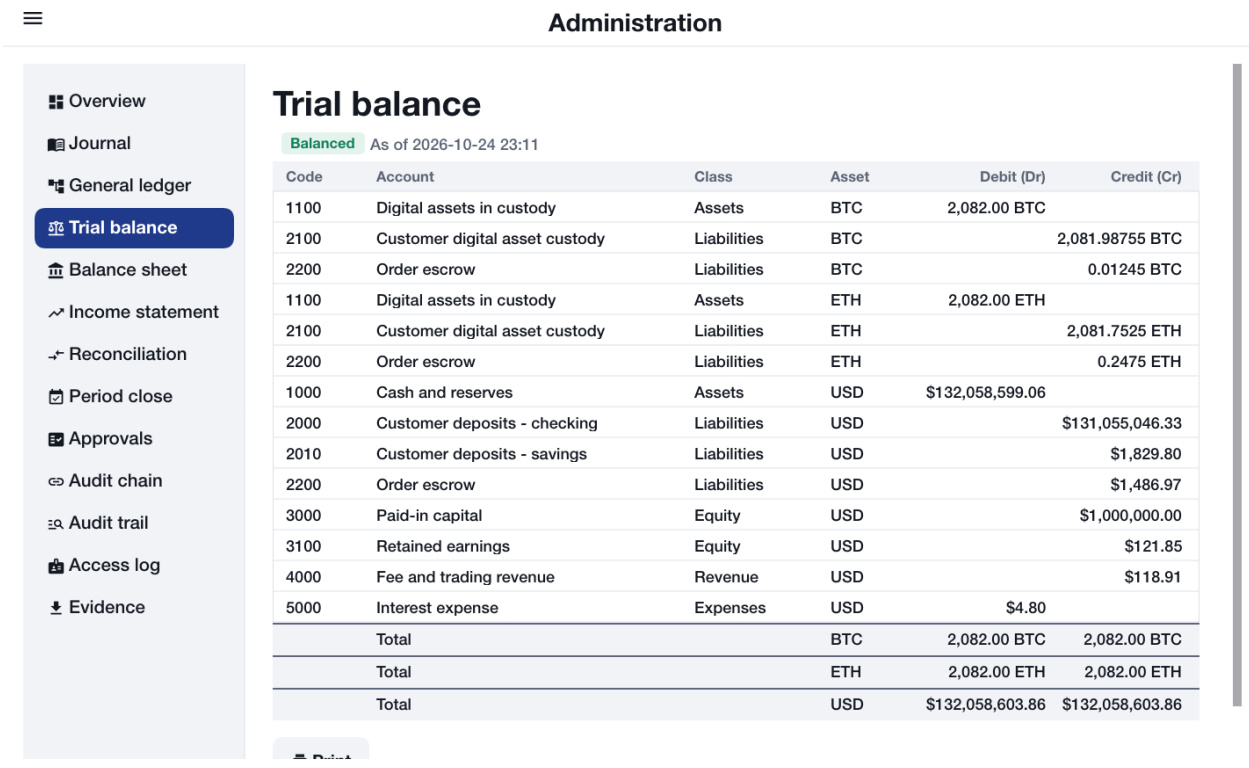


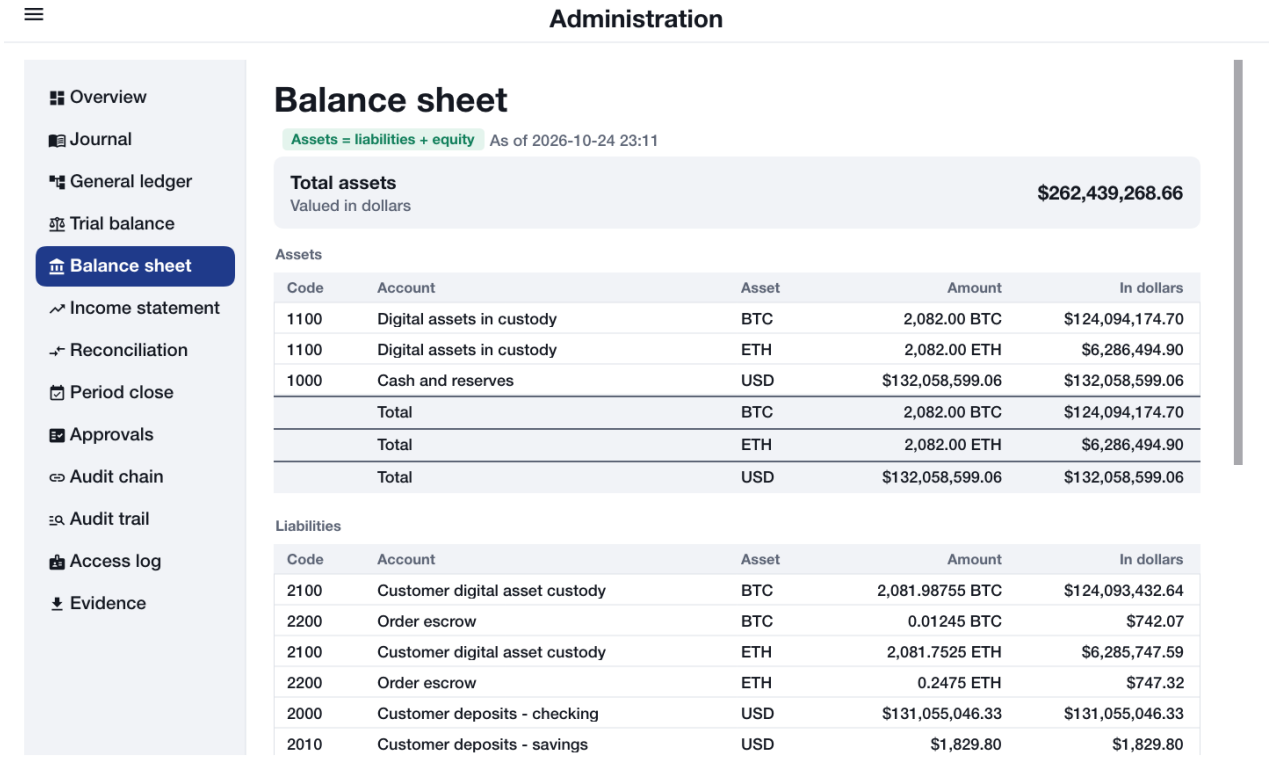
The **Overview** shows whether the trial balance balances, whether reconciliation found breaks, whether the audit chain is intact and how many requests wait for approval, with the dollar volume and the number of journal entries a day. Order holds and their releases are left out of both: they move a customer's own money into escrow and back, and no value changes hands. An administrator also runs the two checks, recomputed from the stored rows each time:

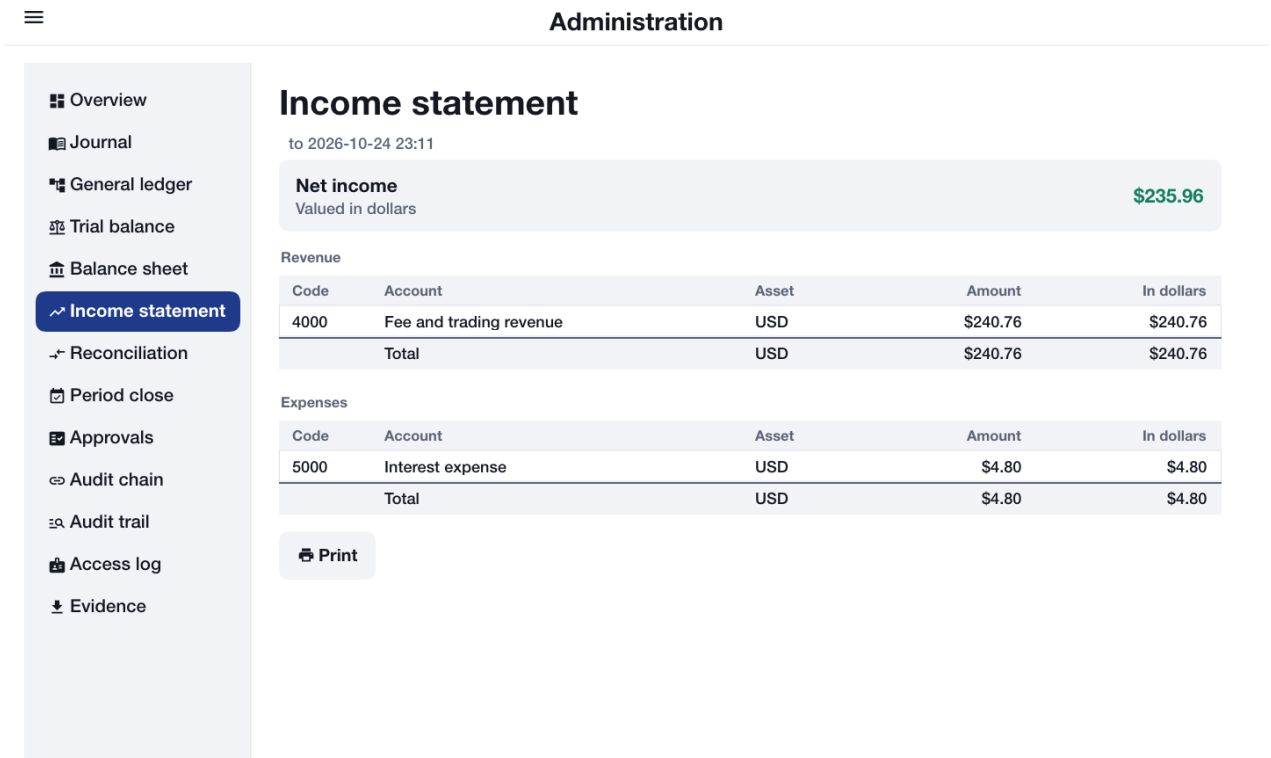


- **Verify the audit log**: every security and money event is a link in a hash chain, and the check reports any row that was changed, removed or inserted out of order.
- **Verify the ledger**: every entry sums to zero in each currency, and every balance equals the sum of its postings.

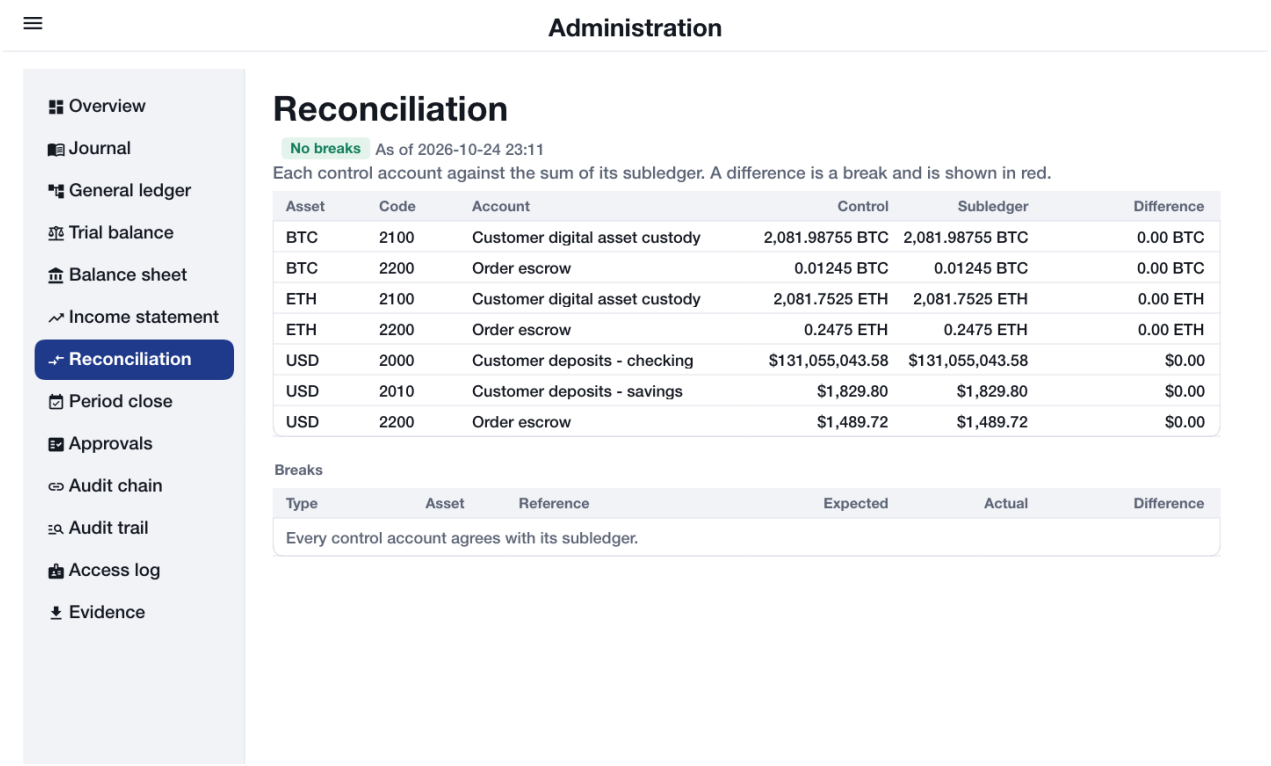
The **Journal** lists every entry with its debit (Dr) and credit (Cr) legs, credits indented under the debits. Tapping an entry shows it in full, with a total per currency that proves its debits equal its credits, the entry it reverses or the one that reversed it, and its audit trail.



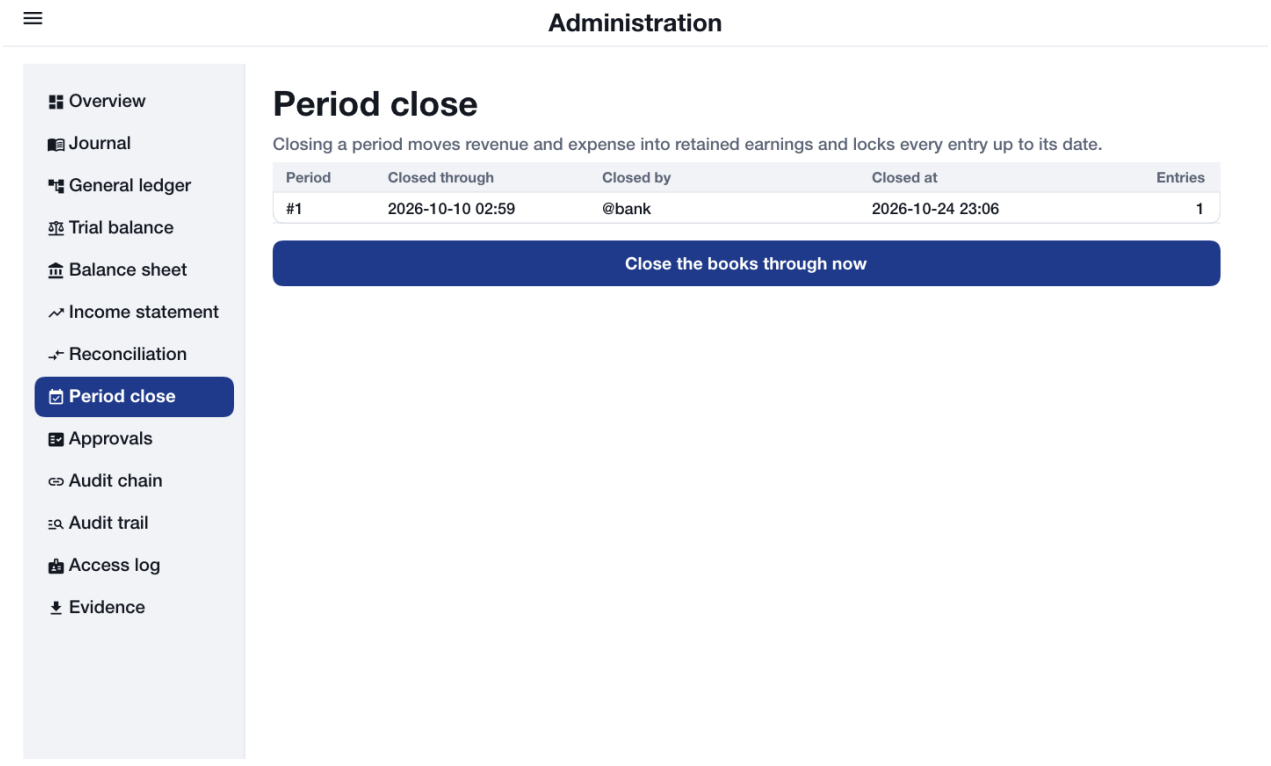


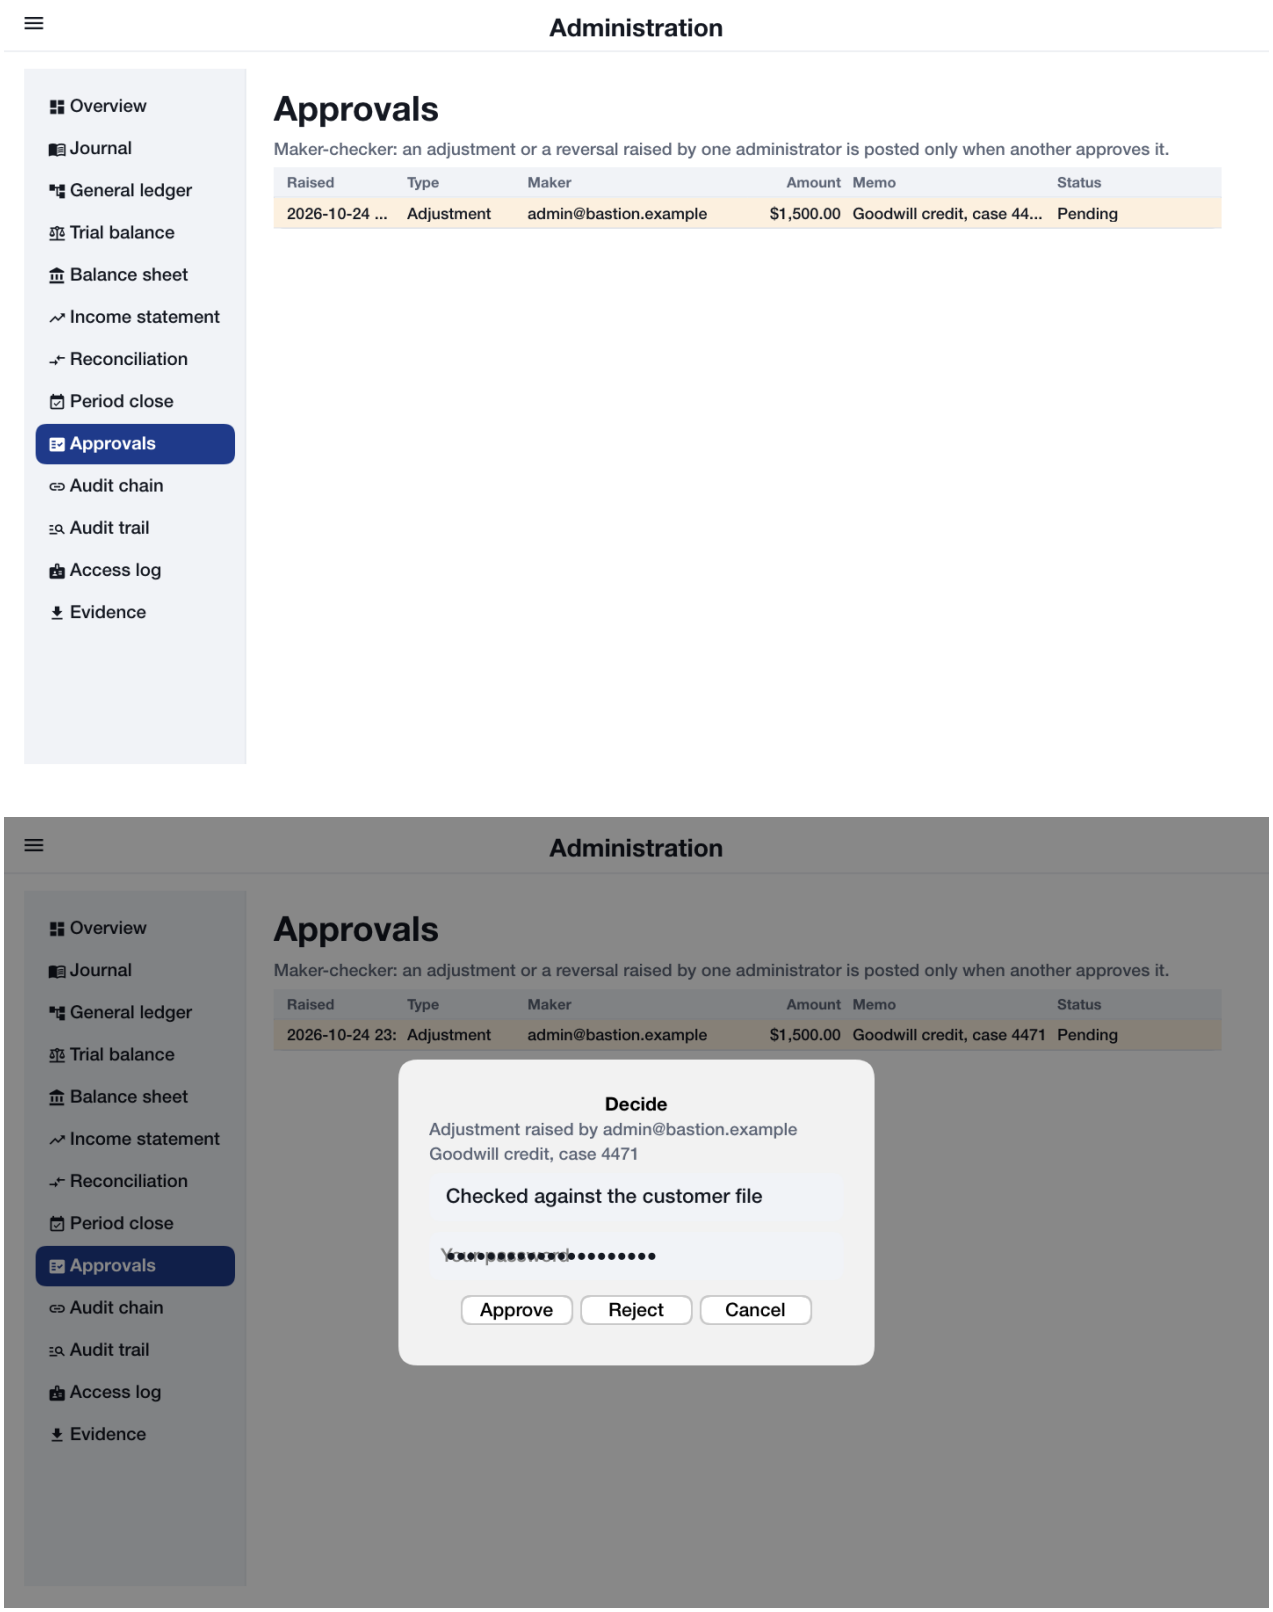


The **General ledger** lists the lines of one account code in one currency with a running balance, and shows the account as a T-account, debits on one side and credits on the other, between its opening and closing balances.

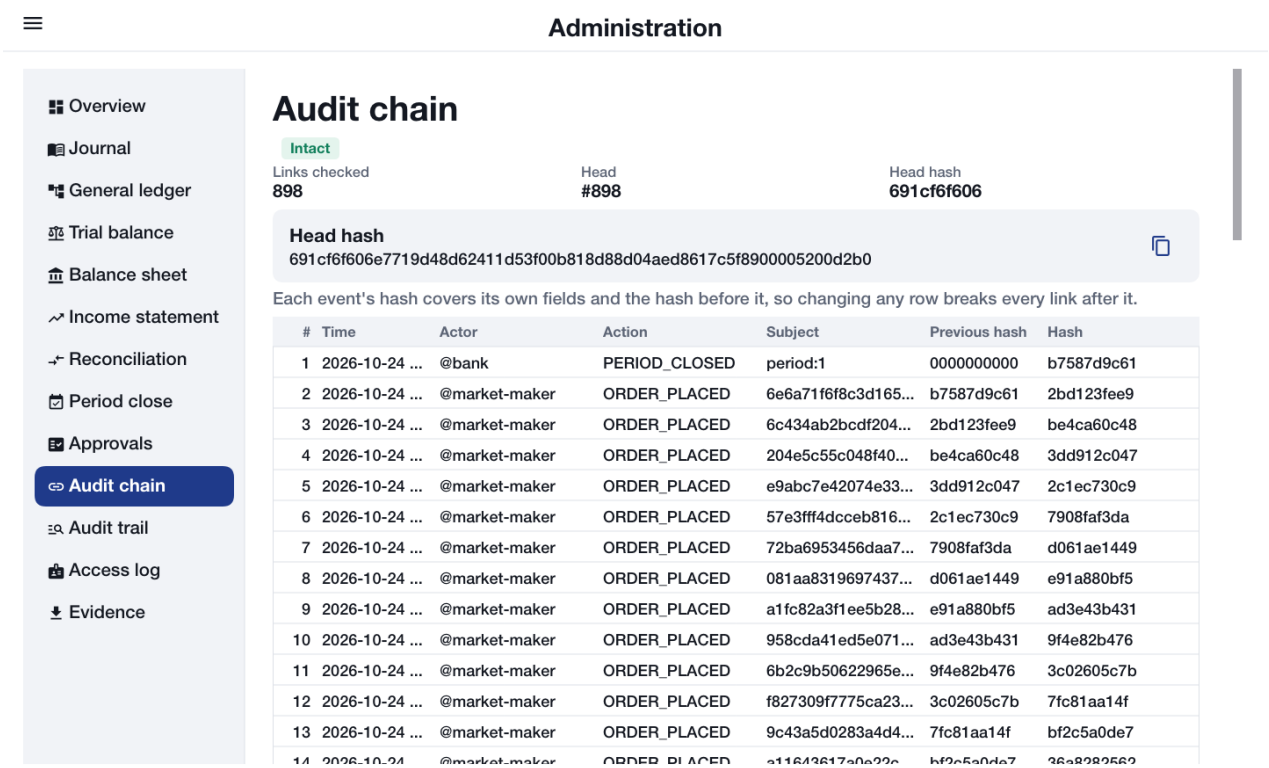


The statements follow from the same postings. The **Trial balance** lists the debit or credit balance of every account code and currency, with totals that must agree. The **Balance sheet** shows assets, liabilities and equity, and that the first equals the sum of the other two. The **Income statement** shows revenue and expenses for the period and the net income, all valued in dollars as well as in their own currency.

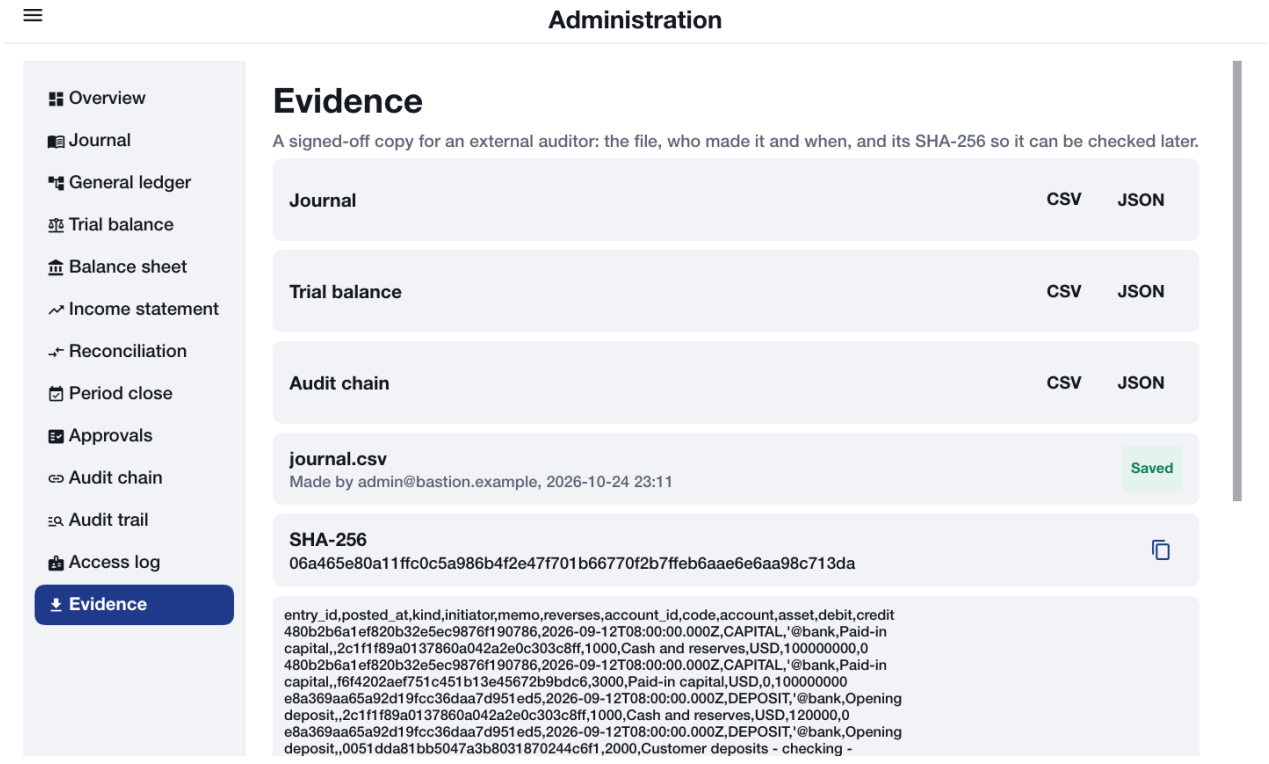




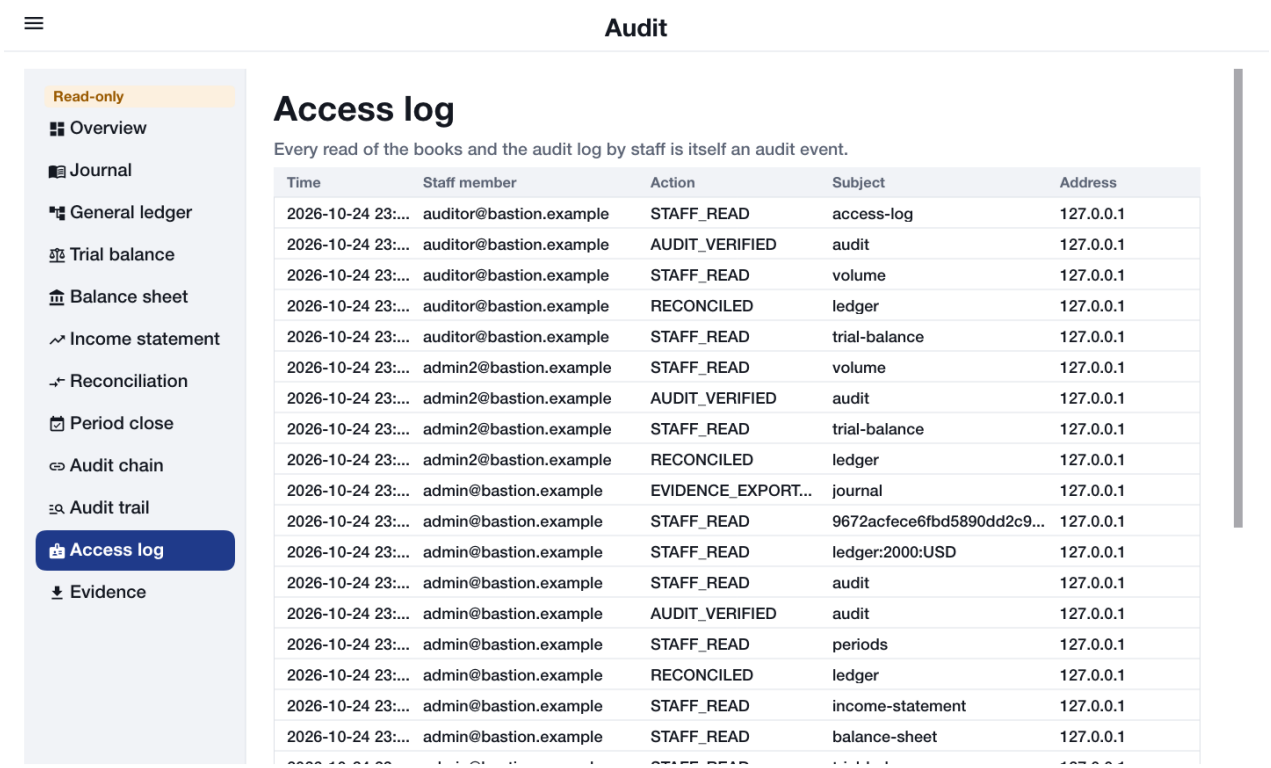
Reconciliation compares each control account with the sum of the customer accounts under it. A difference is a break, and its row is red.



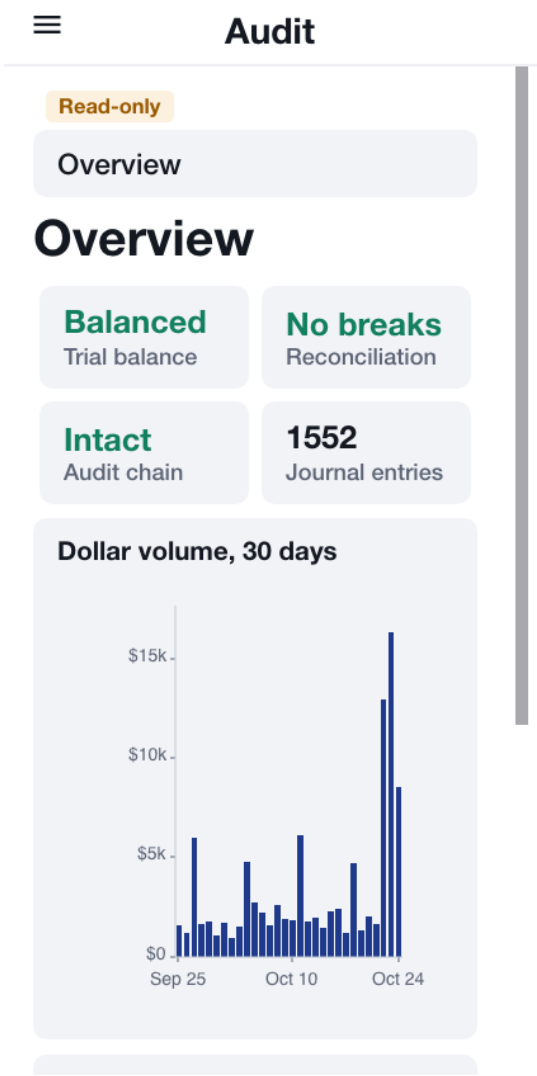
Period close lists the closed periods. Closing one moves revenue and expense into retained earnings and locks every entry up to its date, so its statements never change again.



Changes need two administrators. An administrator can ask for an adjustment to a customer account or for an entry to be reversed; above the approval threshold it waits in **Approvals** until a second administrator approves or rejects it. Every change asks for the administrator's password again.



Audit chain reports how many links were checked and the head of the chain, and lists the latest events with their hashes; if a link is broken, the first broken row is red. **Audit trail** lists every event that names one entry, account or person, and **Access log** lists every time staff read the books.



Evidence exports the journal, the trial balance or the audit chain as CSV or JSON for an external auditor. The file is saved, a browser downloads it, and the screen shows who made it, when, and its SHA-256 digest so the copy can be checked later.

An auditor sees the same console marked **Read-only**, without the approvals queue and without any button that changes something. The server refuses those changes to an auditor whatever the app shows.

No request can make an administrator. Outside the development profile, the one administrator

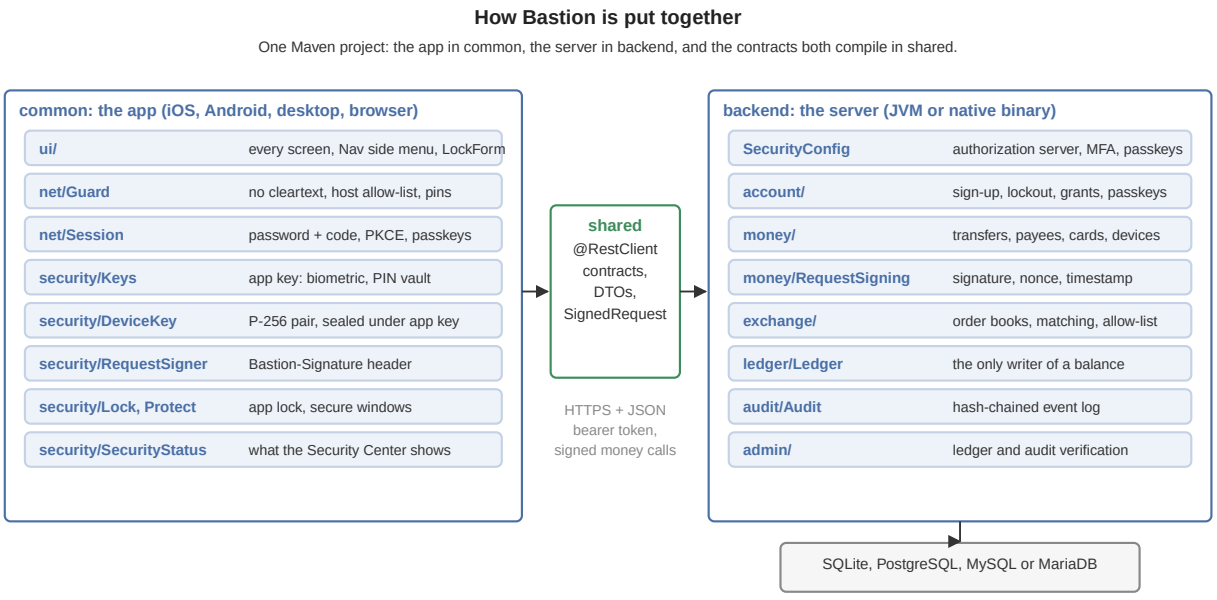
account comes from the server’s environment when it starts.

Chapter 62. Bastion: Building on the sample

This chapter is for the developer who takes `scripts/bastion` as the start of a real banking or exchange app. It covers how the sample is put together, how sign-in, a signed payment, a trade and the audit chain work, every security feature with the file it lives in, the settings and the endpoints, the threats it's built against, what only a cloud build turns on, and the work that stands between the sample and a product.

62.1. Running it

The server runs on the development profile with an in-memory database:



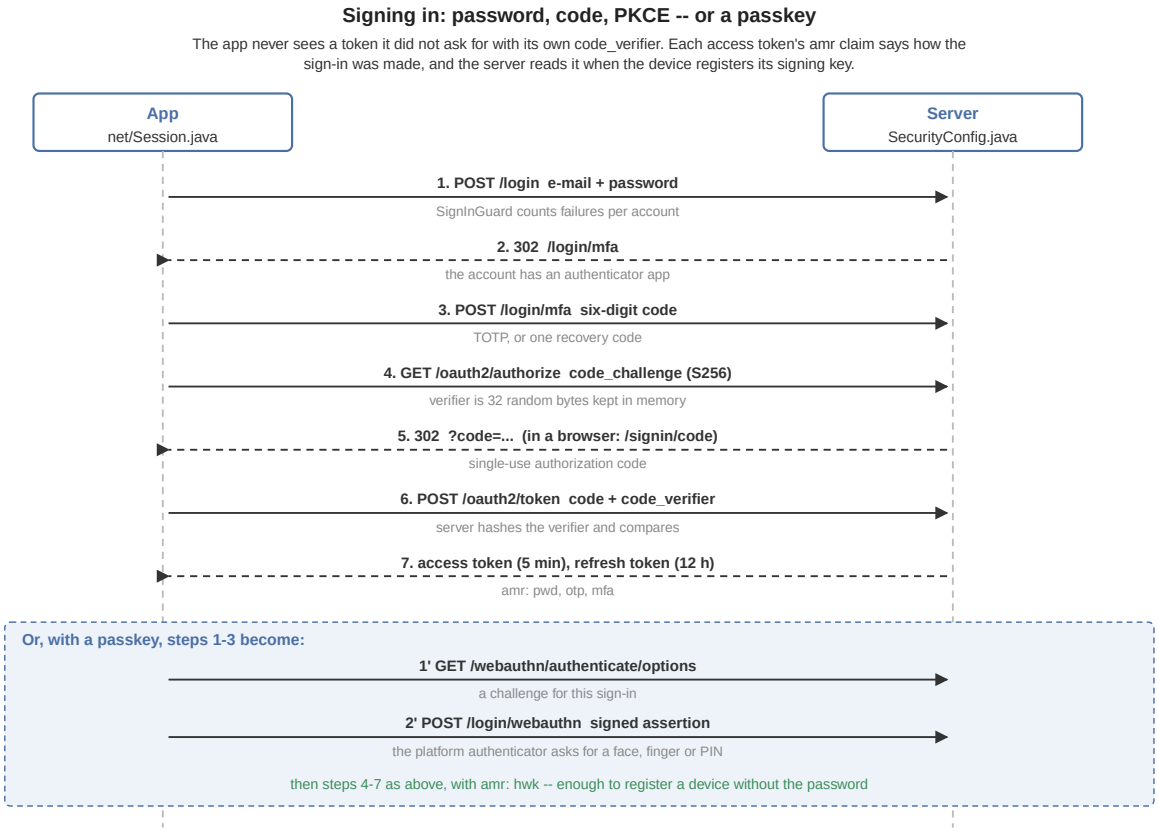
```
cd scripts/bastion
CN1_PROFILE=dev backend/server.sh run
```

The app runs in the simulator from another terminal:

```
mvn verify -Psimulator -DskipTests -Dcodename1.platform=javase
```

`backend/server.sh run --native` runs the same server compiled to a native binary, and `--web` also builds the app for the browser and serves it from the server at `/`.

62.2. The modules

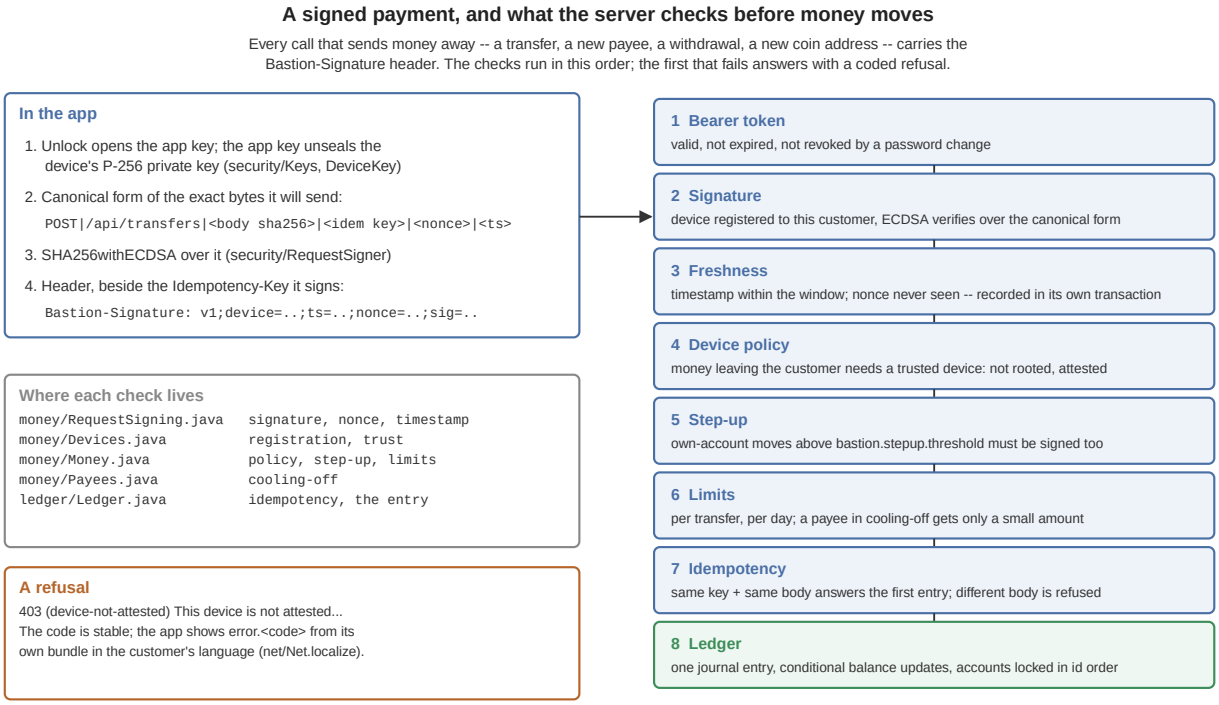


Module	What it holds
`shared`	The transfer objects and the `@RestClient` contracts (`BankingApi`, `ExchangeApi`, `AccountApi`, `AdminApi`), `SignedRequest`, the canonical form both sides sign and verify, and `Refusal`, the stable codes of the server's refusals.

Module	What it holds
`backend`	The Codename One Backend server: the ledger, accounts and sign-in, money movement, the exchange, the audit chain, and the administrator's checks.
`common`	The app: every screen, the network guard, the app key, the device key and request signer, the app lock, the screen protections and the Security Center.

The project has the minimal layout, with no platform modules: `common` builds the simulator, the desktop app, Android, iOS and the browser. The server's classes live under `backend/src/main/java/com/codenameone/examples/bastion` and the app's under `common/src/main/java/com/codenameone/examples/bastion`; the paths in this chapter are relative to those.

62.3. Signing in



The server is its own OAuth 2 authorization server (`SecurityConfig.java`). The app (`net/Session.java`) posts the password, answers the `/login/mfa` step when the account has an authenticator app, and then runs the authorization-code flow with PKCE. A passkey replaces the first three steps with a WebAuthn assertion, and the server asks for user verification on every one (`userVerification("required")`), so a passkey sign-in is always a fingerprint, a face or the device PIN as well as the key.

The sign-in screen (`ui/SignInForm.java`) offers the strongest factor the device has first: a passkey, then the stored sign-in a biometric opens (the app key the lock screen releases, which also seals the

device's payment key), then the password and code. The server doesn't leave that to the app. `account/SignInGuard.java` holds an account to the strongest factor it has enrolled: for an account with a passkey, `POST /login` is answered 403 with `"stronger":"passkey"` before the password is checked, unless the account has an authenticator app, and then the `/login/mfa` step accepts a recovery code and refuses a six-digit code with the same answer. The password and a recovery code are the recovery path for a lost passkey; each code works once, and the sign-in is in the audit log. An account with a passkey and no authenticator app is recovered by the bank removing the passkey after checking who is asking. Every refusal is audited as `SIGNIN_REFUSED`. The answer tells whoever knows the e-mail that the account has a passkey, the same trade the lockout makes. In a browser the app runs the same steps from the page, with the browser's own session cookie, and reads its code from `/signin/code` on the server it came from.

Access tokens last five minutes and refresh tokens twelve hours, rotating on every use. Each access token carries an `amr` claim saying how the sign-in was made: `pwd`, `otp` and `mfa`, or `hwk` for a passkey. `money/Devices.java` reads it: a device key is registered only within ten minutes of a sign-in, and also needs the password unless the sign-in used a second factor or a passkey the authenticator verified the user for (`hwk` together with `user`); `hwk` alone proves only that the key was present. `account/SecondFactor.java` holds adding an authenticator app to the same rule, stricter: after a password-only sign-in both the start and the confirmation carry the password as well as being within those ten minutes, so a stolen token can't enroll the thief's app however fresh it is.

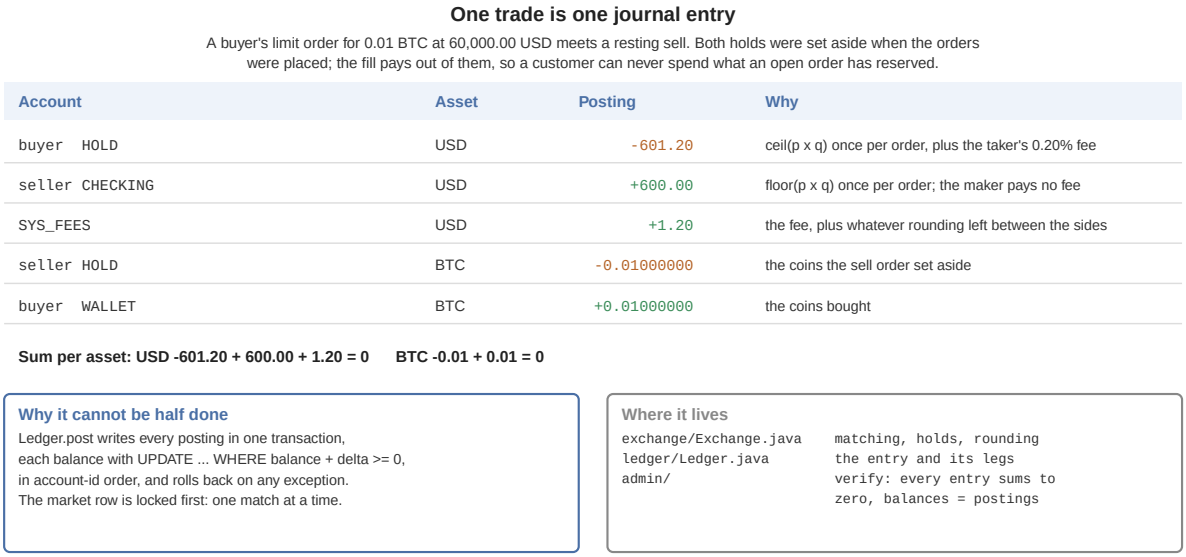
62.4. A signed payment

Every call that sends value away carries a `Bastion-Signature` header made by `security/RequestSigner.java`:

```
Bastion-Signature: v1;device=<id>;ts=<millis>;nonce=<random>;sig=<base64url r||s>
```

The signature is ECDSA P-256 with SHA-256 over `METHOD|target|hex(sha256(body))|idempotency-key|nonce|ts`, built by `SignedRequest` in `shared` so that both sides compute the same bytes. The app signs the exact JSON it sends. The `Idempotency-Key` is signed too (an empty field for a call without one): otherwise a captured request could be sent again under a fresh key and its fresh nonce, and the server would take it for a new payment. The server (`money/RequestSigning.java`) refuses an unknown device, a bad signature, a timestamp outside the window or a nonce it has seen, and commits the nonce in its own transaction before the money transaction starts, so a replay that races the original still loses.

A refusal is answered as `(code|value|value) English text`. The code is one of the `Refusal` constants; the app looks it up as `error.<code>` in its own bundle (`net/Net.java`), so the customer reads it in their language and a reworded English sentence never breaks a translation. `ui/DeviceSetup.java` reacts to the device codes: it offers to register a key and then sends the same request again, with a fresh nonce and the same idempotency key.



62.5. The ledger

Every amount is a `long` in the asset's smallest unit: cents for dollars and euros, satoshi for bitcoin. Ether is kept in units of 10^{-9} (gwei) rather than wei, so that a balance fits a `long`; a real ether product that needs wei precision has to widen the column and the arithmetic.

`ledger/Ledger.java` is the only code that changes a balance. It posts a double-entry journal entry, whose postings sum to zero in every asset, in one transaction:

- **Conditional updates.** A balance moves with one `UPDATE … WHERE balance + :delta >= 0`, so two payments racing for the last dollar can't both succeed, and no balance is ever read, changed in Java, and written back.
- **Lock order.** The accounts an entry touches are updated in the order of their ids, so two entries over the same accounts can't deadlock each other.
- **Idempotency.** Every money request carries an `Idempotency-Key`. The key and a hash of the request are stored with the entry; a retry answers the first entry, and the same key with a different request is refused.
- **Rollback on any failure.** Every transaction is `@Transactional(rollbackFor = Exception.class)`. A checked exception would otherwise commit what was done before it.

A trade is the richest entry the ledger makes:

`exchange/Exchange.java` sets aside what an order could spend in a `HOLD` account when it's placed, and pays fills out of the holds. Each order keeps the exact running sum of price times quantity over its fills and rounds it once: up for what a buyer pays, down for what a seller gets, with the difference and the taker fee going to `SYS_FEES`. The market's row is locked before matching, so one market matches one order at a time.

`ledger/IsolationCheck.java` refuses to start the server on MySQL at its default REPEATABLE READ isolation. The ledger, the audit chain and the order book each serialize their writers on one row and then read what the previous writer committed, and REPEATABLE READ answers those reads from an older snapshot. Run MySQL at READ COMMITTED (`transaction-isolation = READ-COMMITTED` in its configuration). PostgreSQL runs at READ COMMITTED by default, and SQLite serializes every writer.

62.6. The accounting model

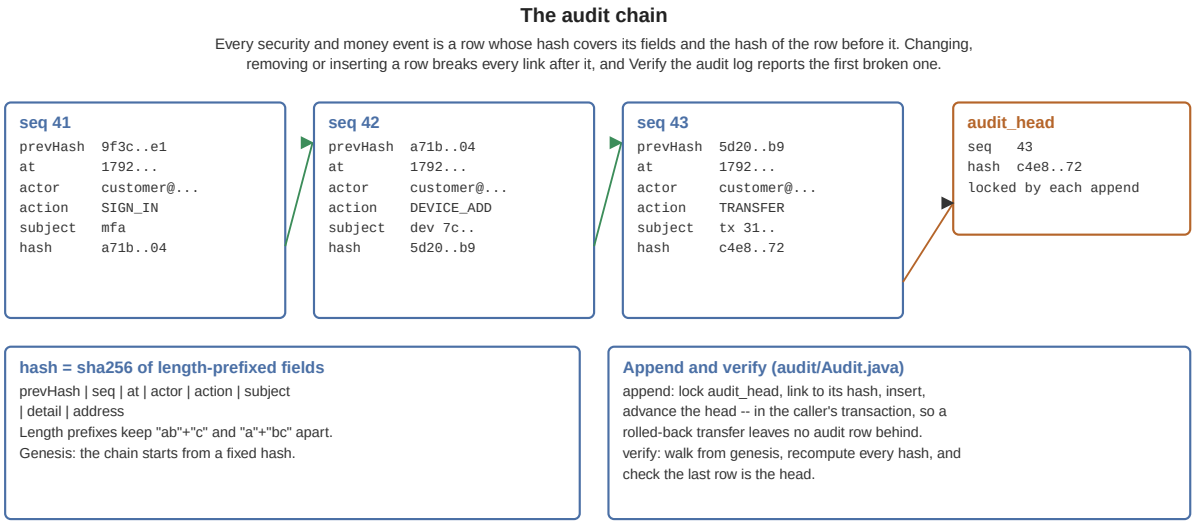
The ledger stores one signed number per posting. Read as accounting, a positive amount is a credit and a negative one a debit, so an entry that sums to zero is an entry whose debits equal its credits. A customer's deposit is money the bank owes, so customer accounts are liabilities; the cash that came in is an asset. `books/Chart.java` maps every account kind to its place in the chart of accounts, in code, so no row can put a customer's deposit among the bank's assets:

Code	Account	Class	Normal balance	Kind
1000	Cash and reserves	Asset	Debit	`SYS_CASH`
1100	Digital assets in custody	Asset	Debit	`SYS_CHAIN`
2000	Customer deposits, checking	Liability	Credit	`CHECKING`
2010	Customer deposits, savings	Liability	Credit	`SAVINGS`
2100	Customer digital asset custody	Liability	Credit	`WALLET`
2200	Order escrow	Liability	Credit	`HOLD`
3000	Paid-in capital	Equity	Credit	`SYS_EQUITY`

Code	Account	Class	Normal balance	Kind
3100	Retained earnings	Equity	Credit	`SYS_RETAINED`
4000	Fee and trading revenue	Revenue	Credit	`SYS_FEES`
5000	Interest expense	Expense	Debit	`SYS_INTEREST`
5100	Operational adjustments	Expense	Debit	`SYS_ADJUST`
9999	Suspense	Asset	Debit	any kind the chart doesn't know, shown rather than hidden

`books/Books.java` derives every report from the postings: the journal, the general ledger of one code, an account's T-account, the trial balance, the balance sheet (with the period's earnings as line 3900 until closing the period moves them to retained earnings) and the income statement. Each total is per asset and also valued in dollars at the index price.

- **Period close.** Closing a period posts one closing entry per asset that moves revenue and expense into retained earnings, and records the close. From then on the ledger refuses any entry dated inside a closed period, so a closed period's statements never change.
- **Reversals.** A posted entry is never edited. A reversal posts the opposite entry, and an entry can be reversed once; closing entries and reversals themselves can't be.
- **Reconciliation.** Each control account (customer deposits, escrow, custody) is compared with the sum of the accounts beneath it, every journal entry with zero, and every stored balance with the sum of its postings. Each difference is reported as a break naming the account and the amounts.
- **Roles.** An `AUDITOR` reads the books and the audit trail and can change nothing; an `ADMIN` operates. Every staff read is appended to the audit chain as `STAFF_READ` before it's answered, and `/api/audit/access-log` lists them.
- **Four eyes.** A manual adjustment or a reversal worth more than `bastion.approval.threshold-usd-cents` waits as a pending approval until a second administrator approves it; the maker can't approve their own request, and the refused attempt stays on the audit chain. The threshold counts what the same administrator posted without a checker in the last 24 hours, so a large change split into small ones still waits. A request in an asset with no dollar price can't be shown to be small, so it waits too. Every change also asks for the administrator's password again.
- **Evidence.** `/api/audit/evidence/{name}` exports the whole journal, the trial balance or the audit chain as CSV or JSON, with its SHA-256 digest, which is itself recorded on the chain. A CSV cell that a spreadsheet would run as a formula is quoted. The chain report names the first row whose link is broken.
- **Long ledgers.** The general ledger and a T-account list the latest 2000 postings and say when there are more; their totals and balances are summed over every posting in the period.



62.7. Charts, tables and the console

The app's screens are in `common/src/main/java/⋯/ui`. Three classes carry the data views:

- `Charts.java` draws every chart with `com.codename1.charts`: a filled line for a balance, paired bars for money in and out, a doughnut for the allocation, and candles for a market, made of a range bar from the low to the high under a body from the open to the close. Colors come from the foreground of the `BnChartLine`, `BnChartIn` and `BnChartOut` styles in `theme.css`, so dark mode and a re-skin reach the charts too.
- `Table.java` is a table of weighted columns over `TableLayout`, with numbers aligned to the end of their column. It mirrors in Hebrew, and on a phone a table wider than the screen scrolls sideways inside itself.
- `ConsoleForm.java` is the staff console. A window at least 165 mm wide gets a sidebar; anything narrower gets a section picker. Its buttons follow the roles: an auditor gets no action at all and an administrator's changes send the password with each request and a fresh `Idempotency-Key` with each adjustment or reversal. The server enforces both; the console only stops offering what would be refused.

`Nav.form` keeps one way out of every screen: a screen reached from the menu has the menu button, a screen pushed from another has a back arrow, never both. The sign-in, code and lock screens have no title bar; `Ui.landing` gives them the brand band as a header instead.

62.8. The audit chain

`audit/Audit.java` appends every security and money event as a row whose SHA-256 hash covers its own fields, length-prefixed, and the hash of the row before it. Appending a row locks `audit_head`, links to its hash and advances it, inside the caller's transaction, so a transfer that rolls back leaves no audit row behind. **Verify the audit log** (`/api/admin/audit/verify`) walks the chain from its fixed starting hash and reports the first row whose hash isn't its own, that doesn't link to the row before, or a head that doesn't match the last row.

62.9. Security features and where they live

The last column says whether the feature needs a build from the Codename One build server to be in force. Everything marked **No** works in the simulator, a local build and the browser too.

62.9.1. On the server

Feature	What it does	Where	Cloud build?
Sign-in	The authorization server with the authorization-code flow and PKCE, five-minute access tokens, rotating twelve-hour refresh tokens and the `amr` claim.	`SecurityConfig.java`, `SignInCodePage.java`	No
Second factor	TOTP enrolment and confirmation, ten single-use recovery codes, and the `/login/mfa` step that holds the session back until the code.	`account/SecondFactor.java`, `SecurityConfig.java`	No
Passkeys	WebAuthn registration and sign-in with user verification required; listing and removing them.	`SecurityConfig.java`, `account/PasskeyList.java`	No
Strongest factor enforced	An account with a passkey can’t sign in with the password, or with the password and an authenticator code; only the password and a recovery code stand in for the passkey.	`account/SignInGuard.java`	No
Lockout	Failed passwords counted per account in `login_failure`, locking it for a period after too many.	`account/SignInGuard.java`	No
Rate limits	Per-address limits on sign-in, registration and transfers.	`SecurityConfig.java`	No
Headers	`nosniff`, frame denial, `no-store`, a strict referrer policy and HSTS over TLS on every answer.	`SecurityConfig.java`	No
Ending sessions	A password change ends every other sign-in by removing its grants, so a refresh token on a lost phone stops working.	`account/Grants.java`	No

Feature	What it does	Where	Cloud build?
Device registration	A device's P-256 public key is registered only within minutes of a sign-in, and with the password again unless the sign-in had a second factor or a passkey. A registration without a platform attestation token is recorded as untrusted, and an untrusted device's signature is refused for any money leaving the customer's accounts. If the app locks while a registration is on its way, the app revokes the server's record of that device after the next unlock.	`money/Devices.java`	No
Request signing	Signature, timestamp window and single-use nonce on every call that sends value away, and on the calls that would let a stolen token do so later: changing a payee or an address, issuing or unfreezing a card, raising its limit, revoking a device or removing a passkey. Placing an order is signed too: selling into a resting order moves value to its owner.	`money/RequestSigning.java`, `SignedRequest.java`	No
Device policy	Money leaving the customer needs a signature from a trusted device: registered, not reported rooted, and passing the integrity check.	`money/Money.java`, `money/Devices.java`	No
Integrity	The check of the platform's attestation token. With `bastion.appattest.app-id` set to the app's team and bundle id, an iPhone's App Attest attestation is verified on the server: the certificate chain to Apple's root, the nonce bound to the device key being registered, the app id, the counter and the environment (`bastion.appattest.production`). Android, and iOS without the setting, use the simulated verifier; see Section 62.18, "Before it's a product".	`money/IntegrityVerifier.java`, `money/AppAttestVerifier.java`, `money/SimulatedIntegrityVerifier.java`	Token: yes

Feature	What it does	Where	Cloud build?
Limits and step-up	Per transfer, per day, per new payee during its cooling-off; own-account moves above a threshold signed too; crypto counted in dollars at the index price. Orders count against the same per-payment and daily limits, valued in dollars at their worst case, and trade only within a price collar around the index (`bastion.exchange.collar-bps`, 10%). A card's own daily limit is in the card account's currency, as a card network counts it.	`money/Money.java`, `money/Payees.java`	No
Allow-list	Coins leave only to a signed, cooled-off address.	`exchange/CryptoWallets.java`	No
Audit chain	Hash-chained event rows appended under a lock on the head.	`audit/Audit.java`	No
Ledger check	Every entry balances and every balance equals its postings.	`admin/AdminEndpoint.java`	No
Administrators	No request makes one. Outside development, the only administrator comes from the environment.	`account/DemoAccounts.java`	No

62.9.2. In the app

Feature	What it does	Where	Cloud build?
Network guard	Installed before the first request: no cleartext, a host allow-list, and certificate pins, through `AppShield`. If the guard can't be installed the app shows a fatal screen and makes no request. A pinned host that presents no certificate chain, as a connection resumed from a TLS cache can, fails like a mismatch. The one exemption from cleartext is a server on this machine, and only in the simulator, under the tests or in a page served from this machine; an installed app never has it.	`net/Guard.java`, `AppConfig.java`	No

Feature	What it does	Where	Cloud build?
Over-the-air pins and attestation tokens	`AppShield's attestation engine fetches pins and stamps requests with a token.	`net/Guard.java`	Yes
Sign-in	The strongest way in first: a passkey, then the biometric unlock of a stored sign-in, then the password and second-factor step; then the authorization-code flow with PKCE, in a browser too.	`net/Session.java`, `ui/SignInForm.java`	No
Copying values	One component for every value a user copies: selectable text and a copy button. Keys and account and card identifiers go through `Protect.copy`, a sensitive clip that clears itself after a minute.	`ui/Ui.java` (`copyable`), `security/Protect.java`	No
Printing	Statements, receipts, transactions and the console's reports laid out as a page of monospaced lines, drawn on an image and handed to `com.codename1.printing.Printer`. No button where `Printer.isPrintingSupported()` is false.	`ui/Printout.java`, `ui/Table.java`	No
App key	32 random bytes that seal the device key and the stored tokens, held in memory only while unlocked. Copies: one in the biometric tier of `SecureStorage` (an iOS Keychain item with biometric access control, an Android Keystore key that requires user authentication), one in a `Vault` opened by the unlock PIN through its `KdfProfile` with a pepper from the OS store, and a plain copy only while neither exists. Five wrong PINs wipe every copy.	`security/Keys.java`, `security/SealedStorage.java`	No (biometric binding: a device)
Token storage	Tokens sealed under the app key in `SecureStorage`: the Keychain on iOS, the Keystore-backed store on Android.	`net/Session.java`, `security/SealedStorage.java`	No
Device key	A P-256 pair from `KeyGenerator.ec(256)`, the private half sealed with AES-256-GCM in a `SecureEnvelope` under the app key.	`security/DeviceKey.java`	No

Feature	What it does	Where	Cloud build?
Request signer	Signs the exact bytes the request sends, in the canonical form the server checks.	`security/RequestSigner.java`	No
App lock	Locks on start with a stored session, after 30 seconds in the background and after two minutes idle; biometric, then PIN, then a fresh sign-in. Locking also drops the session’s tokens from memory and ignores every answer still on its way; the unlock reads the tokens back from the sealed store. Signing out erases every key on the device, and a sign-in by another account starts the device over.	`security/Lock.java`, `ui/LockForm.java`	No

Feature	What it does	Where	Cloud build?
Screen protection	Secure windows on sensitive screens, tapjacking protection, and a clipboard that clears itself after a minute, or as soon as the app can confirm the copy is still there, without reading the clipboard when the app goes to the background. Each copy is a `ClipboardContent` marked sensitive with `setClearAfter`, so Android 13 and newer keep it out of the preview and iOS keeps it local and expires it. On Android 10 and newer a clear that falls due while the app is in the background waits for the app to return, because only then can it confirm the clipboard still holds the copy rather than something the user copied from another app. That wait lives in the running process, so a killed app would leave the copy behind. On Android `Protect` covers it by keeping an HMAC-SHA256 of the copy (never the text) in `Preferences`, under a random key held in secure storage. Once the clear is due it reads the clipboard again as a screen shows, on resume and a moment after the clear: a match clears it, anything else copied since drops the record, and a read that answers nothing (an app without window focus, on Android 10 and newer) keeps the record for the next look. On iOS nothing is recorded or read back, because the pasteboard expires the copy itself and a read would show the paste banner.	`security/Protect.java`	No (a device)
App switcher cover	A blank card in the iOS app switcher.	`codenameone_settings.properties`	Yes
Root and jailbreak	Root signals reported to the server; a jailbroken iPhone refuses to start.	`security/DeviceKey.java`, `codenameone_settings.properties`	Jailbreak exit: yes
Code hardening	Class renaming, string encryption, control-flow flattening and tamper checks.	`codenameone_settings.properties`	Yes

Feature	What it does	Where	Cloud build?
Security Center	Every protection above with its real state on this device and build.	`security/SecurityStatus.java`, `ui/SecurityCenterForm.java`	No

The app can't read its own build hints when it runs, so `SecurityStatus.DECLARED_HINTS` mirrors the hardening hints in `common/codenameone_settings.properties`, and `SecurityStatusTest` fails when the two disagree.

62.10. What only a cloud build turns on

Some protections are applied when the app is built, by the Codename One build server, and do nothing in the simulator, a local build or the browser. The Security Center marks each **Cloud build** there rather than claiming it's on.

Build hint	What it turns on
`cn1.hardenLevel=aggressive`	Code hardening: class renaming, string encryption, control-flow flattening and tamper checks in the built app.
`android.playIntegrity=true`	Play Integrity: the app obtains an attestation token for the server to check.
`ios.detectJailbreak=true`	The iOS jailbreak checks; the app exits on a jailbroken iPhone.
`ios.blockScreenshotsOnEnterBackground=true`	A cover over the app in the iOS app switcher.

A hardware-backed keystore, secure windows and biometrics need a real device; the simulator reports them as unavailable.

62.11. Settings

The server reads these at start-up. A system property of the same name wins, then the environment variable the key maps to (`bastion.payee.cooloff-hours` is read from `BASTION_PAYEE_COOLOFF_HOURS`), then `application-<profile>.properties`, then `application.properties`. Amounts are in cents.

Key	Default	What it controls
`cn1.datasource.url` (`DATABASE_URL`)	none	The database: SQLite, PostgreSQL, MySQL or MariaDB.
`cn1.security.authorizationserver.issuer`	none	The server's public `https` address, written into every token.
`cn1.security.authorizationserver.jwk.keys`	a key made at start-up	The key tokens are signed with. Without it, every token stops verifying when the process ends.
`cn1.security.mfa.encryptionKey`	a fixed development key	The key authenticator secrets are sealed under.

Key	Default	What it controls
`bastion.admin.email`, `bastion.admin.password`	none	The one administrator outside the development profile.
`bastion.webauthn.rp-id`	`localhost`	The domain passkeys belong to.
`bastion.webauthn.origins`	`http://localhost:8080`	The origins passkeys are accepted from, comma separated.
`bastion.lockout.attempts`, `bastion.lockout.window-seconds`, `bastion.lockout.seconds`	5, 900, 900	Failed passwords before the account locks, the window they're counted in, and how long it stays locked.
`bastion.signin.per-minute`, `bastion.register.per-hour`, `bastion.transfer.per-minute`	10, 20, 20	Rate limits per address.
`bastion.device.fresh-minutes`	10	How recent a sign-in must be to register a device key.
`bastion.device.policy.enforce`	`true`	Whether money leaving a customer needs a trusted device. Turn it off only for development and screenshots.
`bastion.stepup.threshold`	100000	Own-account moves above this are signed by the device too.
`bastion.exchange.collar-bps`	1000	How far from the index price, in basis points, an order may trade: the server refuses a limit price outside it and a market order stops at its edge.
`bastion.limit.per-transfer`, `bastion.limit.daily`	500000, 1000000	Transfer limits.
`bastion.payee.cooloff-hours`, `bastion.payee.cooloff-limit`	24, 10000	How long a new payee cools off and what it can receive meanwhile.
`bastion.address.cooloff-hours`	24	How long a new coin address waits.
`bastion.crypto.limit.per-withdrawal`, `bastion.crypto.limit.daily`	1000000, 2000000	Coin withdrawal limits, in dollar cents at the index price.
`bastion.exchange.taker-fee-bps`	20	The taker fee in basis points.
`bastion.markets`	BTC-USD and ETH-USD	The markets, as `id:base:quote:lot:index` entries.
`bastion.approval.threshold-usd-cents`	100000	Adjustments and reversals worth more than this, in dollar cents, need a second administrator.
`bastion.demo.history-days`	42	Days of demo history the development profile posts; above 35 the first four weeks are closed.
`bastion.market-maker.enabled`	`true` (development only)	The random-walk market maker.

In the app, `AppConfig.java` holds the address a release talks to, `RELEASE_SERVER`, the development server the simulator talks to, `ALLOWED_HOSTS` and the certificate `PINS`. The pins in the sample are placeholders, and the Security Center warns about them until they're the SHA-256 digests of the real server's public keys.

62.12. The API

Every endpoint but registration and sign-in needs a bearer token. **Signed** marks the calls that also need the `Bastion-Signature` header; **Idempotent** marks those that take an `Idempotency-Key`.

Endpoint	What it does	Needs
`POST /api/account/register`	Opens an account.	Rate limited
`GET /api/me`	The signed-in customer.	
`POST /api/account/password`	Changes the password and ends every other sign-in.	The current password, held to the lockout
`POST /api/account/mfa/totp`, `… /totp/confirm`	Starts and confirms the authenticator app.	
`POST /api/account/mfa/recovery-codes`	New recovery codes.	
`GET /api/account/passkeys`, `POST …/{id}/remove`	Lists and removes passkeys.	Removing: signed by a device, or the password in the body
`GET /api/assets`	The currencies and coins and their decimals.	
`GET, POST /api/accounts`	Lists and opens accounts.	
`GET /api/accounts/{id}/postings`	An account's history.	
`POST /api/transfers`	Moves money.	Signed, idempotent
`POST /api/accounts/{id}/deposit`	The demo deposit.	Idempotent
`POST /api/accounts/{id}/withdraw`	A withdrawal to the outside.	Signed, idempotent
`GET, POST, PUT, DELETE /api/payees[/{id}]`	Lists, adds, renames and removes payees.	Adding, renaming, removing: signed
`GET /api/cards`, `POST /api/accounts/{id}/card`	Lists and issues cards.	Issuing: signed by a trusted device
`POST /api/cards/{id}/freeze`, `… /unfreeze`, `PUT …/limit`	Freezes, unfreezes and limits a card.	Unfreezing and raising the limit: signed by a trusted device

Endpoint	What it does	Needs
`POST /api/cards/{id}/spend`	The demo card spend.	Idempotent
`GET, POST /api/devices`	Lists and registers device keys.	Registering: recent sign-in
`POST /api/devices/{id}/revoke`	Removes a device key.	Signed by a device, or the password in the body
`GET /api/exchange/markets, …/{id}/book, … /{id}/ticker`	Markets, order book and ticker.	
`POST, GET, DELETE /api/exchange/orders[/{id}]`	Places, lists and cancels orders.	Placing: signed by a trusted device, idempotent
`GET /api/exchange/trades`	The customer’s trades.	
`GET, POST, DELETE /api/crypto/addresses[/{id}]`	The coin address allow-list.	Adding and removing: signed
`POST /api/accounts/{id}/crypto-withdraw`	Sends coins to an allowed address.	Signed, idempotent
`GET /api/accounts/{id}/balance-history?days, GET /api/insights/cashflow?asset&days, GET /api/insights/allocation`	Chart data over the customer’s own accounts.	
`GET /api/exchange/markets/{id}/candles?interval&limit`	Price candles from the trade tape.	
`GET /api/books/chart, … /journal, …/journal/{id}, …/ledger?code&asset, … /accounts/{id}/t-account`	The chart of accounts, the journal, the general ledger and a T-account.	Administrator or auditor, audited
`GET /api/books/trial-balance?asOf, …/balance-sheet?asOf, …/income-statement?from&to`	The statements, per asset and in dollars.	Administrator or auditor, audited
`GET /api/books/reconciliation, …/periods, …/volume?days`	Reconciliation breaks, closed periods, trading volume.	Administrator or auditor
`GET /api/audit/chain, … /events?after&limit, … /trail?subject, …/access-log`	The chain report, the events, one entity’s trail, and the staff reads.	Administrator or auditor
`GET /api/audit/evidence/{name}?format&asOf`	Exports `journal`, `trial-balance` or `audit-chain` as `csv` or `json`.	Administrator or auditor, audited

Endpoint	What it does	Needs
`POST /api/admin/periods/close`	Closes the books through a time.	Administrator, password
`POST /api/admin/adjustments`, `POST /api/admin/journal/{id}/reverse`	A manual adjustment or a reversal.	Administrator, password, idempotent; a second administrator above the threshold
`GET /api/admin/approvals`, `POST …/{id}/approve`, `…/{id}/reject`	The pending approvals and the second administrator's decision.	Administrator, password, not the maker
`GET /api/admin/audit/verify`, `GET /api/admin/ledger/verify`	The administrator's checks.	Administrator

The contracts are the interfaces in `shared/…/api`; the app calls them through the generated `@RestClient` implementations, so a changed path is a compile error on both sides.

62.13. Threat model

Bastion is built against these, the likeliest first:

Threat	What stops it	Where
Stolen or guessed passwords	A second factor or a passkey, a password that stops being a way in once a passkey is enrolled, a lockout per account, rate limits per address, and a password minimum checked on the server.	`SecurityConfig.java`, `account/SignInGuard.java`
A stolen session	Five-minute access tokens; a password change ends every other sign-in; money leaving the account, and every order, also needs a device signature, so a token alone moves nothing out; the step-ups that ask for the password again are held to the sign-in lockout.	`account/Grants.java`, `money/RequestSigning.java`
Account takeover that adds a mule	A new payee or address cools off for a day with a small limit, and adding one is signed by the device.	`money/Payees.java`, `exchange/CryptoWallets.java`
A tampered or replayed request	The signature covers the body and the path; each nonce is accepted once within a short time window.	`money/RequestSigning.java`
An attacker in the network path	No cleartext, a host allow-list and certificate pins in the app; HSTS on the server.	`net/Guard.java`, `SecurityConfig.java`

Threat	What stops it	Where
A lost or stolen phone	The app lock, keys sealed under an app key that only a biometric or PIN opens (five wrong PINs erase the keys, and the count is kept in the OS secure store beside the PIN's pepper rather than in a preferences file a copy of the phone's storage could reset), removal of the device from another sign-in, and secure windows that keep balances out of screenshots and the app switcher.	`security/Lock.java`, `security/Keys.java`, `security/Protect.java`
A rooted device or a repackaged app	Root and jailbreak signals, platform attestation, and code hardening in a cloud build. None is proof; the server treats them as signals that decide whether a device is trusted.	`money/Devices.java`, `codenameone_settings.properties`
A careless or malicious insider	The audit chain makes changing history detectable, the ledger check makes a wrong balance detectable, and no request creates an administrator.	`audit/Audit.java`, `admin/AdminEndpoint.java`
Races and retries	Conditional balance updates, ordered locks and idempotency keys keep money exact under concurrent and repeated requests.	`ledger/Ledger.java`

Out of scope for the sample: a compromised server or database host, an attacker who can read the device's memory while it's unlocked, and denial of service beyond the rate limits.

62.14. Tests

```
cd scripts/bastion
# The server's tests on the JVM, then compiled to a native binary
mvn -Dcodename1.platform=backend -pl shared,backend test -Dcn1.backend.compiledTests=true
# The same tests on PostgreSQL or MySQL
CN1_TEST_DATABASE_URL="postgres://user:password@localhost:5432/db?sslmode=disable" \
  ../ci/sample-server-tests-on-database.sh .
# The app's own tests, which run headless as part of the build
mvn -Dcodename1.platform=javase -Djava.awt.headless=true package
# A running server, driven over HTTP the way the app drives it
./run-e2e.sh
./run-e2e.sh --native
# The app in a headless browser, served by the server
./run-web-e2e.sh
# The same, then every screen in the user's guide, into docs/developer-guide/img
./run-web-e2e.sh --guide
```

The server's tests cover the ledger's invariants under concurrent transfers and trades, idempotency, sign-in with each factor, the access rules of every endpoint, signing and replay, the device policy,

limits and cooling-off, the matching engine and its rounding, and the audit chain's detection of a changed row. `run-e2e.sh` registers two customers, enrols an authenticator and signs in with it, registers device keys, makes a signed payment and checks that the unsigned and replayed copies are refused, fills an order between the two, and checks that a withdrawal is refused until its address is allowed and cooled off. `run-web-e2e.sh` does it in a headless browser, through the app's own screens: it opens an account, turns on the authenticator app, creates a passkey, signs in again with the password and a code and checks that the server refuses the code because the account has a passkey, signs in with the passkey instead, moves money between two accounts, then signs in with the passkey alone and registers the browser as a device without the password. With `--guide` it runs the server on the development profile with the device policy off, then signs in as the demo customer and the administrator and photographs each screen; run it after changing a screen so the user's guide stays true.

62.15. Making it yours

- **Name, icon and colors.** The name and package come from the Initializr, the icon is `common/icon.png`, and the colors are the variables at the top of `common/src/main/css/theme.css`, with a dark set below them.
- **Server address and pins.** Set `AppConfig.RELEASE_SERVER` to your API's `https` address, `AppConfig.ALLOWED_HOSTS` to its host and `AppConfig.PINS` to its key digests before the first release build.
- **Languages.** The bundles are in `common/src/main/l10n`; `BundleTest` checks that every bundle has every key and every server refusal code.
- **Markets and assets.** `bastion.markets` lists the markets; the assets are rows in the ledger's migrations (`V2__ledger.sql`), served to the app by `/api/assets`.
- **Limits.** Every limit and cooling-off period is a setting in the table above.

62.16. On a real chain

With `bastion.chain.rpc-url` set, ether is real: deposits arrive at an address of the customer's own, withdrawals are signed and broadcast, and the ledger follows the chain. Left empty, ether is a ledger balance like the other coins. The code is in `backend/⋯/chain`, and each piece follows a published standard, checked against known answers in `ChainVectorTest`:

Piece	What it does
`EvmTransaction`	Encodes and signs type-2 transactions (EIP-1559), with a chain id so a signature can't be replayed on another network (EIP-155). It's part of the framework's `com.codename1.crypto.evm` package.
`Secp256k1`	secp256k1 signatures with deterministic nonces (RFC 6979) and low-S values, from the Codename One security API.
`Wallet`, `DerivationPath`, `SeedSigner`	Derives every key from one seed the way wallets do (BIP-32, BIP-44): deposit address number *n* is `m/44'/60'/0'/0/n`, the hot wallet `m/44'/60'/1'/0/0`. A key is wiped after each signature.

Piece	What it does
`EvmAddress`	Checksummed addresses (EIP-55). A withdrawal address with a wrong checksum is refused when it's added.
`EthRpc`	The framework's `EvmRpc` over the backend's web client: JSON-RPC to a node over HTTPS (plain HTTP only to the local host), with the bank's own rules on what it may send.
`Chain`	Scans blocks, credits deposits, signs, broadcasts and settles transfers, sweeps deposits into the hot wallet, and checks reserves.

How the money stays right:

- **Confirmations and reorganizations.** A block is read only once it's `bastion.chain.confirmations` deep, and each block's parent must be the block read before it. If it isn't, the chain reorganized deeper than the setting allows: scanning stops, an audit event is written, and nothing more is credited until someone looks. Only transactions whose receipt reports success are credited.
- **Exactly once.** A deposit is posted under the key `chain:in:<transaction>`, so reading a block twice credits it once. Every transfer moves between states by a conditional update, and one instance at a time holds a lease on the chain, so two servers or two overlapping ticks can't sign the same withdrawal twice.
- **Nonces.** A withdrawal takes the larger of the node's pending nonce and the highest nonce the database has used, plus one. A transaction that's dropped is broadcast again after `bastion.chain.rebroadcast-seconds`, unchanged, so it can only ever land once.
- **Withdrawals in transit.** A withdrawal moves the coins to the liability account 2300 when it's requested. A confirmed one moves them out to the chain; a failed one returns them to the customer. The network fee is posted to the expense account 5200 at what the receipt says was spent.
- **Rounding toward the bank.** The ledger counts ether in gwei. Deposits round down and fees round up, so the ledger never claims coins the chain doesn't hold.
- **Reserves.** Before signing a withdrawal, the server adds up what it owes (every customer's ether plus what's in transit) and what it holds on the chain. If it holds less, or the hot wallet can't pay the amount and the worst-case fee, the withdrawal waits, says why, and an audit event `CHAIN_RESERVES_SHORT` is written. Coins the demo data would mint aren't minted for a coin on a real chain.
- **A float for fees.** Sweeps and withdrawals pay the network out of the bank's own coins, while the customer is still owed the full deposit. Until the hot wallet holds a float of the bank's own, the first sweep leaves custody short by its fee and the reserves check holds every withdrawal. Fund the hot wallet before opening deposits, and alert when the float runs low.
- **The wrong network.** At startup the node's chain id must match `bastion.chain.id`, or the server refuses to start rather than sign for another network.

The console's custody report (`/api/books/custody`) shows the hot wallet, what's on the chain, what's owed and what's in transit.

Setting	Default	Meaning
`bastion.chain.rpc-url`	empty	The node. Empty turns the chain off.
`bastion.chain.id`	11155111 (Sepolia)	The network the node must be on.
`bastion.chain.confirmations`	12	How deep a block must be before it's read.
`bastion.chain.seed`	none	64 hex digits of seed. Keep it in a secret store, and in production replace `SeedSigner` altogether.
`bastion.chain.rebroadcast-seconds`	300	When a transaction that hasn't landed is sent again.
`bastion.chain.sweep-minimum-gwei`	1000000	The smallest deposit balance worth a sweep's fee.
`bastion.chain.period-ms`	15000	How often the chain is read.

`run-chain-test.sh` checks the whole path against a local development node in a container: a deposit is credited after its confirmations and swept, a withdrawal arrives on the chain to the wei, the ledger and custody agree, and the reserves check holds a withdrawal the chain can't back. To try it on a public test network, point `bastion.chain.rpc-url` at a Sepolia node, set the seed, and fund the deposit address the app shows from a faucet.

What the chain code doesn't do yet: tokens (ERC-20 transfers are calls into a contract and need their own scan of the transfer logs), deposits sent by a contract rather than in a plain transaction, more than one withdrawal in flight per nonce at a time, and a fee policy beyond twice the base fee plus the node's suggested tip.

62.17. Security checklist

Work through this before a release. The first list is what the sample already does; keep each item true as you change it. The second is what a product has to add.

Already in place, keep it so:

- ▢ Passwords hashed with an adaptive hash, a minimum checked on the server, and a lockout per account with rate limits per address and per user.
- ▢ A second factor or passkey for every sign-in that registers a device, and for every staff session that reaches the console.
- ▢ Short-lived access tokens; a password change ends every other session.
- ▢ Money leaving an account, every order and every new payee or address signed by a registered device key, over the body, the path and a single-use nonce.
- ▢ New payees and addresses cool off, with a daily cap on how many are added; removing one and adding it again doesn't restart the clock.
- ▢ Every balance change is a balanced ledger entry under an idempotency key, with conditional updates and ordered locks.
- ▢ The audit log is hash-chained, and the ledger and audit checks run and alert.

- ▢ The server refuses to start outside development with default token keys, encryption keys or passkey origins.
- ▢ No cleartext, a host allow-list and certificate pins in the app; HSTS on the server; forwarded addresses trusted only from configured proxies.
- ▢ Keys on the device sealed by the OS and opened by a biometric or PIN; the app locks in the background and keeps balances out of screenshots.
- ▢ Withdrawal addresses validated by their checksum; chain transfers only after confirmations, with the reserves check on.

A product adds:

- ▢ Server keys, the authenticator-sealing key and chain keys in an HSM or key service; cold storage for most reserves, with signing that needs more than one person.
- ▢ `bastion.appattest.app-id` set so iPhones are attested by Apple, a Play Integrity verifier for Android, and a policy for what an unattested device may do.
- ▢ The audit head published at intervals to storage the database's administrators can't write.
- ▢ Identity verification, sanctions screening and transaction monitoring, and the reports the law asks for.
- ▢ A web application firewall and a proxy in front of the server, with `cn1.server.trustedProxies` set to it.
- ▢ Monitoring and alerting on sign-in failures, refused signatures, reserve shortfalls, reorganizations and the ledger check, with an incident response plan that's been rehearsed.
- ▢ Encrypted backups that have been restored in a test, and a plan for the loss of a region.
- ▢ A support console with its own second factor, least privilege and audit.
- ▢ Dependencies and build tools kept current; release builds from a clean machine with code hardening on, and their signing keys off developer machines.
- ▢ A penetration test and a code review by someone outside the team, before launch and after major changes.
- ▢ The certifications your market expects, such as PCI DSS for cards, SOC 2, strong customer authentication rules, and data protection law for personal data and its deletion.

62.18. Before it's a product

The sample is complete as a demonstration and stops where a real bank's own systems begin. A product needs at least:

- **Identity verification.** Opening an account takes an e-mail and a password. A bank verifies who the customer is (know your customer) through a vendor, screens them against sanctions lists, and keeps the evidence.
- **Payment rails and core banking.** Deposits are a counter and transfers stay inside the sample's ledger. Real money arrives and leaves through card networks, bank transfers and instant payment schemes, and a bank's core banking system is usually the ledger of record, which this ledger would then mirror or replace.

- **Keys in a hardware security module.** The server's token-signing key, the key that seals authenticator secrets, and any card or custody keys belong in an HSM or a cloud key service, never in the server's configuration.
- **Keys out of the server for ether.** The chain code in Section 62.16, "On a real chain" works on a real network, but `SeedSigner` derives its keys from a seed in the server's settings. A product binds `ChainSigner` to a key service or an HSM, and moves most reserves to cold storage that needs people to sign.
- **Bitcoin.** Only ether settles on a chain. Bitcoin stays a ledger balance until it gets an adapter of its own.
- **A real integrity check on Android.** `AppAttestVerifier` checks an iPhone's attestation against Apple's root, but `SimulatedIntegrityVerifier` still believes an Android device. Production sends the Play Integrity token to Google's `decodeIntegrityToken` with the project's service account. A product also sends App Attest receipts to Apple's fraud metric service, and checks the signed assertions a device sends after it's registered.
- **A real market.** The market maker is a development-only random walk. A product takes its prices from a market data provider and its liquidity from real counterparties, and runs the exchange's own surveillance.
- **Regulatory reporting.** Suspicious activity reports, transaction reporting, statements and tax documents, and records kept for as long as the law asks.
- **Audit anchoring off the database.** The audit chain shows that history was changed, but whoever controls the database can rewrite the whole chain. Publishing the chain's head at intervals to a store the database's administrators can't write, such as write-once storage or a timestamping service, closes that.
- **Reviewed translations.** The non-English bundles are machine translations; have them reviewed before release.
- **A PIN checked off the device.** The attempt counter is in the OS secure store beside the pepper, so restoring the app's files doesn't reset it, and the pepper keeps a copy of those files from being tried offline. Both still sit on the device: someone who controls the OS store controls the counter too. A product that must hold against that checks the PIN on the server or in a secure element.
- **Biometric-bound keys on the web and desktop.** Only iOS and Android bind a key to a biometric in the OS. In a browser and on the desktop the lock offers the PIN, and the Security Center says so.
- **Your own origin for passkeys.** A deployment sets `bastion.webauthn.rp-id` and `bastion.webauthn.origins` to its own domain, and adds the Android app's `android:apk-key-hash:` origin and the iOS app's associated domain.
- **Operations.** Monitoring and alerting on the audit and ledger checks, fraud scoring on transfers, a support console with its own access controls and audit, backups and disaster recovery, and penetration testing.

Chapter 63. Pulse: A fitness studio app from every side

Pulse is a sample app with a server behind it, for a gym or a studio that runs classes. Members book classes for themselves and their children, open the door with their phone, pay for a membership and train with their friends. Trainers run their classes, the front desk lets people in, and the owner reads the numbers and fills the quiet classes. The app and the server are one Maven project, written in Java on both sides.

This chapter is the user's guide: what each kind of user sees and can do. Chapter 64, *Pulse: Building on the sample* is the other half. It explains how the project is built and what to change to make it yours.

One app serves everyone. The server gives every account a set of roles, and the app offers a mode for each role the account holds. Someone who holds more than one switches between them from the menu.

Role	What it adds
Member	Every account is a member. Book classes for yourself and your household, show the door pass, manage the membership, say when you're away, see your visits and workouts, and keep up with friends.
Trainer	Granted by the owner. See the week's classes and who's coming, mark attendance, follow heart rate zones live in class, and swap shifts.
Front desk	Granted by the owner. Check people in by pass, fob or name, take walk-ins, and read the day at a location. A tablet signed in as the desk runs as the kiosk by the door.
Owner	Runs the studio: the dashboard, plans, the timetable, staff, campaigns and accounts.

63.1. Trying it

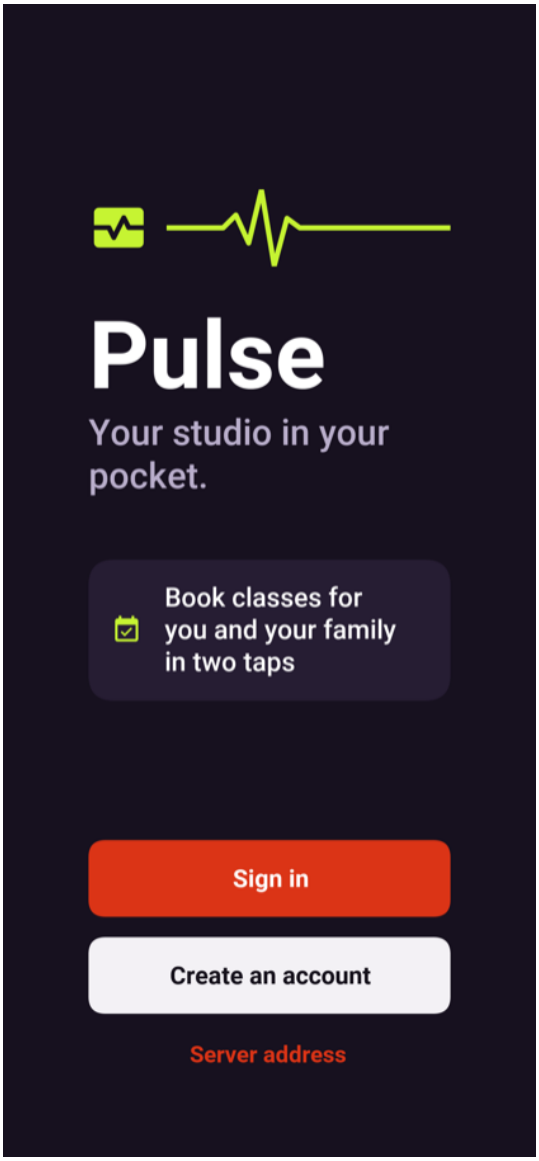
Start the server on the development profile. It needs nothing installed: the database is in memory, text messages and push notifications are printed on the console, and cards are simulated.

```
cd scripts/pulse
CN1_PROFILE=dev backend/server.sh run
```

Then run the app in the simulator, from another terminal:

```
cd scripts/pulse
mvn verify -Psimulator -DskipTests -Dcodename1.platform=javase
```

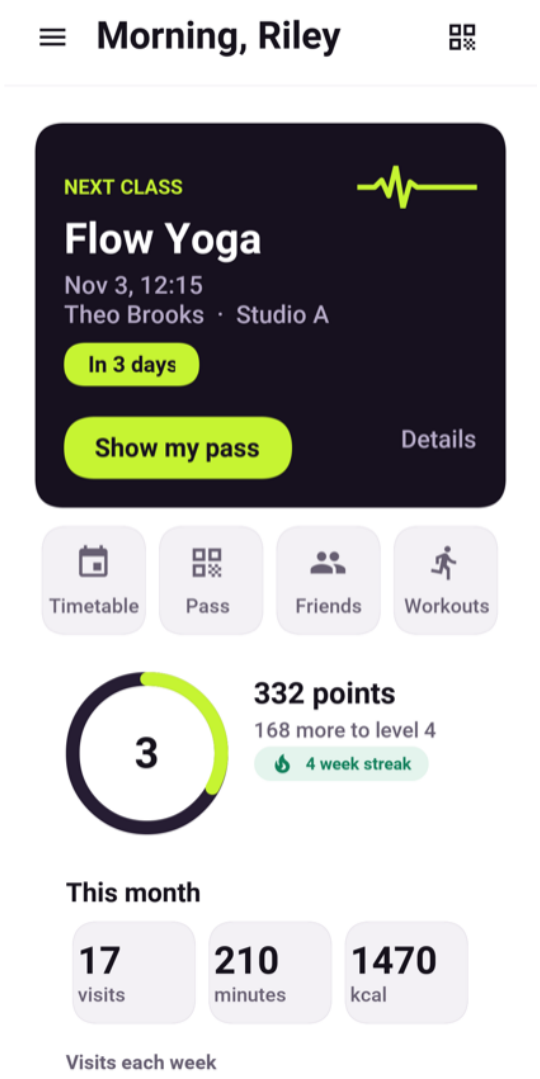
The development profile seeds a studio with two locations, a timetable of adult and children's



classes from three weeks back to three weeks ahead, the plans on sale, and a few weeks of bookings, visits and paid invoices, so every screen has something to show. Every demo account has the password `pulse-demo`:

Account	Who
`member@pulse.example`	A member with two children in the household and a card on file.
`member2@pulse.example`	A new member: no household and no card.
`member3@pulse.example`	A member the owner has flagged.
`member4@pulse.example`	A member who hasn't been in for weeks.
`trainer@pulse.example`, `trainer2@pulse.example`	Trainers.
`desk@pulse.example`	The front desk and the door kiosk.
`owner@pulse.example`	The owner.

The simulated card `4242 4242 4242 4242` is accepted and `4000 0000 0000 0002` is declined. No money moves.

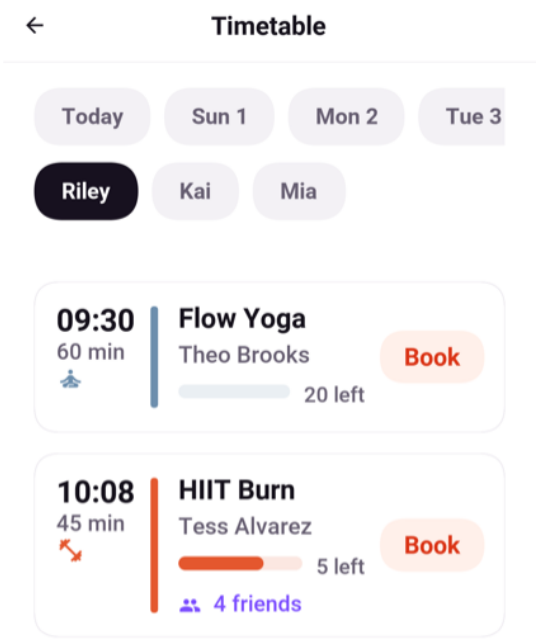


63.2. Getting in

A new member registers with a name, an e-mail address, a password and a phone number, which is confirmed with a code sent by text message. On the development profile the code is printed on the server's console and filled in for you. Before the first booking the app asks the account holder to sign the studio's waiver, for themselves and for each child they add.

63.3. The member

The member’s home leads with the next class booked, with the time, the trainer and the room, and how long until it starts. Under it are this month’s visits, the week streak, the points and level, and the badges.



63.3.1. The timetable and booking

The timetable lists the classes at each location by day, with the places left, which update live as other members book. Pills at the top pick the day and the person in the household, and picking a person shows only the classes open to them. Booking takes a place if one is free and joins the waitlist if not. When someone gives a place back, the first person waiting is moved into the class and told so at once.

A place given back at least 12 hours before the class is free. Later than that it counts as a late cancellation, and a class from a pack is spent. Someone booked who never comes is marked a no-show once the class is over.

A booking is refused when the class has already started, when the person is outside the class’s age range on the day of the class, when the waiver isn’t signed, or when no membership covers the class.

63.3.2. The household

An account holder books for up to eight people: themselves and their children. Each child has their own membership, their own place in a class and their own door pass, but only the account holder signs in. A child's age is worked out from their date of birth on the day of each class, so a child grows into the next age band without anyone changing anything.

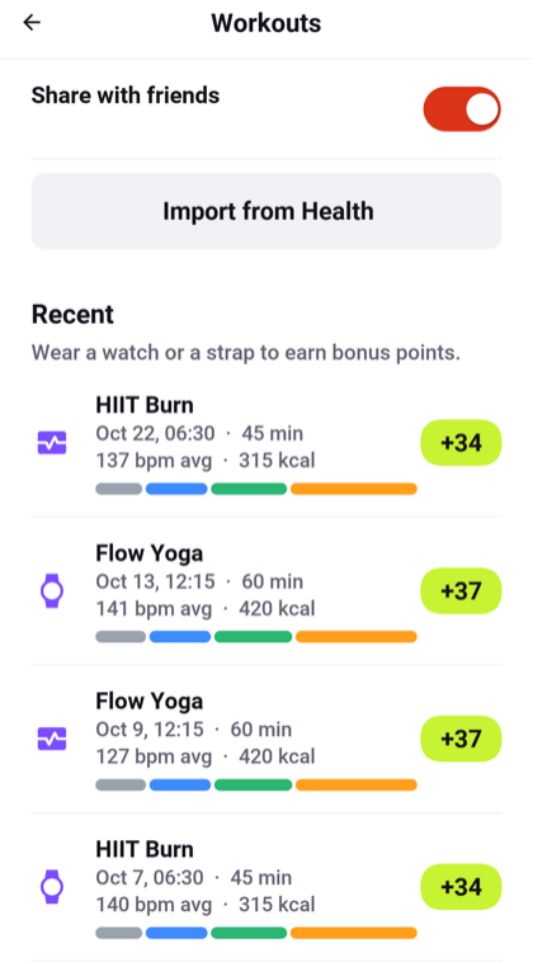
63.3.3. The door pass

The pass is a QR code that changes every 30 seconds. It's computed on the phone, so it works with no signal. A pass is good once: a screenshot shown a second time is refused as already used. A child without a phone gets an NFC fob or wristband instead. If a phone is lost, replacing the pass makes the old codes and the old fob stop opening the door at once.

63.3.4. The membership

The plans on sale are monthly, annual, class packs and drop-ins. Joining takes the first payment; changing plan takes what's left of the old period off the first invoice. A membership can be frozen for one week to three months, and cancelled.

When a renewal is declined the card is tried again after one, three and seven days. The membership stays usable through the first retry; from the second failure it's past due and the door says so; after the last retry the invoice waits to be paid by hand from the wallet. A member who brings a friend gets a credit when the friend first pays.

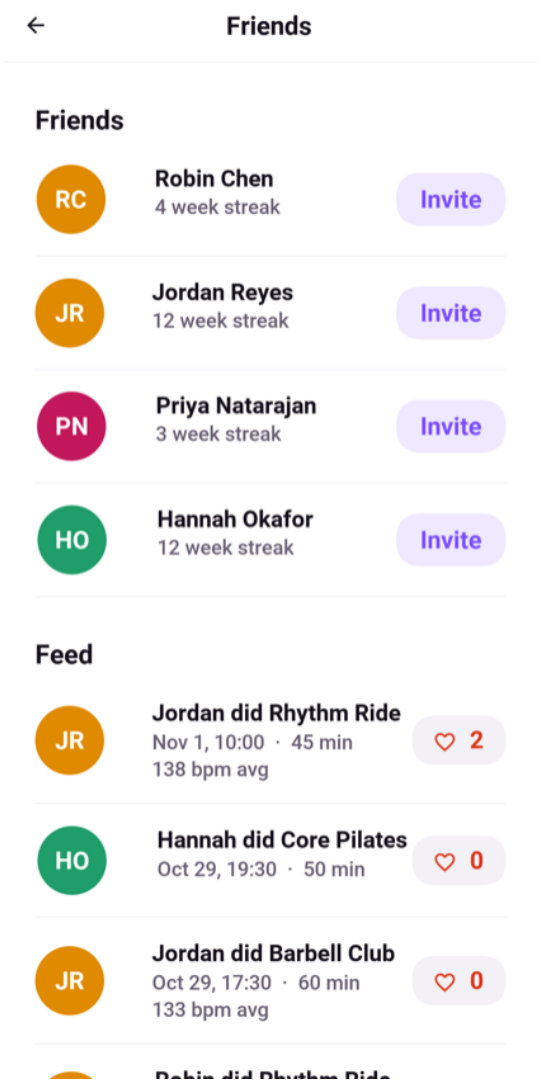


63.3.5. Away periods

A member who is travelling or injured says when they'll be away. No marketing reaches them meanwhile, and they can choose to freeze their billing for the same time.

63.3.6. Visits, workouts and friends

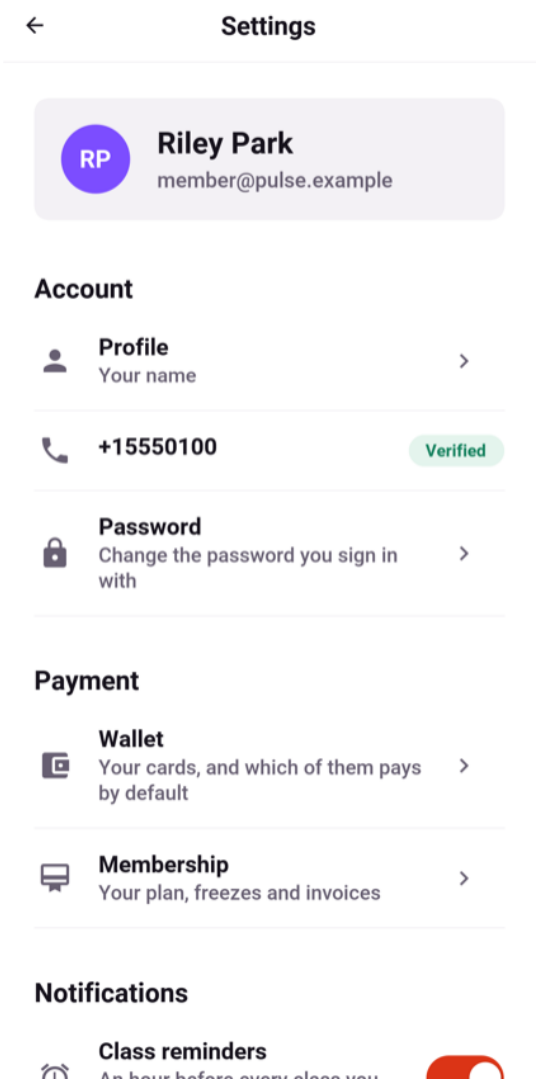
The member's page shows this month's visits, the streak of weeks with a visit, and the last twelve weeks. Workouts recorded by the phone's health store or the watch are kept with their heart rate. A



member can share their heart rate with the trainer during a class.

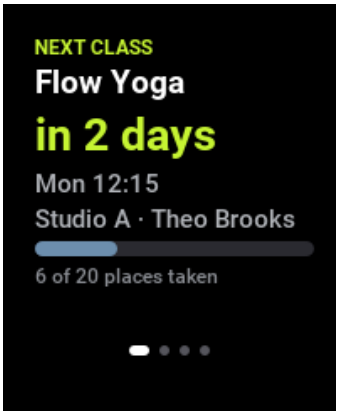
63.3.7. Points, levels and badges

Coming to a class, recording a workout and keeping a weekly streak earn points, and points raise the member’s level. A workout recorded with a heart-rate strap or a watch earns extra points, since it shows how hard the member worked. Badges mark milestones: the first class, ten and fifty classes, a four- and a twelve-week streak, a first workout with heart rate, a class worn with a strap or a watch, a minute in zone 5, and ten hours of workouts. Tapping a badge says how it is earned.



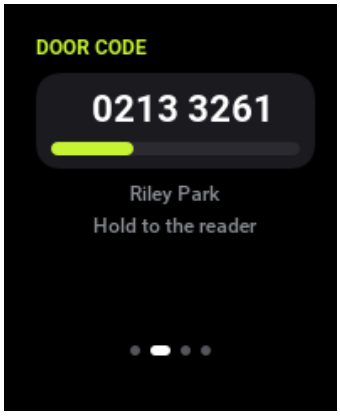
Friends are added by the e-mail they sign in with, and nothing about a member is shown to someone they haven’t accepted. The feed shows friends' visits and the workouts they chose to share, kudos can be given for them, and a friend can be invited to a class.

The timetable shows which friends are booked into each class.

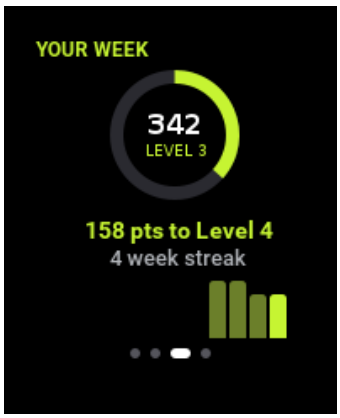


63.3.8. Messages and quiet hours

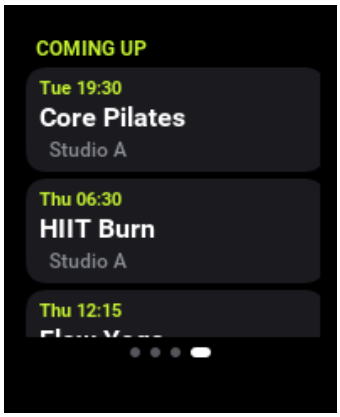
Two kinds of message arrive without anyone sending them: an invitation to a class starting within a day and a half that's still under 60% full, sent to members who have taken that kind of class before, and a reminder that the studio misses them after two weeks without a visit. Neither is sent to a member who is away or who turned promotions off, and neither arrives during quiet hours, which are 10 PM to 7 AM until the member changes them in the settings.



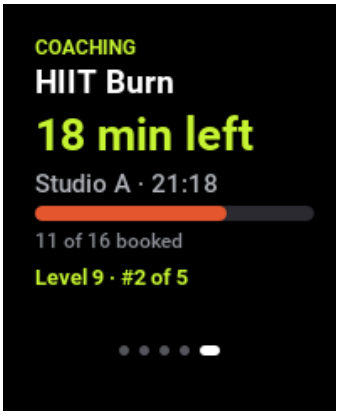
63.3.9. The watch



On a paired watch, Pulse is four pages, swiped sideways, and a fifth for a trainer. The first is the next class: its name, a countdown, the room and the trainer, and a bar of how full it is.

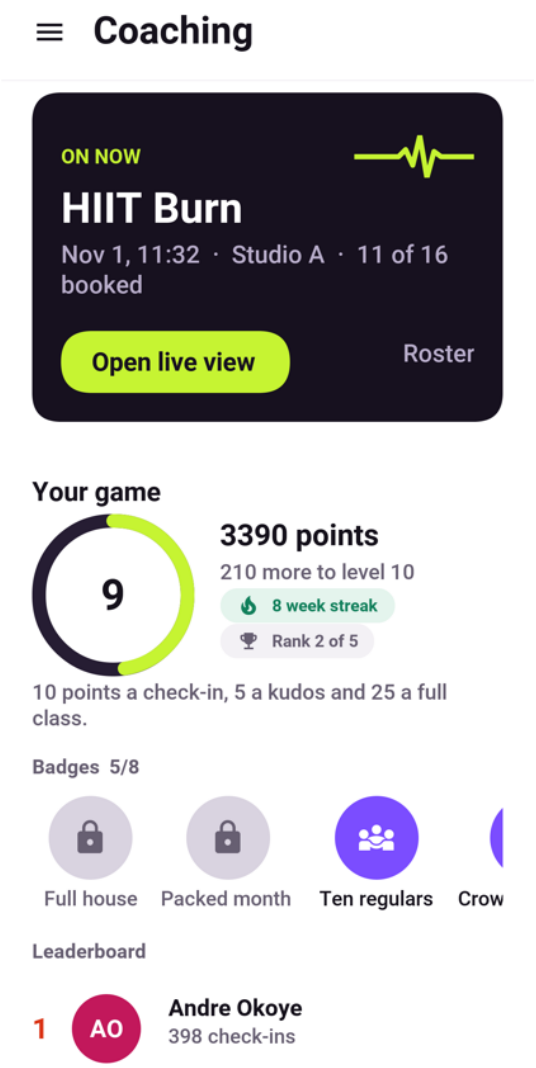


The second is the door code, with a bar counting down to the next one. The code is the same one the phone’s pass shows, so the watch opens the door with the phone left in the locker.

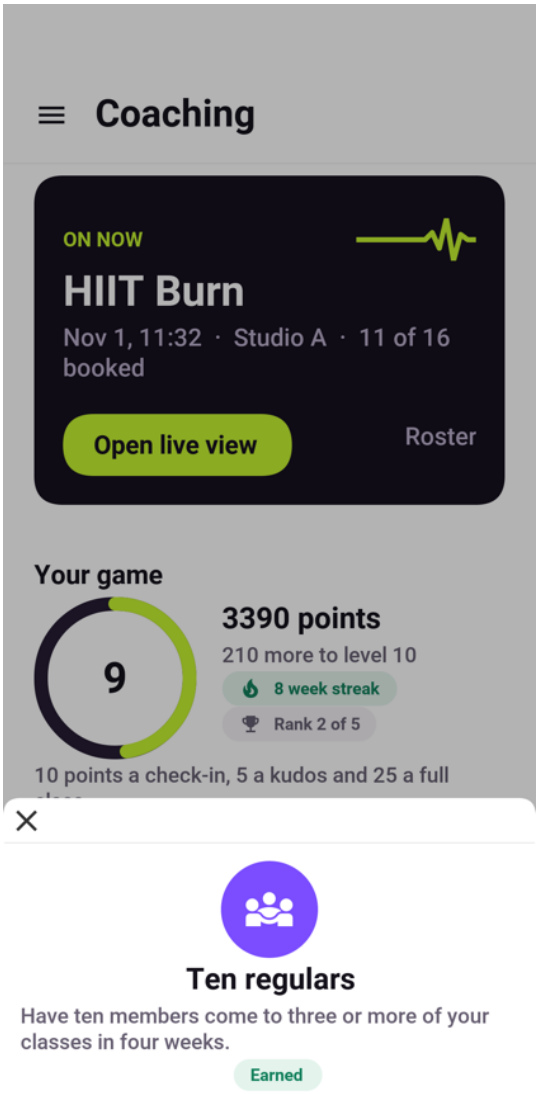


The third is the week: a ring of the points toward the next level, the points still needed, the week streak and the visits of the last eight weeks as bars.

The last lists the classes booked after the next one.

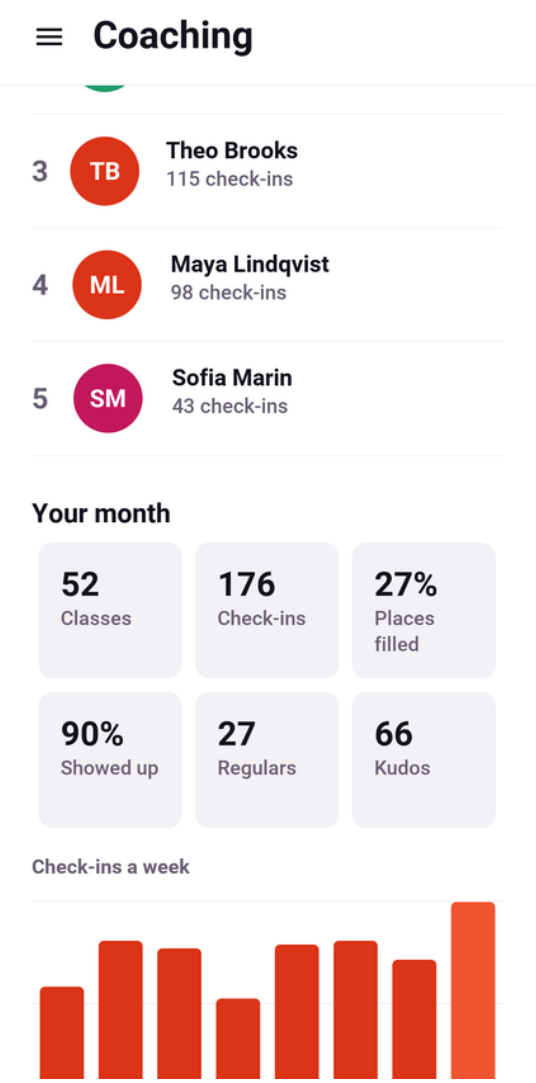


A trainer’s watch adds a coaching page: the class they teach now or next, the minutes until it starts or until it ends, the room and its places taken, and the trainer’s level and place among the studio’s coaches.

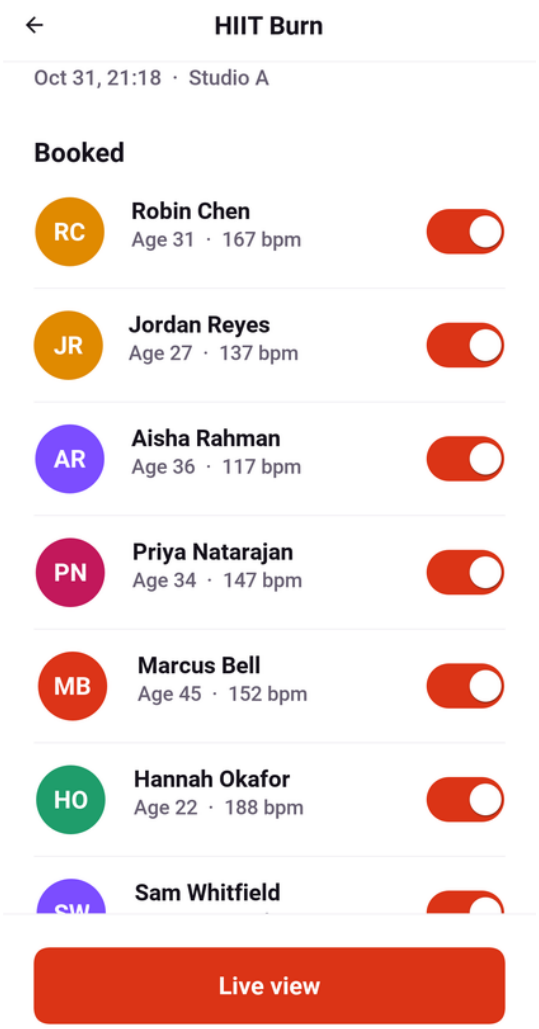


63.4. The trainer

The trainer's home leads with the class on now, or the next one, on a dark card with a button for the live view and one for the roster.

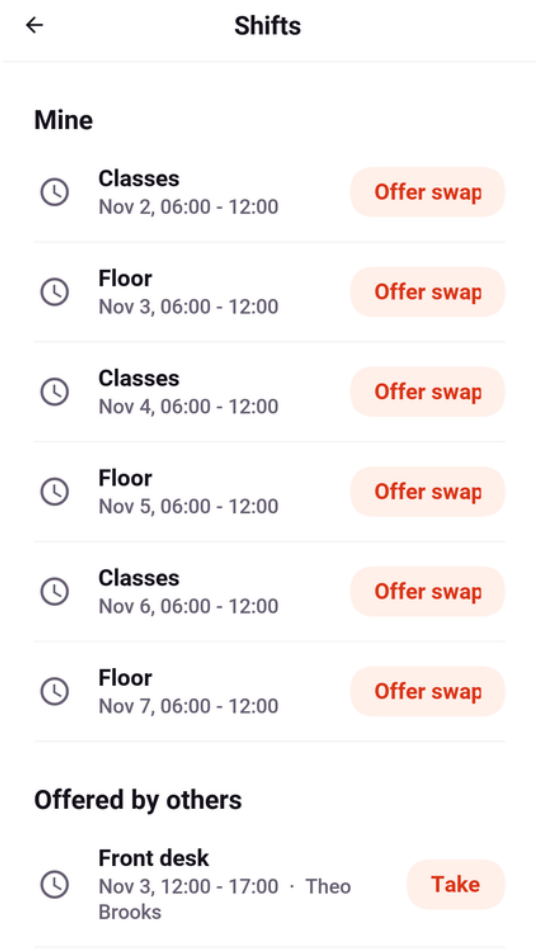


Under the card is the trainer's own game. Members earn points for coming; a trainer earns them for the people they coach: 10 for each check-in to their classes, 5 for each kudos on a workout from them, and 25 for a class with every place booked. The points count over the last eight weeks, so a level reflects how the trainer is coaching now rather than how they once did, and every 400 points is a level. The ring shows the level and the way to the next one, and next to it are the weeks running in which the trainer taught, and their place among the studio's coaches.



The badges reward what a studio needs from a coach: a full class, five full classes in four weeks, ten regulars, 25 kudos, nine in ten booked members turning up, eight weeks of teaching without a gap, a hundred check-ins, and being the studio's top coach. Tapping a badge says how it's earned and whether it is.

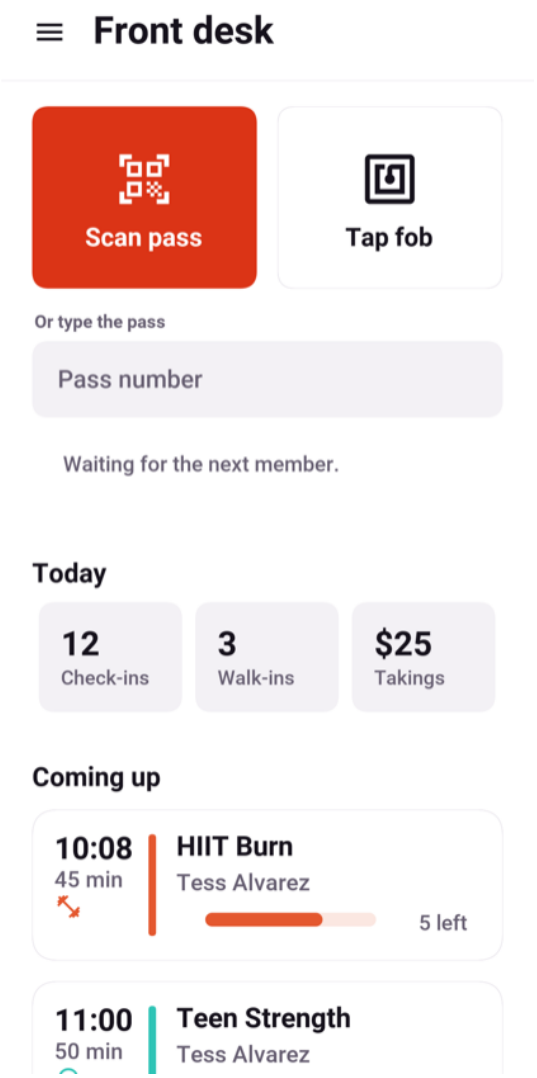
The leaderboard ranks every coach who taught in the last four weeks by the people who came, with the trainer's own row marked. The trainer's month follows: the classes taught, the check-ins, how full the classes were and how many of those booked came, the regulars who came three times or more, and the kudos received. A chart shows the check-ins of each of the last eight weeks, and under it the kinds of class that drew the most people.



The week’s classes follow, a day at a time, each with how many places are taken, and a full class says so. The roster of each class shows the members booked, the ones waiting and the ones who came, with what the trainer needs to know about each person: a first visit, their age, their heart rate, and any medical note. Attendance can be marked by hand for someone the door didn’t see, and corrected for 30 minutes after the class ends.

During a class, members who share their heart rate appear with their current zone, one to five, worked out from their age.

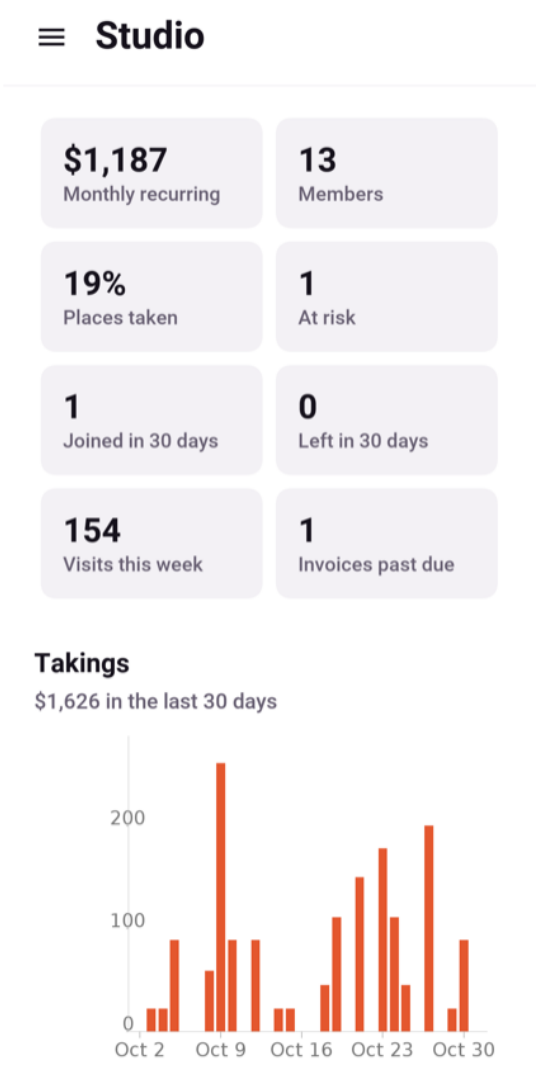
The trainer's shifts list the ones to come. A trainer offers a shift they can't work to the others, withdraws the offer while nobody has taken it, and takes a shift another trainer offered.



63.5. The front desk and the kiosk

The desk checks people in by scanning the pass, reading a fob, or finding the member by name. Every check-in answers: admitted, or refused with the reason to read out, such as a membership that's past due or a class the person isn't booked into. A booking counts for a visit from an hour before its class until 30 minutes after it starts.

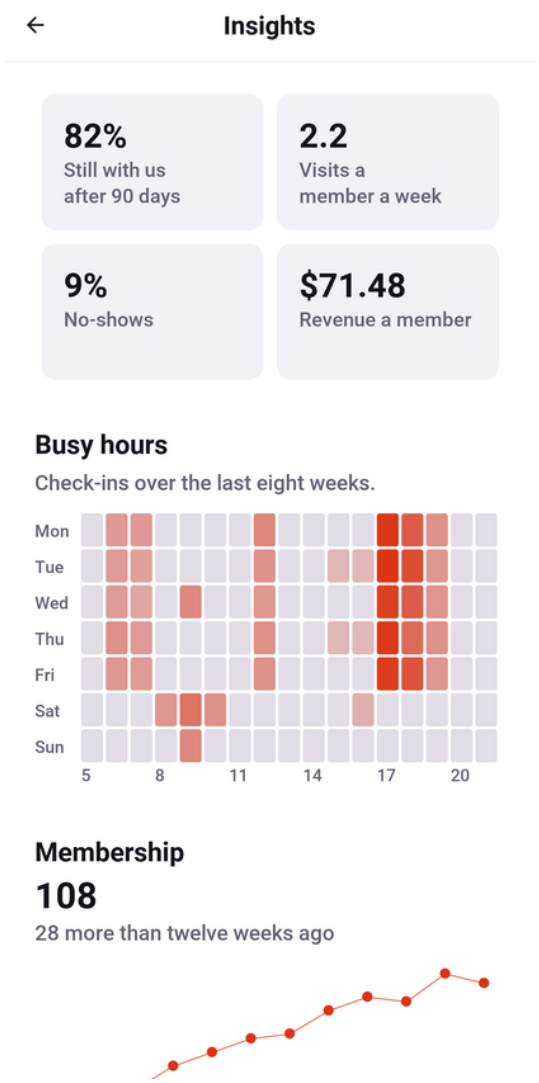
Someone who comes in without a membership is recorded as a walk-in: a guest, a day pass or a free trial, paid in cash, by card or not at all. The owner's campaigns follow up on them.



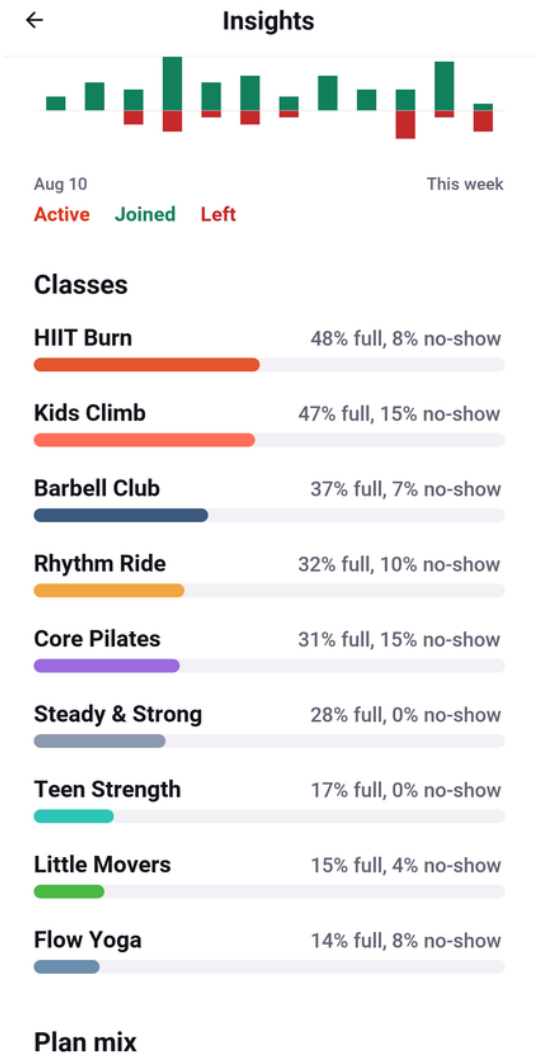
The desk's day shows who came, what was taken and what starts soon. Signed in on a tablet by the door, the desk account runs as the kiosk: a member holds up their pass and the screen turns green or red.

The desk's home opens with two large buttons, one to scan a pass and one to read a fob, and a field to type a pass number. Under them are today's check-ins, walk-ins and takings, the classes coming up, and the people who just came in, admitted or turned away.

63.6. The owner

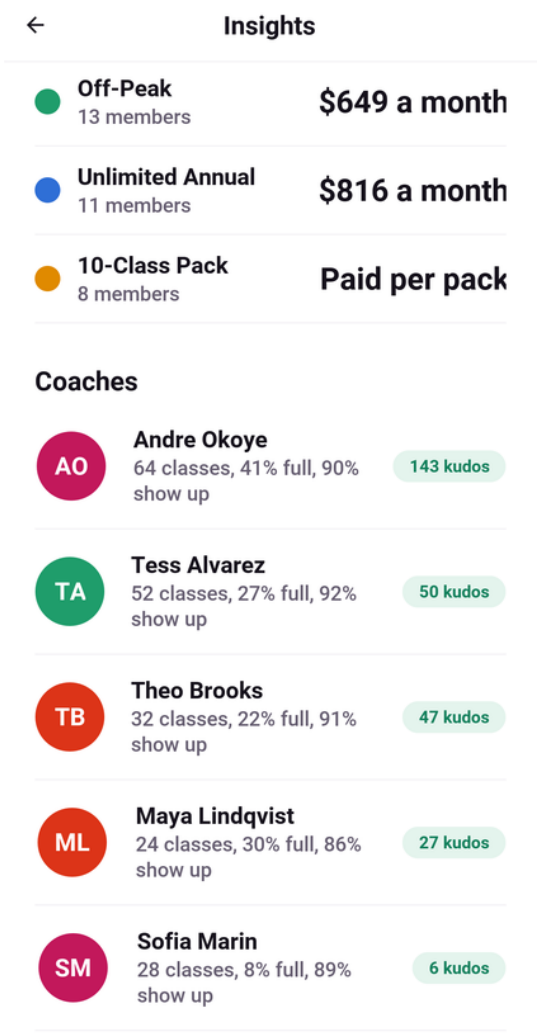


The dashboard opens with the recurring revenue a month, the members, the share of places taken in the last week's classes, and the members who haven't been in for two weeks and didn't say they'd be away. Under them are who joined and who left in the last 30 days, the visits this week and the invoices past due; the takings of each day for the last 30 days; the kinds of class booked most, ranked; and the classes in the next two days that are under half full, each with a button to fill it.



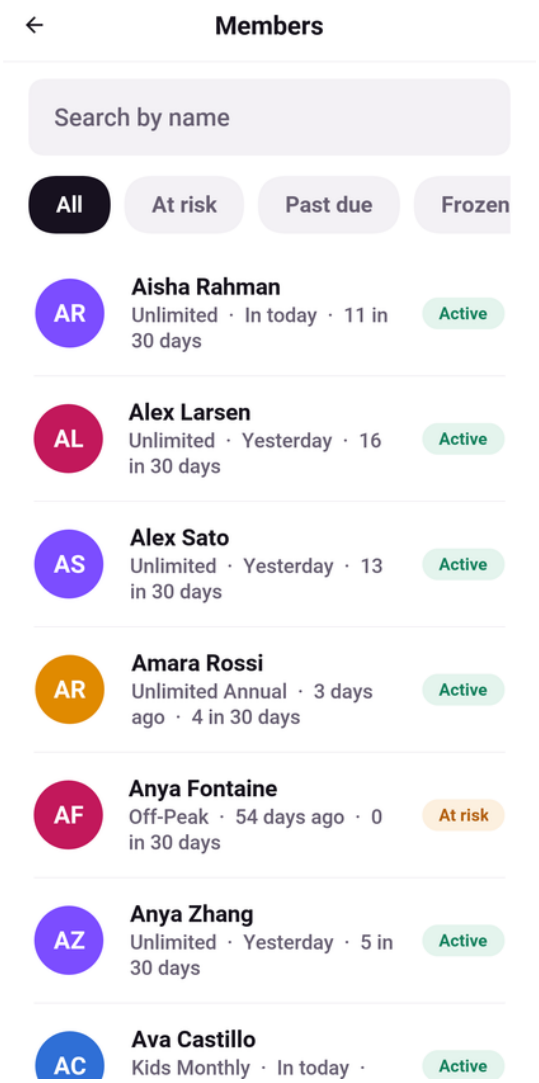
63.6.1. Insights

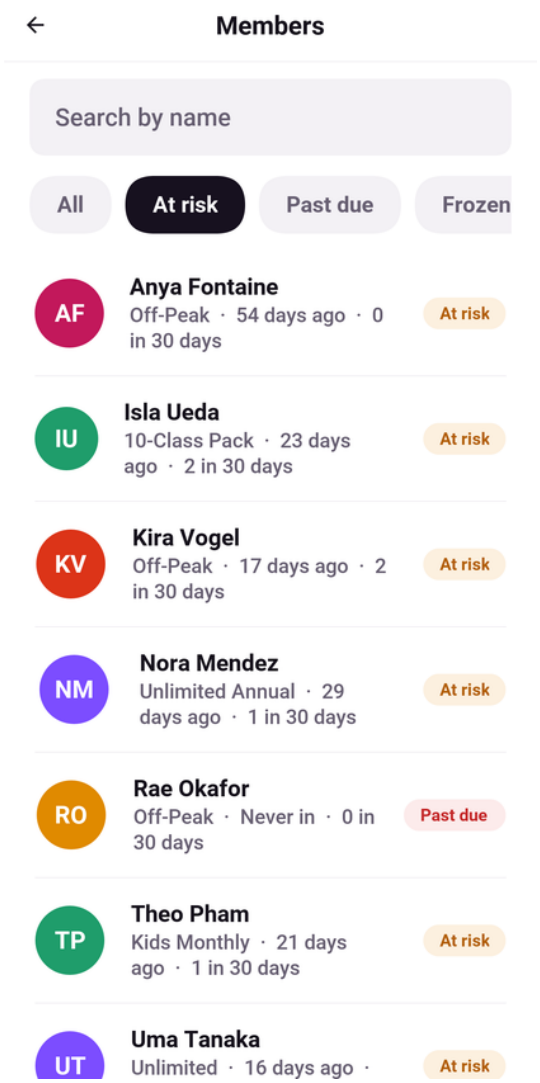
The Insights screen is where the owner looks further back. It opens with four numbers: the share of members who joined 90 days ago or more and are still members, the visits of a member in a week, the share of bookings nobody came to, and the monthly recurring revenue of a member.



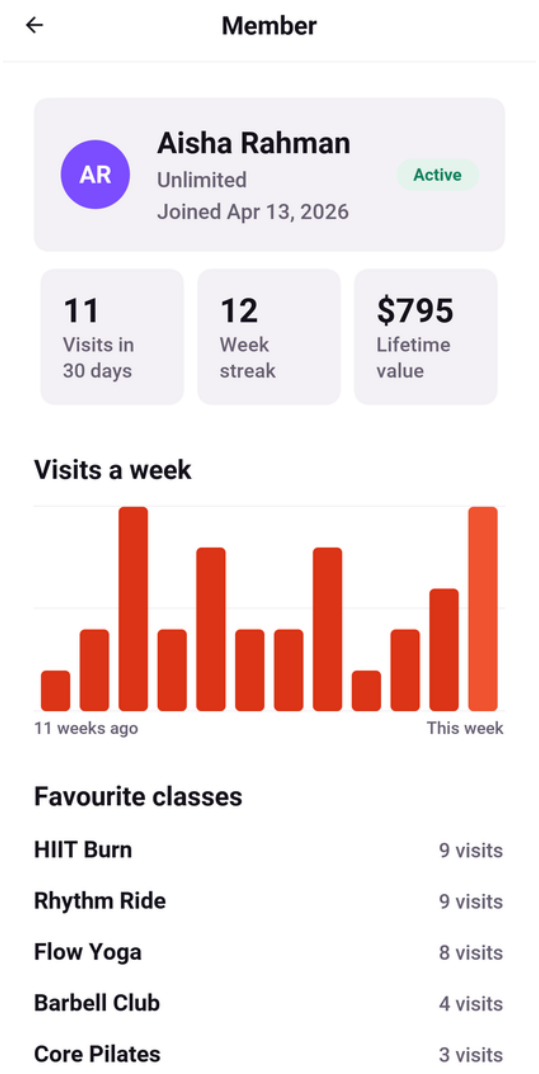
The busy hours are a grid of the days of the week by the hours the studio is open, each cell as dark as the check-ins in that hour over the last eight weeks. Under it, the membership: how many members there are against twelve weeks ago, a line of the active members of each week, and bars of who joined and who left.

The classes are ranked by how full they ran, each with its share of no-shows. The plan mix is a ring of the members on each plan, with what each plan brings in a month; a class pack is paid by the pack, so it says that instead.





The coaches are ranked by their check-ins, each with their classes, how full those were, how many booked came, and their kudos.



63.6.2. Members

The members list searches by name and filters to the members at risk, past due or frozen. Each row shows the plan, the last visit and the visits in 30 days, and a pill that says where the member stands.

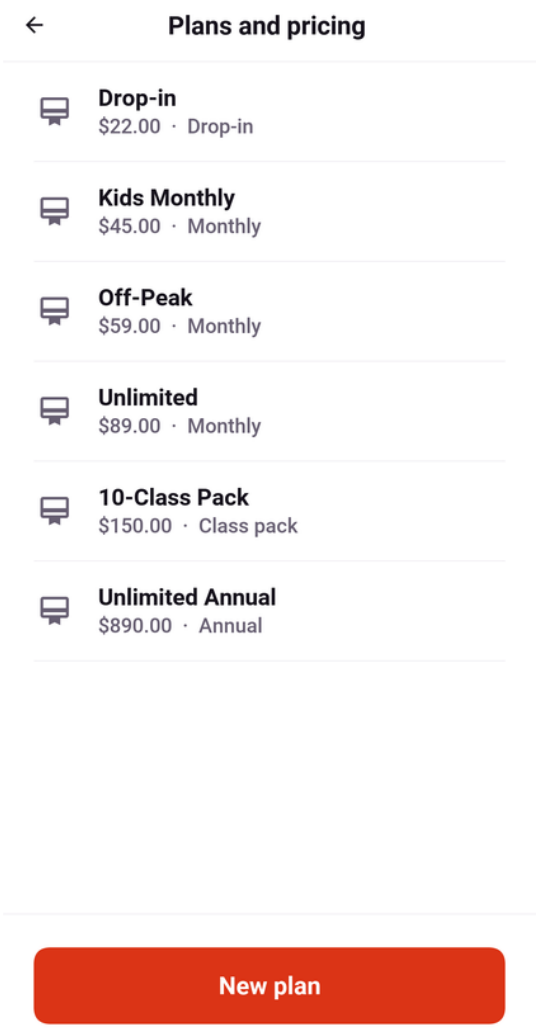
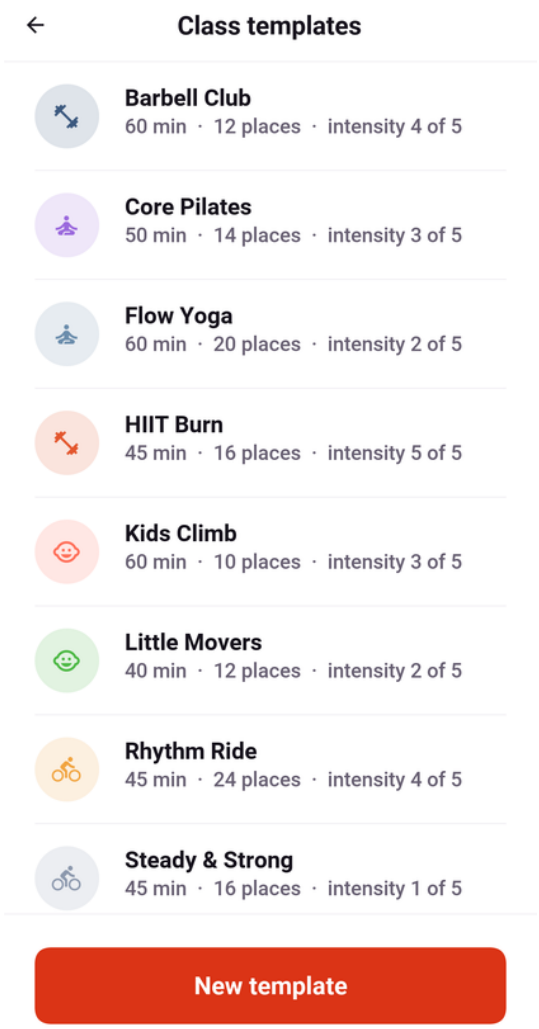
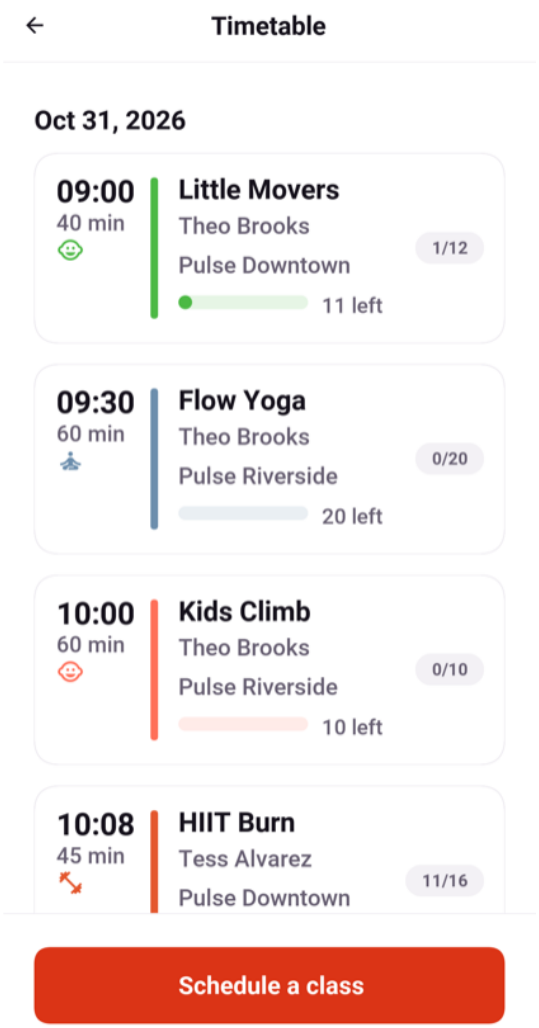
A member’s page has the visits in 30 days, the week streak and what the member has paid in all, a chart of the visits of each of the last twelve weeks, the classes they come to most, and their invoices.



63.6.3. Billing

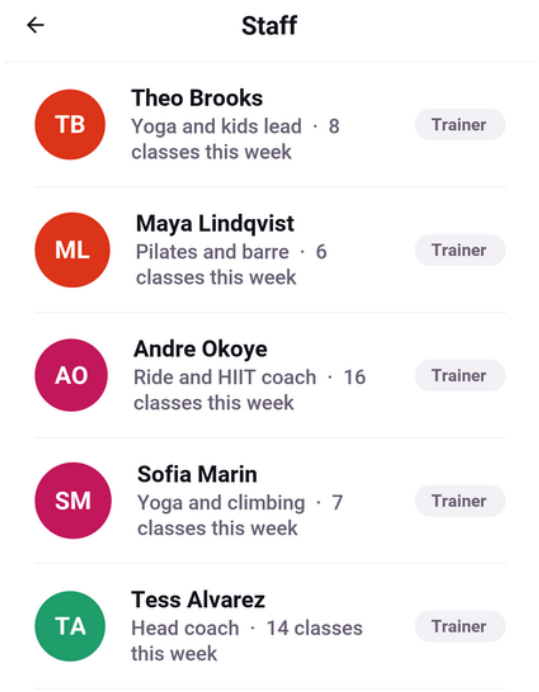
Billing totals what was collected in the last 30 days, what's outstanding and how many charges failed, and lists the invoices, filtered to paid, failed, or open. A failed invoice shows which attempt it's on and when the next one runs; the owner can void a failed or open invoice, with a reason.





63.6.4. Plans, classes and the timetable

The plans list every way to pay: drop-ins, monthly and annual memberships, class packs, and plans for children or off-peak hours. The owner adds and changes them, and a change of price reaches members at their next renewal.



The class templates are the kinds of class the studio gives, each with its length, its places, and how hard it is. A template is what the timetable schedules: the owner puts a class on the timetable for a number of weeks, with its trainer and its room, and cancels a single class with a reason the members booked into it are told.

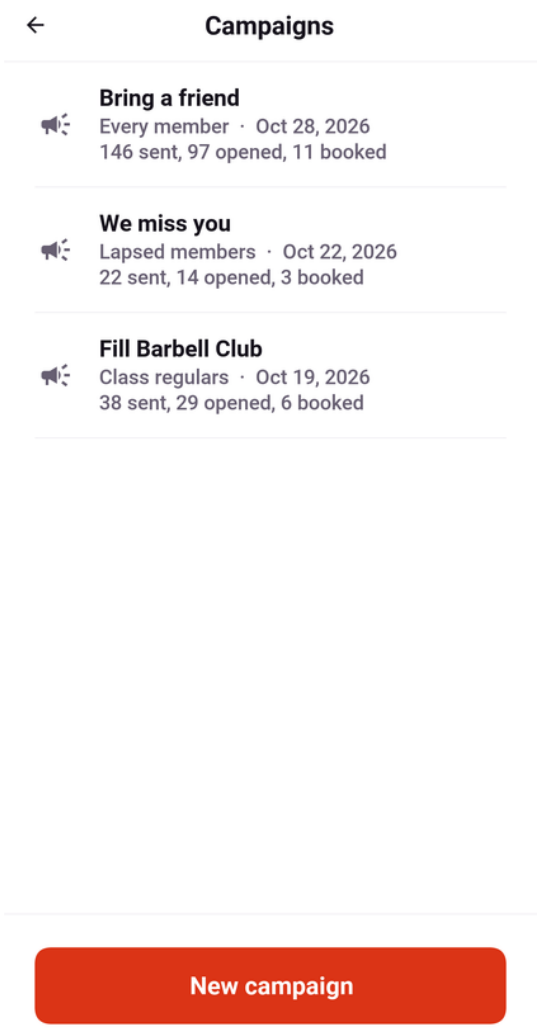
63.6.5. Staff and shifts



The staff list shows each person’s title and their classes this week, and the owner gives or takes away their roles. The shifts are the whole studio’s rota a day at a time: who works, the duty, the hours, and the site when there is more than one. A shift a trainer offered to the others is marked, and the owner adds shifts.

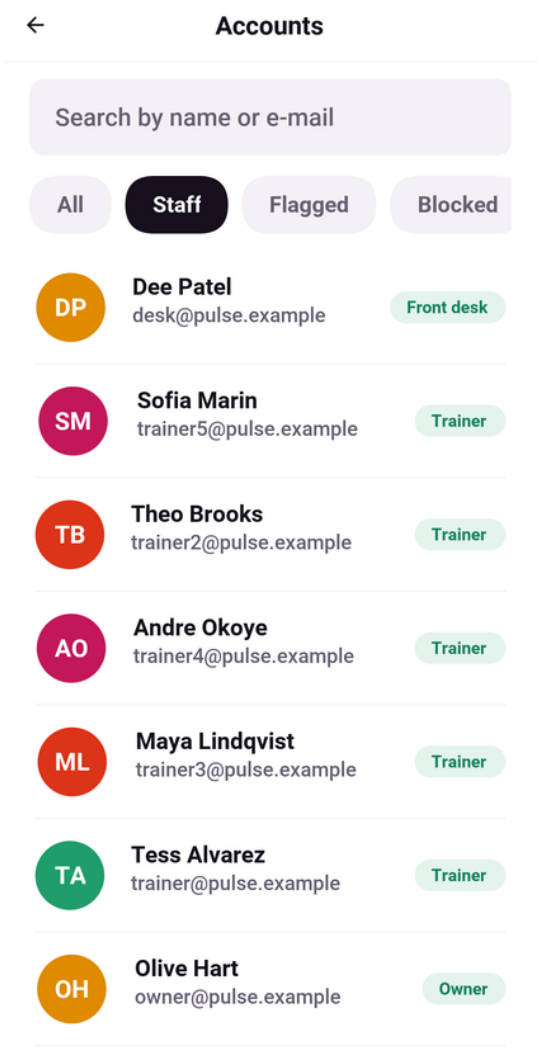
63.6.6. Campaigns



A campaign goes to everyone who took a kind of class, to every active member, or to the members who haven't been in for a month, as a push notification and a message in the member's inbox. Each campaign counts how many were sent, opened, and booked. The dashboard's quiet classes and its members at risk each open a new campaign aimed at them.

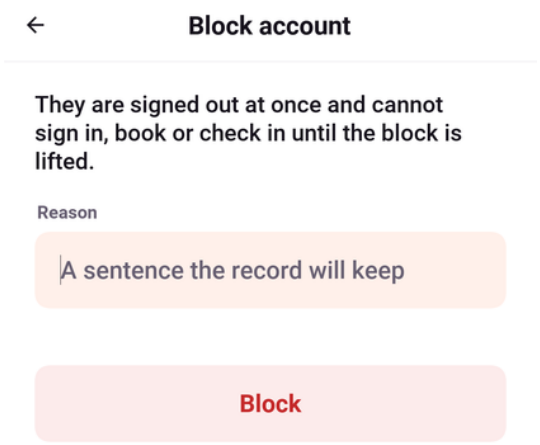
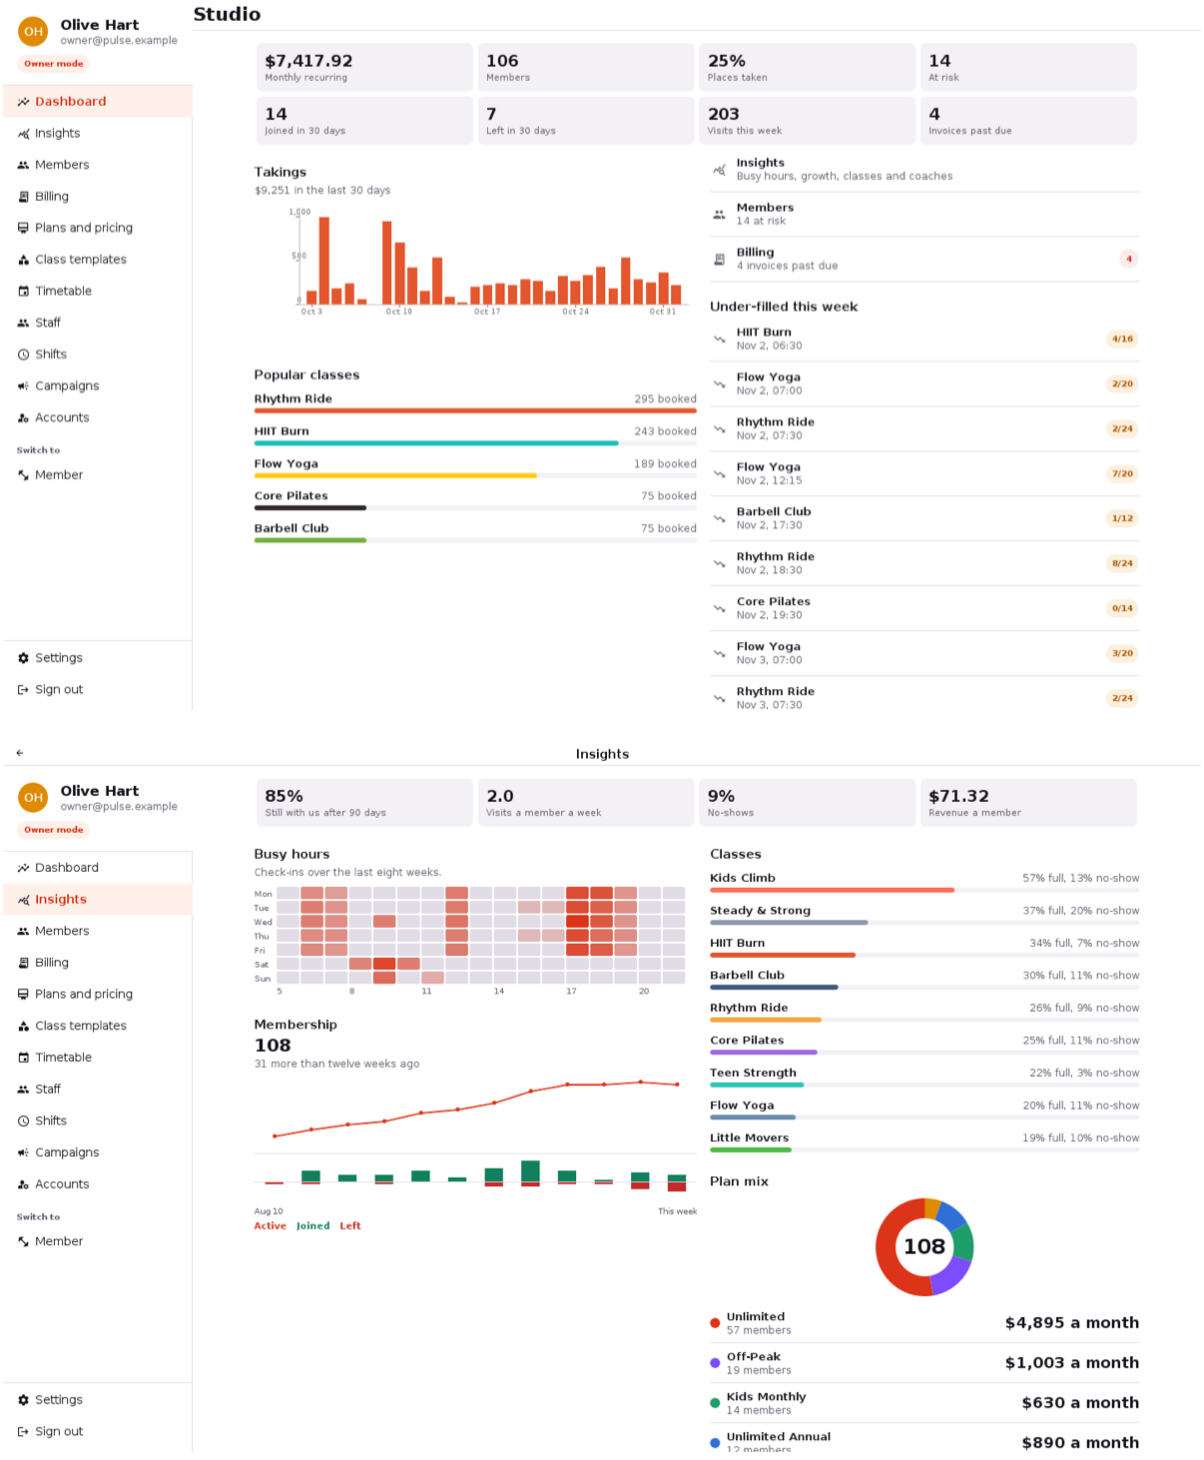
63.6.7. Accounts

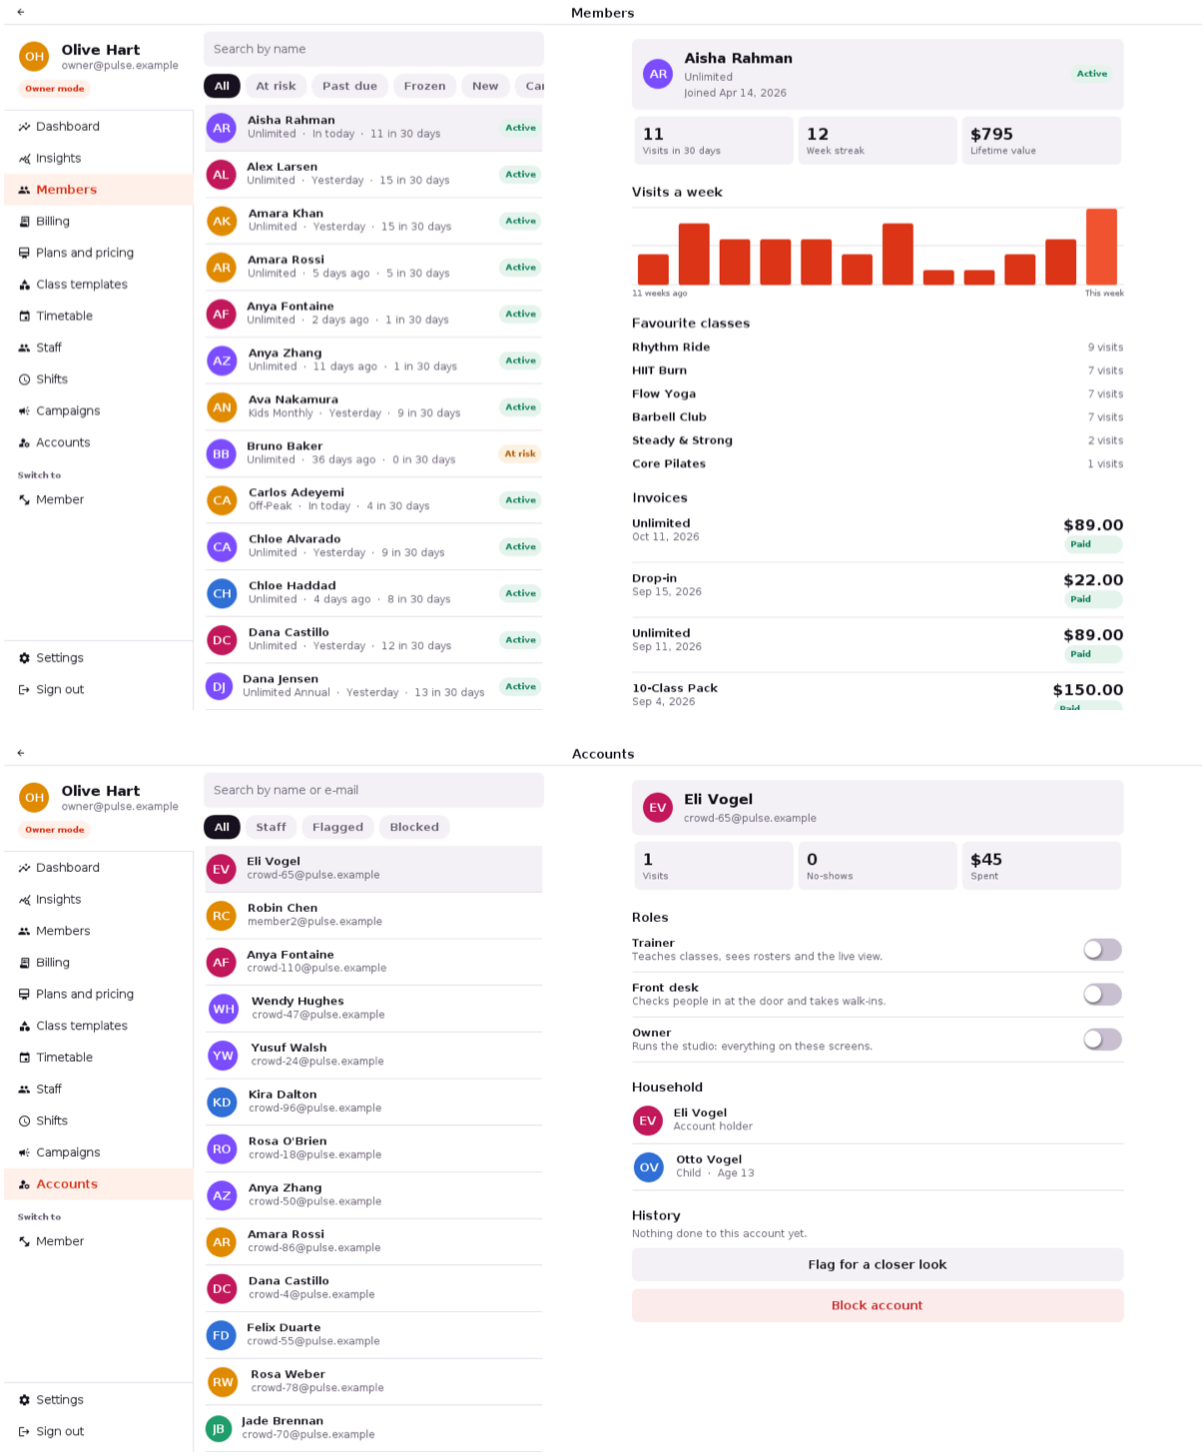


Accounts is the administration of everyone who can sign in: members and staff alike, searched by name or e-mail and filtered to the staff, the flagged, or the blocked. Each row carries the account's highest role or its standing.

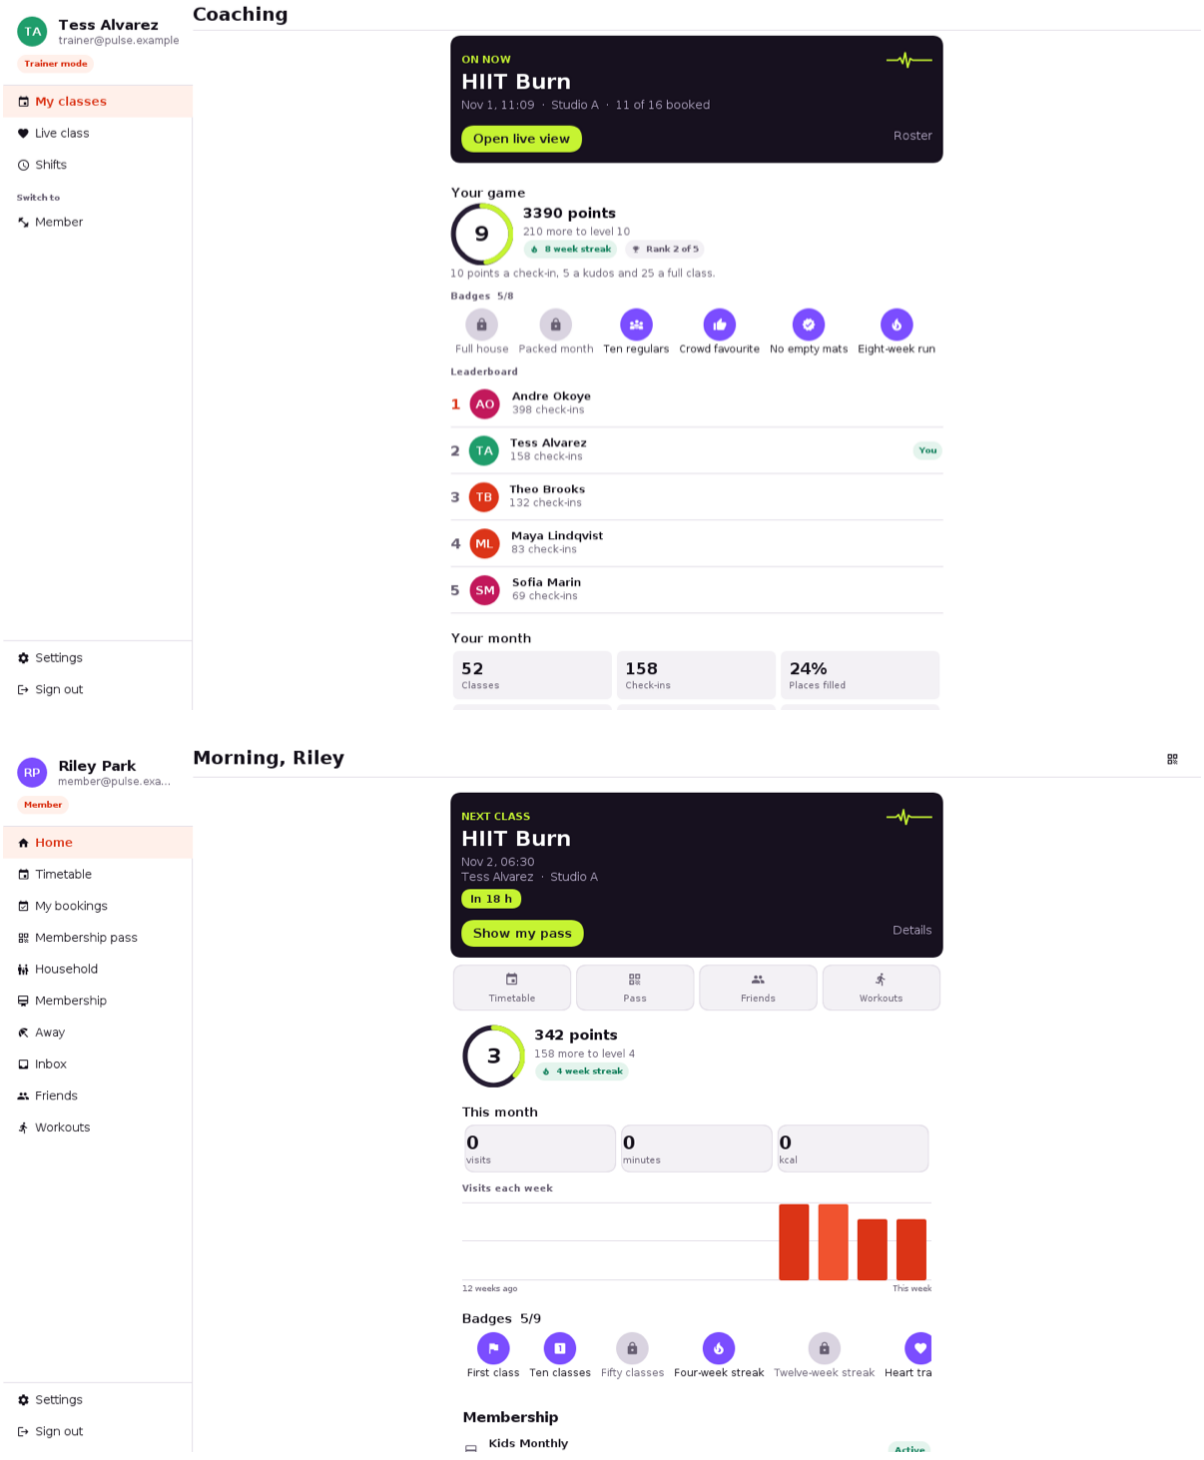
An account’s page has its visits, its no-shows and what it has spent, its roles as switches, the people in its household with any missing waiver, and its history: every flag, block and change of roles, with who did it, when, and why. An owner can’t take away their own owner role, which would leave nobody to give it back.



The owner flags an account for the other owners to look at, which leaves it working, or blocks it, which signs it out at once and stops it signing in, booking, or checking in. Both ask for a reason, which the history keeps.



63.7. On a desktop



The front office usually runs on a computer, so Pulse rearranges itself on a wide window: the desktop app, a tablet, or a browser window wider than a phone. The menu stays open down the left edge, with the current screen highlighted, and the dashboards spread into two columns.

Lists become master and detail. Picking a member or an account opens it next to the list rather than on a screen of its own, and the search and filters stay where they were.

The trainer and the member get the same docked menu, with their home centered next to it.

63.8. In a browser

The server can host the app itself, so the whole studio can be tried in a browser:

```
cd scripts/pulse
backend/server.sh web
CN1_PROFILE=dev backend/server.sh run
```

Then open `http://localhost:8080/`. A browser offers less than a phone: the door pass, health data and the watch are features of the phone app.

Chapter 64. Pulse: Building on the sample

Pulse shares its shape with Savor and Wayline: the module layout, accounts and sign-in, cards and the payment provider, text messages, push notifications, the live channel and hosting the app in a browser. This chapter covers what a studio changes: households, a timetable that never oversells, a door pass, recurring billing, and the marketing that runs by itself.

64.1. Running it

The project is in `scripts/pulse`. Start the server on the development profile, which seeds the demo studio and its accounts and simulates the cards:

```
cd scripts/pulse
CN1_PROFILE=dev backend/server.sh run
```

Then run the app in the simulator:

```
cd scripts/pulse
mvn verify -Psimulator -DskipTests -Dcodename1.platform=javase
```

64.2. The modules

`shared` holds the data classes and the `@RestClient` interfaces both sides build from, so a change one side didn't follow is a compile error. `common` is the app, for every platform. `backend` is the server, in packages by subject:

Package	What it holds
`account`	Accounts, phone verification, preferences and quiet hours, moderation, and the demo accounts.
`studio`	Locations, the timetable, households, bookings and the waitlist, door passes, and the demo studio.
`desk`	Check-in at the desk and the kiosk, member lookup, walk-ins and the desk's day.
`trainer`	Rosters, attendance, shifts and live heart rates.
`billing`	Memberships, invoices, proration, freezes, dunning and referral credits.
`pay`	The payment provider: simulated or Stripe.
`engagement`	Visit statistics, workouts, away periods and the automatic nudges.
`social`	Friends, the feed, kudos and class invites.
`owner`	The dashboard, plans, the timetable, staff and campaigns.
`live`, `push`, `sms`	The WebSocket, push notifications and text messages.

Roles are `MEMBER`, `TRAINER`, `DESK` and `OWNER`, in `Roles`. Every account is a member; the others are granted by an owner. The kiosk is a desk account on a tablet, so it needs no role of its own.

64.3. A class that never oversells

The rule that must never break is that a class isn't booked past its capacity, however many people tap Book at once. `Bookings` leaves it to the database: the places taken are a column of the class, and the only statement that raises it does so on condition that it's still below capacity. A booking whose statement changed no row joins the waitlist instead. Two requests for the last place both run that statement, and the database makes the second find the class full.

Everything else is checked first: the class is still to come, the person fits its age range on the day, the waiver is signed, and a membership covers it. A place given back promotes the first person on the waitlist, one promotion at a time per class, and a job settles finished classes, turning the absent into no-shows.

The same pattern takes a trainer's offered shift: two trainers tapping Take together are told apart by one conditional statement.

64.4. The door pass

A pass on a phone is a QR code reading `pulse:<member id>:<code>`, where the code is an HOTP (RFC 4226, SHA-256, eight digits) of the pass's secret over the number of 30-second periods since the epoch. The phone and the server make the same `com.codename1.security.Otp` call, so the phone needs no signal. The server takes a code one period either side of now, for a phone whose clock is slightly off, and keeps every code it accepted until it could no longer be valid, so a screenshot shown twice is refused as a replay.

An NFC id is the other kind of pass, for a fob or wristband. It doesn't change, so it's as good as the thing it's written on; replacing the pass's secret replaces it too.

A check-in always answers, admitted or refused with a reason, and never fails for a member who simply isn't allowed in. The kiosk turns that answer into a green or a red screen. Each check-in is also sent to staff over the live channel.

64.5. Billing

`Billing` charges in three steps and only the middle one talks to the processor: a transaction writes the invoice and claims it, the card is charged with no transaction open, and a second transaction records the result. The invoice id is the processor's idempotency key, so a server that dies between the charge and the record charges the same invoice again on the next run and is answered the first charge, not a second one.

- **Proration.** A member moving plans has what's left of the old period taken off the first invoice of the new one.
- **Freezes.** One week to three months.
- **The dunning ladder.** A declined renewal is retried after one, three and seven days. From the

second failure the membership is past due and the door says so; after the last, the invoice waits to be paid by hand.

- **Referral credits.** A member whose referral first pays gets a credit.
- **Amounts** are `long` minor units in `pulse.currency`.

The processor is behind `PaymentProvider`: a customer, a card saved to it once as a token, and charges against that token with nobody present. The server keeps the token, a brand and four digits, never a card number. `SimulatedPayments` takes the test cards; `StripePayments` adds cards on Stripe's hosted page. Another processor is one more implementation of the interface, chosen in `Services`.

64.6. Nudges and campaigns

The nudge job in `engagement` runs every 15 minutes and sends two kinds of message on its own: a class starting in 3 to 36 hours that's under 60% full is offered to members who took that kind of class before, at most three per empty place; and a member who hasn't been in for 14 days is told the studio misses them, at most every 21 days. Neither reaches a member who is away, one who turned promotions off, or one inside their quiet hours; those are left for a later run. Each message is its own transaction, checked again inside it, so two servers running the job send it once.

Campaigns are the owner's: a message to those who took a kind of class, every active member, or the lapsed, counted as sent, opened, and booked.

64.7. Live heart rates

A member's watch sends heart rate readings during a class. `HeartRates` keeps the latest per member in memory only: a reading matters for a few seconds, and the workout, which is kept, arrives whole when it ends. The zone, one to five, is the reading's share of 220 less the member's age, in fifths from 50%. Readings go to the class's trainer over the live channel.

The live channel carries four frames: a class's places changing, one of an account's bookings changing, a heart rate, and a check-in. The connections are those of one process; running more than one instance needs a channel between them, such as a database `LISTEN/NOTIFY` or a message broker, feeding the same methods.

64.8. Settings

`backend/application.properties` lists every setting. A deployment sets the database (`DATABASE_URL`), the issuer and signing key, the first owner (`pulse.admin.email`, `pulse.admin.password`), and the providers:

Setting	Choices
`pulse.sms.provider`	`twilio`, `vonage`, `messagebird`, or `console` on a development profile.
`pulse.payments.provider`	`stripe`, or `simulated` on a development profile.
`pulse.push.provider`	`cloud` (with `pulse.push.app` and `pulse.push.key`), or `console` and `recording` on development profiles.

Setting	Choices
`pulse.currency`, `pulse.timezone`	The studio's currency and the time zone quiet hours are counted in.

Unset, each provider is the development one on a development profile and the real one elsewhere. A real provider with missing settings is logged at start-up, naming them, and every call to it fails with the same message; nothing falls back to a development stand-in. Secrets go in the environment, in upper case with _ for each dot (`PULSE_PAYMENTS_STRIPE_SECRET`).

64.9. Tests

```
cd scripts/pulse
# The server's tests on the JVM, then compiled to a native binary
mvn -Dcodename1.platform=backend -pl shared,backend test -Dcn1.backend.compiledTests=true
# The same tests on PostgreSQL or MySQL
CN1_TEST_DATABASE_URL="postgres://user:password@localhost:5432/db?sslmode=disable" \
  ../ci/sample-server-tests-on-database.sh .
# The app against a running server, in the simulator
./run-e2e.sh
./run-e2e.sh --native
# The app in a headless browser, served by the server
./run-web-e2e.sh
```

The server's tests run on in-memory SQLite, which accepts any value in any column. `sample-server-tests-on-database.sh` runs them against PostgreSQL or MySQL, where the ORM checks every mapping against its migration. CI runs both, in `.github/workflows/pulse.yml`.

64.10. Making it yours

- **Your studio.** Replace `DemoStudio` with your locations, rooms, class types and plans, or create them from the owner's screens on an empty database.
- **Your brand.** Colors and shapes are in `common/src/main/css/theme.css`, text in `common/src/main/l10n`.
- **Your rules.** The late-cancellation window, the dunning ladder, freeze limits, the referral credit and the nudge thresholds are constants beside the code that uses them, in `Bookings`, `Billing` and the nudge job in `engagement`.
- **A chain of studios.** Locations are already a dimension of the timetable and the desk; a chain adds location-scoped staff roles and reporting.

64.11. Before it's a product

The sample is complete as a demonstration and stops where a studio's legal and physical systems begin. A product needs at least:

- **A real payment processor and PCI scope.** Wire `PaymentProvider` to your processor and test it

with its test keys. Keep card entry on the processor's hosted page so card numbers never reach your app or server, and confirm your PCI DSS self-assessment with the processor. Add receipts, tax, refunds and the disputes process your market expects.

- **Waivers and medical consent that hold up.** The waiver is a flag and a date. A binding waiver needs the text your lawyer approves for your jurisdiction, a record of exactly which version was signed, by whom and how, and a health questionnaire or medical consent where the law or your insurer asks for one. Minors usually need a parent or guardian to consent for them.
- **Child safeguarding.** Children's classes need background checks for the staff who teach them, rules on who may collect a child, consent for photos, and limits on what other members can see about a child. Check what your country's safeguarding rules require.
- **Door hardware.** The kiosk decides; it doesn't open anything. A real door needs an access controller and reader, integrated through their vendor's API, with a fail-safe for fire exits and a plan for when the network is down.
- **Health data privacy.** Heart rates and workouts are health data. Under GDPR that's special category data, needing explicit consent, a stated purpose, a retention limit and deletion on request. In the United States, check whether your service falls under HIPAA (for example through a healthcare partner) and what state privacy laws ask. Follow Apple's and Google's rules for data read from HealthKit and Health Connect.
- **Marketing consent.** Nudges and campaigns respect the promotion switch and quiet hours. Check your market's rules on marketing messages, such as opt-in requirements and an unsubscribe link in every message.
- **Reviewed translations.** The non-English bundles are machine translations; have them reviewed before release.
- **Operations.** Monitoring, backups that have been restored in a test, a support process for members, and a channel between server instances before you run more than one.

Chapter 65. Slate: An appointment booking app from every side

Slate is a sample app with a server behind it, for any business that sells time with a person: a salon, a tutor, a personal trainer, a consultancy, a clinic. Clients book an appointment and see only the times that are free. Providers run their day and connect their own calendars. The owner reads the numbers, keeps the catalogue and sets the rules every booking obeys. The app and the server are one Maven project, written in Java on both sides.

This chapter is the user's guide: what each kind of user sees and can do. Chapter 66, *Slate: Building on the sample* is the other half. It explains how the project is built and what to change to make it yours.

One app serves everyone. The server gives every account a set of roles, and the app offers a mode for each role the account holds. Someone who holds more than one switches between them from the menu.

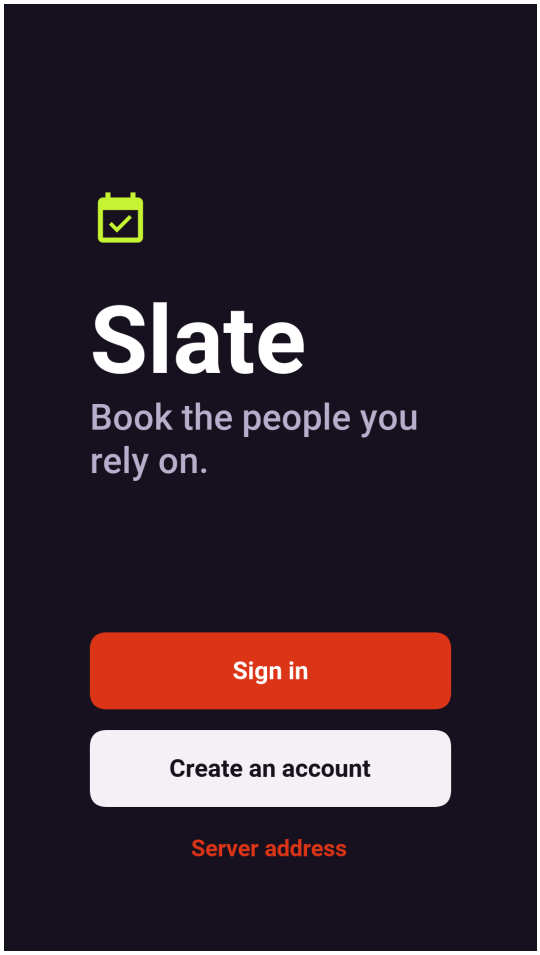
Role	What it adds
Client	Every account is a client. Book, move and cancel appointments, check free times against your own calendar, put appointments in your phone's calendar with a reminder, and join the waiting list for a full day.
Provider	Granted by the owner. See your day, week and agenda in one timeline, mark appointments done or missed, set your hours and time off, and connect the calendars that make you busy.
Owner	Read the dashboard, see every provider's day side by side, edit services, providers, locations and rooms, and change the booking rules with a preview.

65.1. Trying it

Start the server on the development profile, which creates a demo salon and its accounts and simulates cards and the Google and Microsoft calendars:

```
cd scripts/slate
CN1_PROFILE=dev backend/server.sh run
```

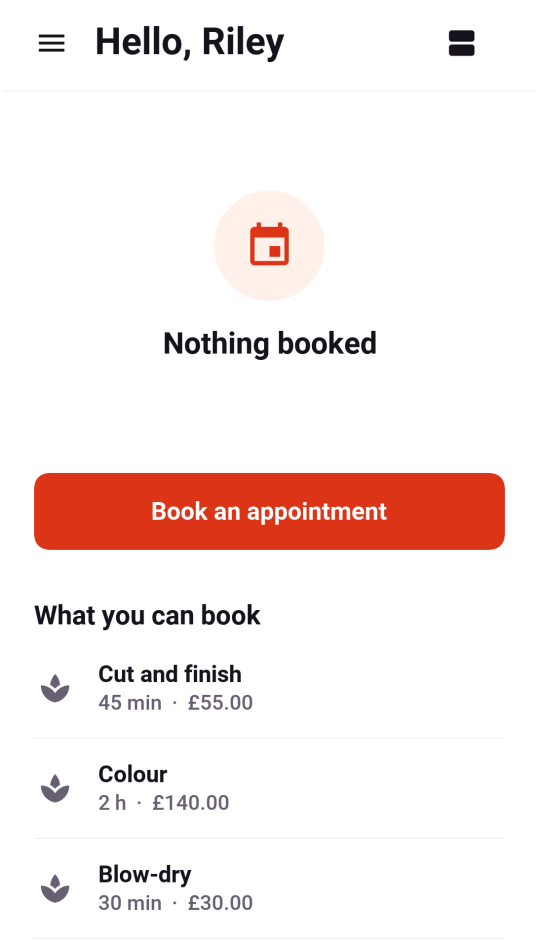
Then run the app in the simulator:



```
cd scripts/slate
mvn verify -Psimulator -DskipTests -Dcodename1.platform=javase
```

Every demo account has the password `slate-demo`:

`client@slate.example`	a client with a card on file and a history
`client2@slate.example`	a new client, with no card and nothing booked
`provider@slate.example`	the provider most demo appointments are with
`provider3@slate.example`	works at both locations
`owner@slate.example`	runs the business



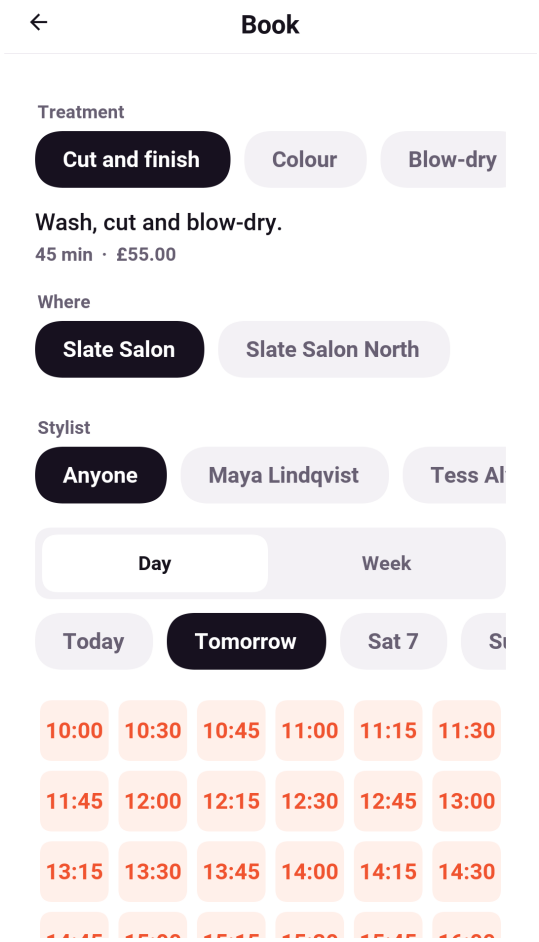
The demo is a salon. The same server can run as a tutoring business, a personal trainer, a consultancy or a clinic: the words change (a stylist and a chair become a tutor and a room), and every rule and screen stays the same.

Cards are simulated: `4242 4242 4242 4242` is accepted and `4000 0000 0000 0002` is declined. No money moves.

65.2. The client

The client's home leads with the next appointment and lists what can be booked, each service with its length and price.

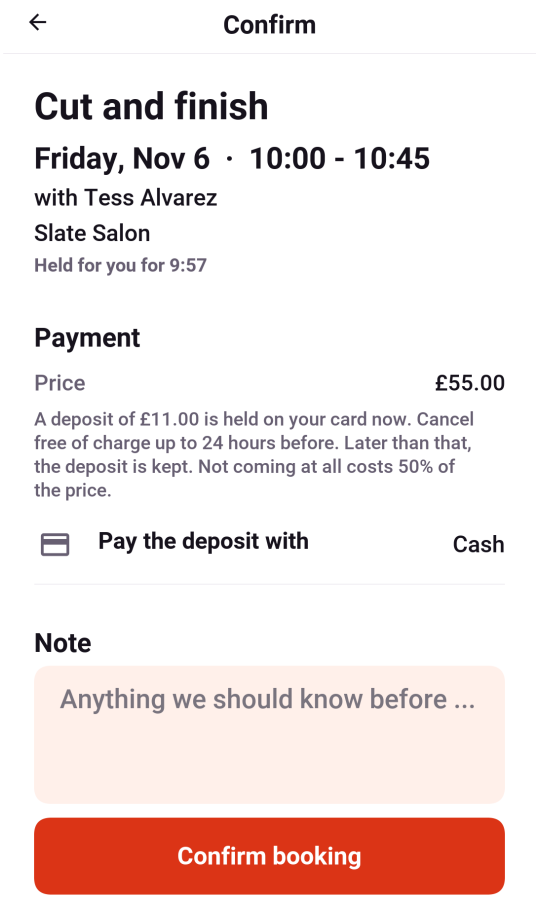
65.2.1. Finding a time



Booking starts from a service. Pills at the top choose the location and the provider, or anyone who offers it, and a strip of days chooses when. The screen shows only the starts that are free. A start appears only when every rule agrees:

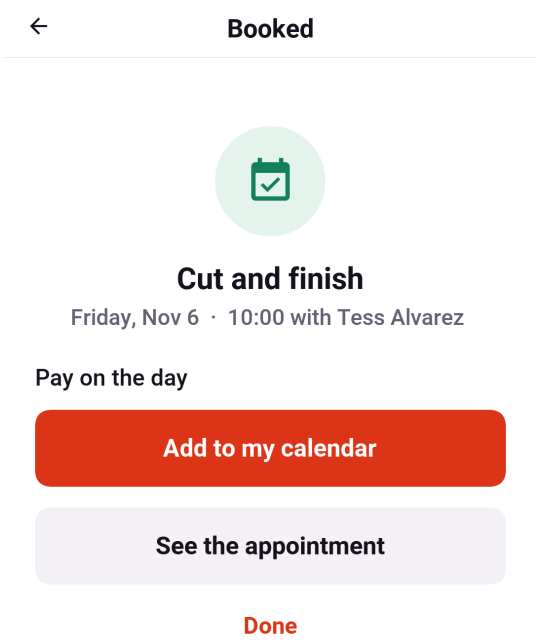
- the provider works then, isn't already booked, isn't on time off and isn't busy in a calendar they connected;
- the service's buffers before and after fit, and so does the travel time when the provider's previous appointment was at the other location;
- a room or a chair the service needs is free;
- the provider hasn't reached their limit for the day and gets the break they asked for after a long stretch;
- the start doesn't leave a gap too short to sell, if the business asks for that;
- the client isn't booked elsewhere at the same time, and hasn't reached the business's limit for the day.

When a day has nothing, the screen says why — fully booked, not working that day, or too soon to book — and offers the waiting list. The week view shows the next seven days at once, for a client who cares about the time more than the day.



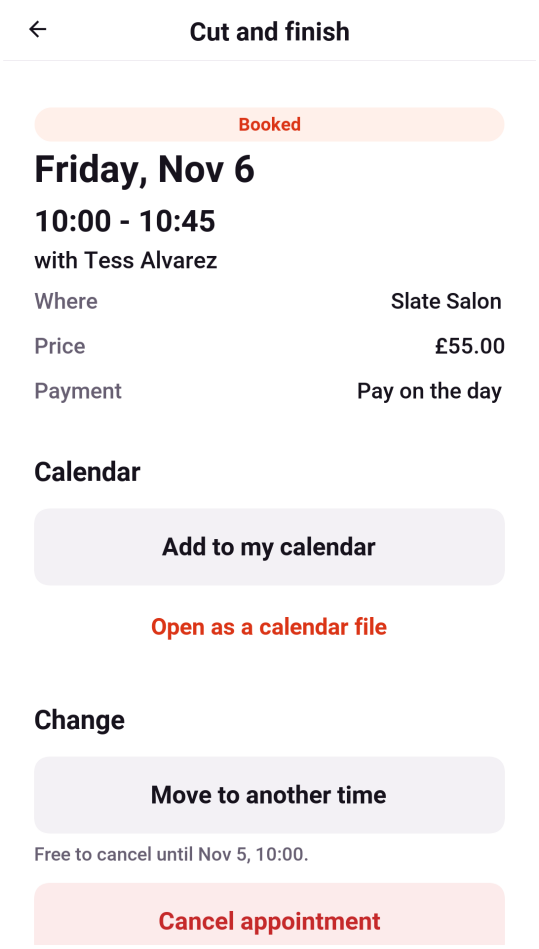
With **Check my calendar** on, the app reads the phone's own calendars and marks any start that clashes with something already there. Only busy times are read, on the phone. Nothing about the

client’s calendar is sent anywhere.



65.2.2. Holding and confirming

Choosing a start holds it for a few minutes, with a countdown, so nobody else can take it while the client decides. The confirm screen shows the price, the deposit if the business takes one, the card it comes from, and the terms: until when cancelling is free and what a no-show costs. A note answers the service’s question, if it has one ("Anything the stylist should know?"). Going back lets the time go.

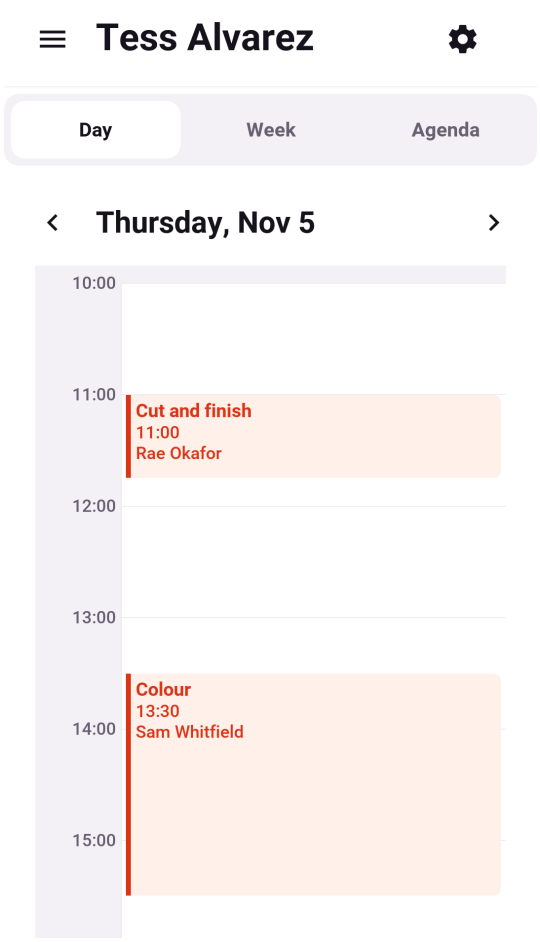


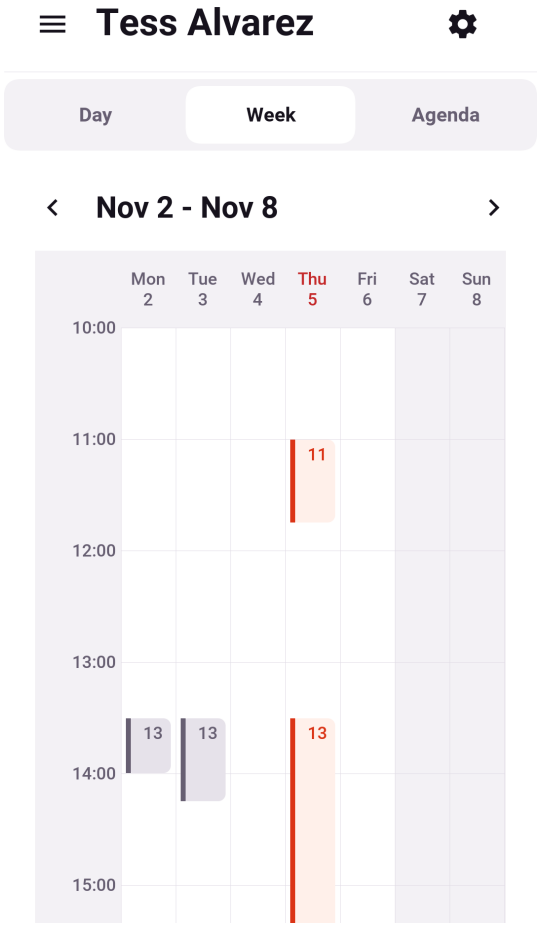
Once it's confirmed, the appointment can go into the phone's calendar with a reminder an hour ahead. The event belongs to the app. When the appointment moves, the event moves with it, and when it's cancelled, from any device, the event is deleted.

65.2.3. Appointments

Upcoming bookings are listed in **My appointments**, a day at a time, and past ones below them. An appointment's screen shows when, where, who with and what was paid. It says exactly what cancelling costs right now: free until a stated time, or the deposit kept once that time has passed. It can open the appointment as an `.ics` file for any calendar the app can't write to.

Moving an appointment opens the same time picker with the same service and provider. The old time is kept until the new one is confirmed, so a move never loses the booking.



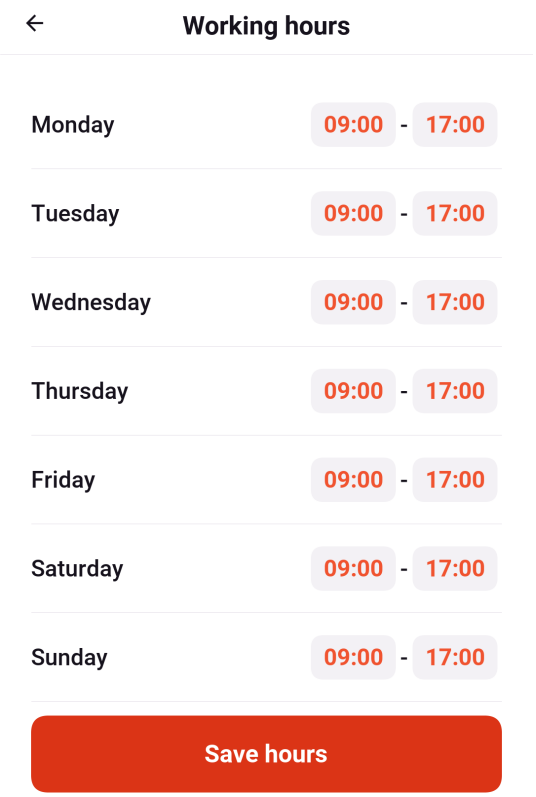


65.2.4. The waiting list

When a day is full, **Tell me if a time frees up** asks which part of the day suits and joins the list for that week. When a matching appointment is cancelled, the first person waiting gets a push notification. The time isn't held, so the first person to book it gets it.

65.3. The provider

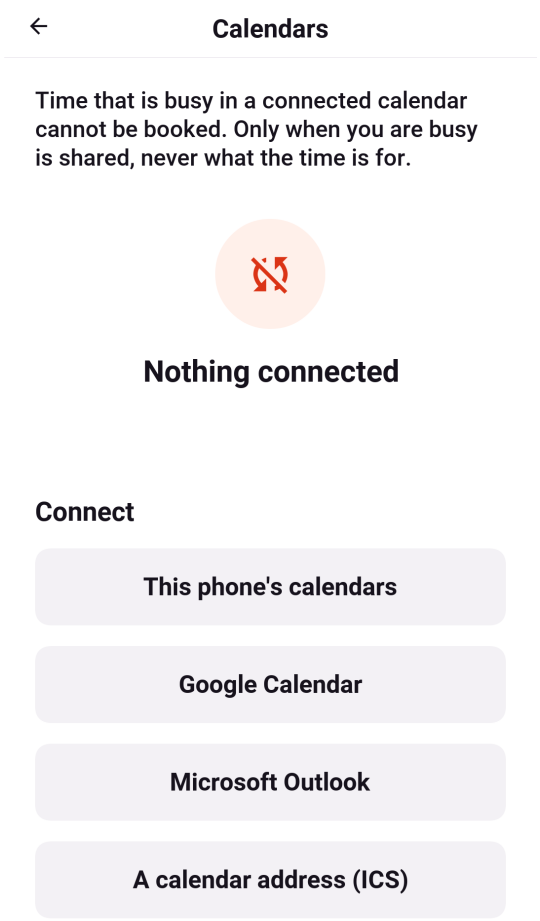
The provider's home is their time: the day, the week or an agenda of what's booked. One timeline merges their working hours, every appointment, their time off and every block that a connected calendar says is busy. When a client books or cancels, the timeline updates at once.



An appointment opens to the client's name, note, and payment. Once it has started, the provider

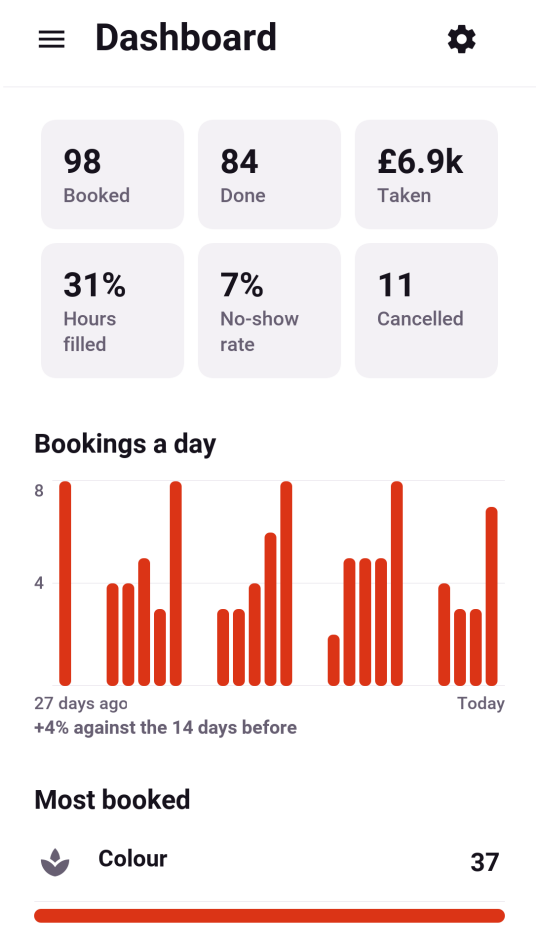
marks it done or missed. Before that, they can cancel it, which refunds the client in full and tells them at once.

65.3.1. Hours and time off



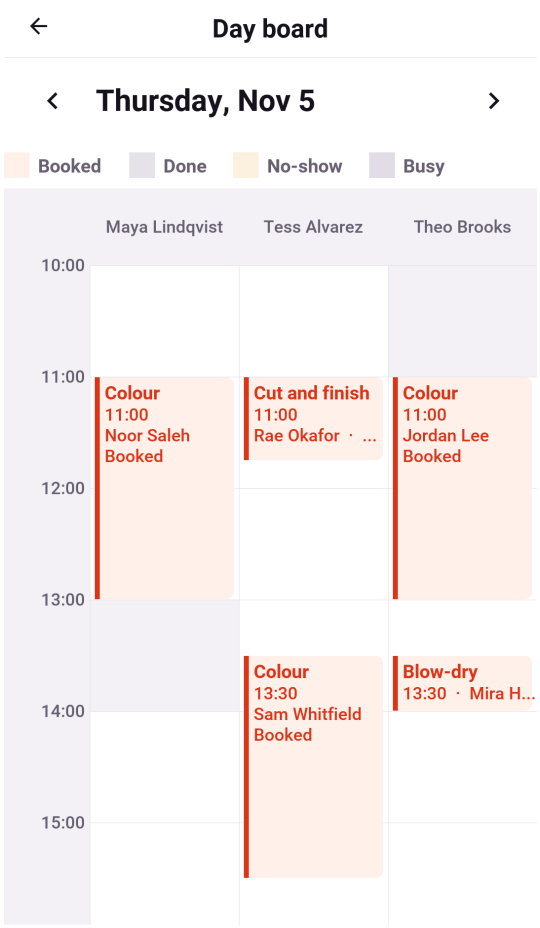
Working hours sets the week: which days and from when to when. Saving replaces the whole week at once, so a half-edited week is never bookable. **Time off** blocks anything from an hour to a holiday. Appointments already booked inside it aren't moved; the provider sees them and decides.

65.3.2. Calendars



A provider's other commitments keep clients away once their calendars are connected:

- **This phone's calendars.** The provider picks which of the phone's calendars count. Only busy intervals go to the server: a start and an end, with no title, attendees or place. The app sends the next month again when it opens and whenever the calendar changes.
- **Google Calendar** and **Microsoft Outlook.** The provider signs in once, in the app. From then on, the server reads only the free/busy view every few minutes. On the demo server both are simulated, and connecting needs no account.
- **A calendar address.** Most calendars can publish a private `.ics` address, which the server reads.



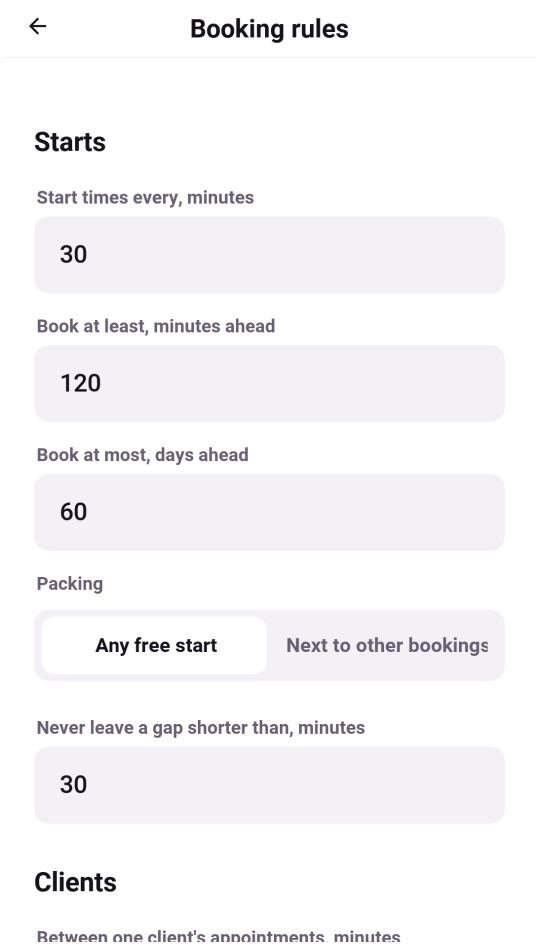
65.4. The owner

The dashboard covers the last few weeks: appointments booked and done, no-shows, cancellations, money taken and how full the providers' hours were. It also charts bookings by day and lists the most booked services and the busiest providers.

The **Day board** puts every provider's day side by side, one column each. It's wide enough on a tablet or a desktop to see who is free at a glance, and scrolls sideways on a phone.

65.4.1. The catalogue

Services, providers, locations, and rooms and equipment each have a list and an editor. A service has its length, price, buffers before and after, how many clients it takes at once, how many providers it needs, the kind of room it needs and its deposit. A provider has their title, a daily limit and a break after a long stretch. Nothing is deleted, only switched off, so past appointments keep the names they were booked under.



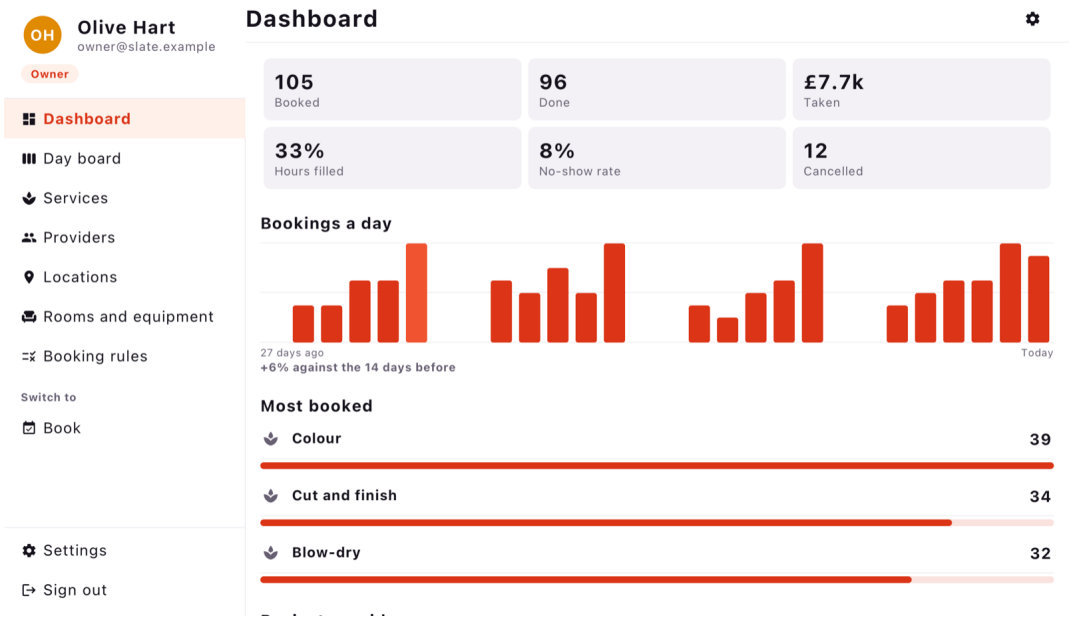
65.4.2. The booking rules

The rules decide which starts are offered:

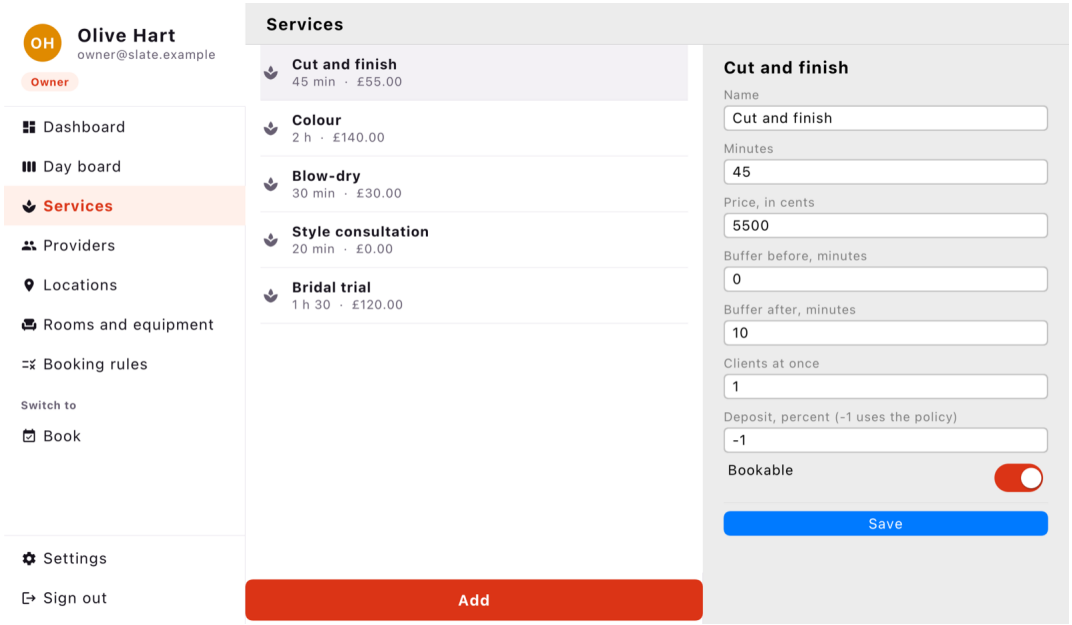
Rule	What it does
Start times every	The step between starts: every 15 minutes, every half hour.
Book at least / at most ahead	The notice a booking needs, and how far ahead the calendar opens.
Packing	**Any free start**, or **Next to other bookings**, which offers only starts that touch an existing appointment or the edge of the day, keeping the free time in one piece.
Never leave a gap shorter than	Refuses a start that would strand a gap too short to sell.

Rule	What it does
Between one client's appointments / a day	Keeps one client from booking back to back, or more than the business allows in a day.
A chosen time is held for	How long the hold lasts while the client confirms.
Deposit, free cancellation, moving, no-show fee	The money and the deadlines.

Rules interact. A small step, a minimum gap and tight packing together offer far fewer starts than any one of them suggests. **Preview tomorrow** runs the edited rules against tomorrow's real schedule without saving anything. It shows every provider's starts, with the reason for each one that's refused.

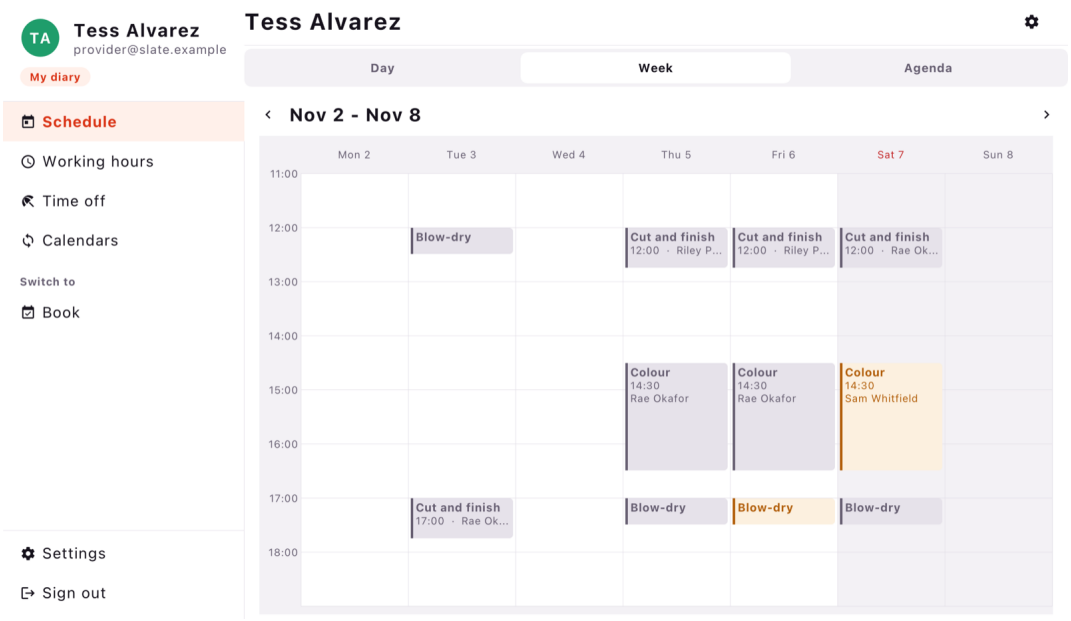


65.5. On the desktop

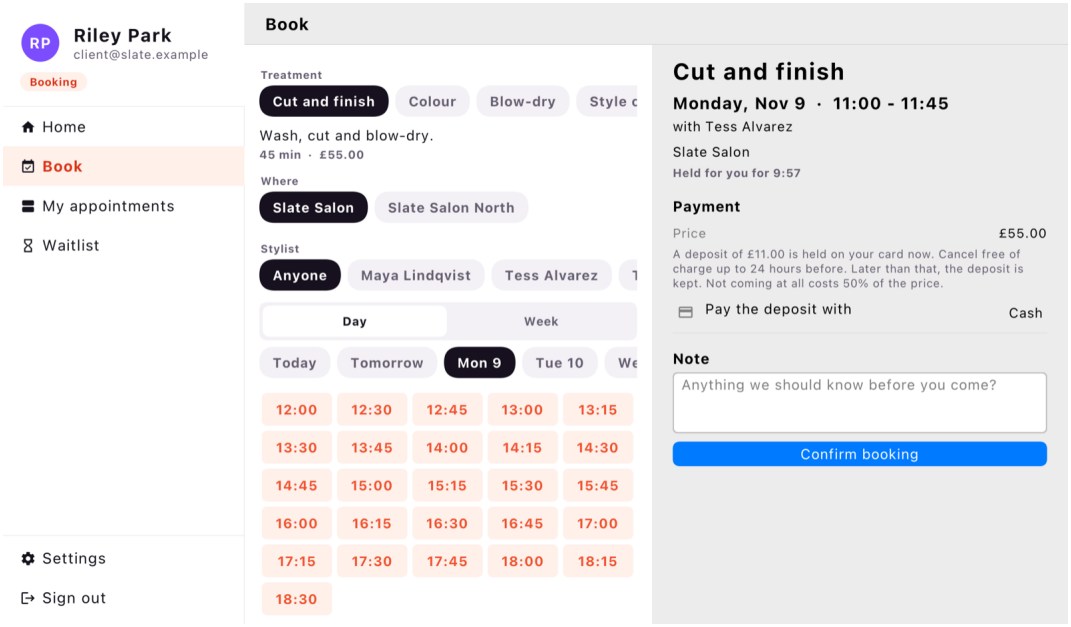


The same app runs as a desktop application, and on a window that wide it isn't a phone screen stretched out. It opens at the size of a desktop window and is laid out for one:

- The menu is docked down the side, with who is signed in at its top. You move between screens with it, so there are no back arrows; Back is in the window's menu, with its shortcut.
- The controls are the platform's own: macOS, Windows or GNOME buttons, fields and lists.



- The dashboard spreads its numbers across the window, and the day board shows every provider’s day side by side.



- The catalogue keeps its list on the left and edits the row picked on the right, so working down the services never leaves the list.

- The provider’s week shows all seven days at once.

- Booking has no confirm screen. Picking a time holds it and shows the price, the terms and the button that books it beside the times, so picking another time is one click and the hold on the last one is let go.
- The client's home shows what's coming up beside what can be booked.

65.6. In a browser

The server can host the app itself, so the whole business can be tried in a browser:

```
cd scripts/slate
backend/server.sh web
CN1_PROFILE=dev backend/server.sh run
```

Then open `http://localhost:8080/`. A browser offers less than a phone: it can't read the phone's calendars or add events to them.

Chapter 66. Slate: Building on the sample

Slate shares its shape with Pulse, Savor and Wayline: the module layout, accounts and sign-in, cards and the payment provider, text messages, push notifications, the live channel and hosting the app in a browser. This chapter covers what an appointment business changes: a slot engine that asks every party at once, rules about gaps, and calendars that are read and written in both directions.

66.1. Running it

The project is in `scripts/slate`. Start the server on the development profile, which seeds the demo salon and its accounts, simulates the cards and the online calendars:

```
cd scripts/slate
CN1_PROFILE=dev backend/server.sh run
```

Then run the app in the simulator:

```
cd scripts/slate
mvn verify -Psimulator -DskipTests -Dcodename1.platform=javase
```

66.2. The modules

`shared` holds the data classes and the `@RestClient` interfaces both sides build from. `common` is the app, for every platform. `backend` is the server, in packages by subject:

Package	What it holds
`account`	Accounts, phone verification, preferences and the demo accounts.
`catalog`	The business, its locations, services, providers, resources and verticals.
`booking`	The slot engine, availability, holds, bookings, rescheduling, the waitlist and the demo business.
`provider`	Working hours, time off and a provider’s schedule.
`sync`	Connected calendars: Google, Microsoft, published ICS addresses, the phone’s own calendars and the feed Slate publishes.
`owner`	The dashboard and the board of the day.
`pay`	Deposits and no-show fees: simulated or Stripe.
`live`, `push`, `sms`	The WebSocket, push notifications and text messages.

Roles are `CLIENT`, `PROVIDER` and `OWNER`, in `Roles`. Every account is a client; the others are granted by an owner, and the app offers a mode for each.

66.3. One business, many verticals

A salon books a stylist and a chair, a tutor a room, a clinic a practitioner and a treatment room. The rules and the screens are the same; only the words and the accent colour differ:

```
/// The kinds of business Slate is set up for, and what each calls things.
///
/// A vertical is words and a colour, nothing more. The booking rules, the
/// slot engine and every screen are the same for a salon and a consultancy;
/// what differs is that one books a stylist and a chair and the other a
/// consultant and a meeting room. A new vertical is a row here and, for the
/// demo, a set of services in `DemoBusiness`.
public final class Verticals {
    public static final String SALON = "SALON";
    public static final String TUTOR = "TUTOR";
    public static final String TRAINER = "TRAINER";
    public static final String CONSULTANT = "CONSULTANT";
    public static final String CLINIC = "CLINIC";

    public static final String[] ALL = {SALON, TUTOR, TRAINER, CONSULTANT, CLINIC};

    /// vertical, provider, providers, client, service, resource, accent
    private static final String[][] WORDS = {
        {SALON, "Stylist", "Stylists", "Client", "Treatment", "Chair", "#c2185b"},
        {TUTOR, "Tutor", "Tutors", "Student", "Lesson", "Room", "#3949ab"},
        {TRAINER, "Trainer", "Trainers", "Client", "Session", "Studio", "#00897b"},
        {CONSULTANT, "Consultant", "Consultants", "Client", "Meeting", "Meeting room",
            "#455a64"},
        {CLINIC, "Practitioner", "Practitioners", "Patient", "Appointment", "Treatment room",
            "#1e88e5"},
    };
```

66.4. The slot engine

`SlotEngine` decides which starts can be booked. A start is offered only when every party the service needs is free — the providers, one resource of the right kind, and the client — and every rule the business set holds: notice and horizon, buffers before and after, a provider's daily cap and breaks, travel time between locations, the client's gap between bookings and their bookings per day, and the shortest gap worth leaving on a provider's day. It reads nothing and writes nothing, which is what lets each rule be tested by itself:

```
/// Decides which start times can be booked: every party a booking needs has to
/// be free, and every rule the business set has to hold.
///
/// It reads nothing and writes nothing. What it is given -- the start times to
/// try, each provider's shifts and busy time, the resources, the client's own
/// day -- is assembled by [Availability] from the database, and the same
/// decision is made again by [Bookings] for the one start a client picks, just
/// before the time is claimed. Keeping it pure is what lets the rules be
/// tested one at a time, and lets the owner's preview say, for every start and
```

```
/// every provider, which rule turned it down.
///
/// Times are milliseconds since the epoch. The engine knows nothing of zones:
/// the start times it is handed were already chosen on the local clock, and a
/// shift is already the two instants it runs between, so a day that changes to
/// or from daylight saving is the caller's to get right, once.

        }
        return out;
    }
```

Starts are read off the business's local clock, so a day when the clocks go forward has no slot at a time that doesn't exist:

```
/// The start times of a day, read off the local clock every `step`
/// minutes. A time that does not exist that day -- skipped by a change to
/// summer time -- is left out rather than moved.
public static long[] starts(LocalDate day, ZoneId zone, int step) {
    int each = Math.max(SlotEngine.CELL_MINUTES, step);
    List<Long> out = new ArrayList<Long>();
    for (int minute = 0; minute < 24 * 60; minute += each) {
        LocalTime wanted = LocalTime.of(minute / 60, minute % 60);
        ZonedDateTime at = ZonedDateTime.of(day, wanted, zone);
        if (!at.toLocalTime().equals(wanted) || !at.toLocalDate().equals(day)) {
            continue;
        }
        out.add(Long.valueOf(at.toInstant().toEpochMilli()));
    }
    long[] starts = new long[out.size()];
    for (int iter = 0; iter < starts.length; iter++) {
        starts[iter] = out.get(iter).longValue();
    }
    return starts;
}
```

66.5. Never double booked

Time is claimed in five-minute cells. A `SlotClaim` row's key is the party and the cell, so two appointments over the same five minutes of one stylist or one chair are refused by the database itself, however many clients tap at once. A client picking a start first holds it, in a transaction of its own, for the business's hold time:

```
/// Holds a start for `client` while they finish booking. Answers 409 with
/// the reason when the start is not free, or was taken a moment ago.
public AppointmentDto hold(String client, String clientName, HoldRequestDto ask)
        throws IOException {
    if (ask == null) {
        throw new ResponseStatusException(400, "Nothing to hold");
```

```
    }
    AppointmentDto held;
    try {
        held = placeHold(client, clientName, ask);
    } catch (ResponseStatusException answered) {
        throw answered;
    } catch (IOException failed) {
        throw taken(client, ask.serviceId(), ask.locationId(), ask.start(), failed);
    } catch (RuntimeException failed) {
        throw taken(client, ask.serviceId(), ask.locationId(), ask.start(), failed);
    }
    changed(held, null);
    return held;
}
```

Placing the booking asks the engine again for that one start, then writes the parties and claims their cells:

```
/// Puts `a` at `start`: asks the engine, writes who and what it takes, and
/// claims their cells. A group service joins the slot's existing seat
/// count, or opens it.
private void place(Appointment a, Business business, Service service, Location location,
        long start, List<String> required, long now) throws IOException {
    List<Provider> candidates = availability.candidates(service, required);
    for (int iter = 0; iter < candidates.size(); iter++) {
        providers.hold(candidates.get(iter).getUsername());
    }
    ZoneId zone = ZoneId.of(location.getTimeZone());
    java.time.LocalDate day = Instant.ofEpochMilli(start).atZone(zone).toLocalDate();
    SlotEngine.Request request = availability.request(business, service, location, day,
            candidates, required, a.getClient(), now, a.getId());
    if (!offered(request.starts, start)) {
        throw new ResponseStatusException(400, "That is not a start this day offers");
    }
    request.starts = new long[] {start};
    request.explain = true;
    SlotEngine.Result result = SlotEngine.evaluate(request);
    SlotEngine.Slot slot = result.at(start);
    if (slot == null) {
        throw new ResponseStatusException(409, say(result.reason(start)));
    }
    a.setStartsAt(Instant.ofEpochMilli(start));

The app's slot picker shows the server's starts and adds the one thing the server can't know: with the calendar check on, a start that clashes with the client's own phone calendar is marked, though it can still be booked:

```
/// Choosing when: a service, who with, and a free start, by the day or the
/// week.
```

```
///
/// The free starts are the server's answer and nobody else's: the slot
/// engine has every provider's hours, bookings, buffers and connected
/// calendars, and the rules the business set. The phone adds one thing the
/// server cannot know -- the client's own calendar on this phone. With
/// "Check my calendar" on, a start that clashes with something there is
/// marked, though it can still be booked: the client knows whether that
/// dentist appointment can move.
///
/// The same screen moves an existing appointment: given one, a start is a
/// reschedule rather than a new hold.

66.7. Hours and schedules

A provider’s week is shifts on the five-minute grid. Saving new hours never moves a booking already made: hours decide what’s offered, not what was sold.

```
/// Replaces a provider's week. Shifts are on the five-minute grid, at an
/// open location, and do not overlap on one day. Bookings already made
/// keep their time: hours decide what is offered, not what was sold.
public WeekDto saveWeek(String username, WeekDto week) throws IOException {
```

```
    WeekDto saved = saveWeekTx(username, week);
    live.scheduleChanged(username);
    return saved;
}
```

```
private void save() {
    List<WorkingHoursDto> hours = new ArrayList<WorkingHoursDto>();
    for (int d = 0; d < 7; d++) {
        if (!open[d].isSelected()) {
            continue;
        }
        int start = starts[d].getTime();
        int end = ends[d].getTime();
        if (end <= start) {
            Ui.say(Lang.tr("{0} ends before it starts", Lang.tr(DAYS[d])));
            return;
        }
        hours.add(new WorkingHoursDto(null, location, d + 1, start, end));
    }
    Api.provider().saveHours(new WeekDto(hours), Net.to(saved -> {
        Ui.say("Hours saved");
        form.getBackCommand().actionPerformed(null);
    }, Ui::fail));
}
```

The provider's day, week and agenda are one schedule read over a range, drawn as a timeline: a lane per day, the working hours as a band, bookings as blocks as long as they last, calendar busy time hatched and a line at the current time. The owner's day board is the same component with a lane per provider, so a gap reads the same on both.

The grid itself is the framework's `Scheduler`: the day and the week are its `DAY` and `WEEK` views, the board its `RESOURCE_DAY` view with a resource per provider. `Timeline` is the translation from Slate's data to the scheduler's — a shift becomes a background item, calendar busy time a blocked one, an appointment an event styled by its state — and the scheduler supplies the scrolling, the pinned hours and names, the zoom and the layout of bookings that overlap:

```
/// One provider's schedule for `days` days from `from`, the start of a day
/// on the device that asks.
///
/// The device's day is not the location's: midnight in Paris is 23:00 the
/// day before in London, and reading `from` as a London date answered a
/// Paris phone's "today" with yesterday. So the answer covers every day of
/// the location that the device's range touches, and the device keeps what
/// falls inside its own days.
@Transactional(readOnly = true)
public ScheduleDto schedule(String username, long from, int days) {
    Provider p = provider(username);
    int span = Math.max(1, Math.min(MAX_DAYS, days));
```

```
    ZoneId zone = zoneOf(p.getDefaultLocation());
    LocalDate first = Instant.ofEpochMilli(from).atZone(zone).toLocalDate();
    LocalDate last = Instant.ofEpochMilli(from + span * 86400000L - 1).atZone(zone)
            .toLocalDate();
    int touched = (int) (last.toEpochDay() - first.toEpochDay()) + 1;
    return schedule(p, first, Math.min(MAX_DAYS + 1, touched), zone);
}
```

```
/// The provider's home: their own time, by the day, the week or as an
/// agenda, with every appointment, every block a connected calendar says is
/// busy and the hours they work, merged into one timeline.
///
/// One request answers all of it (`/api/provider/schedule`), and the live

/// Time running down the page, one lane per day or per person: the hours a
/// provider works as a band, bookings as blocks as long as they last, busy
/// time from a calendar hatched, and a line at the current time.
///
/// It is the provider's day (one lane), their week (seven) and the owner's
/// board (a lane per provider), and all three are one `Scheduler` in a
/// different view. What this class adds is the translation: a lane becomes a
/// day or a `ScheduleResource`, a block a `ScheduleItem` of the kind that
/// draws it -- a band under the bookings, a hatched block, a booking a tap
/// opens. The scheduler does the rest: the pinned hours and lane titles,
/// scrolling both ways, pinch to zoom, bookings that overlap side by side.
///
/// Colours come from `theme.css`. `Scheduler`, `SchedulerGrid`,
/// `SchedulerHeader` and the others style the grid, and each item names the
/// style it is painted with -- `SvTimelineShift`, `SvTimelineBusy`,
/// `SvTimelineBooking`, `SvTimelineDone`, `SvTimelineNoShow` -- so dark mode
/// is a stylesheet change, as it is for every other screen.

66.8. Calendars, both ways

A provider's other commitments keep clients from booking over them, and their bookings appear in the calendar they already use. Slate reads busy time from four kinds of calendar and writes in two ways.

The phone's own calendars are read by the app, never the server: `DeviceSync` reads the events of the calendars the provider chose and uploads only busy intervals, so the server never sees what an event is called.

```
/// The phone's own calendars, through `com.codename1.calendar`.
///
/// Three things are asked of them, and nothing else:
///
/// - **busy time**, as free/busy intervals and never as events: a client is
///   warned that a slot clashes with their own day, and a provider's busy time
///   is uploaded so nobody books over it. A title, a place or a guest never
///   leaves this class.
/// - **adding an appointment**, with an alarm ahead of it, once it is booked.
/// - **keeping that event true** when the appointment moves or is cancelled.
///
/// Each asks for access the first time it needs it, which is when the user
/// has just tapped the thing that needs it: the platform's prompt then makes
/// sense. Every answer arrives on the EDT.
public final class DeviceCalendar {

}
```

The development profile simulates both services. On a real deployment the choice is made from configuration:

```
/// The calendars the server reads for providers.
///
/// - Google: `slate.calendar.google.id` and `slate.calendar.google.secret`,
///   an OAuth client of type "Web application" with the Calendar API on and
///   the `calendar.freebusy` scope.
/// - Microsoft: `slate.calendar.microsoft.id` and
///   `slate.calendar.microsoft.secret`, an Entra app registration with the
///   delegated `Calendars.ReadBasic` and `offline_access` permissions.
/// - A published iCalendar feed needs nothing.
///
/// On a development profile a kind with no client is simulated, so the
/// demo connects calendars without an account anywhere. Elsewhere it is
/// not offered. `slate.timezone` is the zone a feed's all-day events and
/// the simulated busy time are read in.
@Bean
public CalendarSources calendarSources(Config config,
        @Value("${slate.calendar.google.id:}") String googleId,
        @Value("${slate.calendar.google.secret:}") String googleSecret,
        @Value("${slate.calendar.microsoft.id:}") String microsoftId,
        @Value("${slate.calendar.microsoft.secret:}") String microsoftSecret,
        @Value("${slate.timezone:Europe/London}") String zone) {
    return new CalendarSources(googleId.trim(), googleSecret.trim(), microsoftId.trim(),
            microsoftSecret.trim(), config.isDevelopmentProfile(), Catalog.zone(zone));
}
```

A published ICS address is fetched on a schedule, the same way.

Writing goes the other way. Every provider has a calendar feed any calendar app can subscribe to, and every appointment has an `.ics` file a client can open:

```
/// A whole calendar of `events`, with CRLF line ends and long lines folded.
public static String write(String name, List<Event> events) {
    StringBuilder out = new StringBuilder();
    line(out, "BEGIN:VCALENDAR");
    line(out, "VERSION:2.0");
    line(out, "PRODID:-//Codename One//Slate//EN");
    line(out, "CALSCALE:GREGORIAN");
    line(out, "METHOD:PUBLISH");
    line(out, "X-WR-CALNAME:" + text(name));
    String stamp = UTC.format(Instant.now());
    for (int iter = 0; iter < events.size(); iter++) {
        Event e = events.get(iter);
```

```
        line(out, "BEGIN:VEVENT");
        line(out, "UID:" + e.uid + "@slate");
        line(out, "DTSTAMP:" + stamp);
        line(out, "DTSTART:" + UTC.format(Instant.ofEpochMilli(e.start)));
        line(out, "DTEND:" + UTC.format(Instant.ofEpochMilli(e.end)));
        line(out, "SUMMARY:" + text(e.summary));
        if (e.description.length() > 0) {
            line(out, "DESCRIPTION:" + text(e.description));
        }
        if (e.location.length() > 0) {
            line(out, "LOCATION:" + text(e.location));
        }
        if (e.url.length() > 0) {
            line(out, "URL:" + e.url);
        }
        line(out, "STATUS:" + (e.cancelled ? "CANCELLED" : "CONFIRMED"));
        if (e.alarmMinutes > 0 && !e.cancelled) {
            line(out, "BEGIN:VALARM");
            line(out, "ACTION:DISPLAY");
            line(out, "DESCRIPTION:" + text(e.summary));
            line(out, "TRIGGER:-PT" + e.alarmMinutes + "M");
            line(out, "END:VALARM");
        }
        line(out, "END:VEVENT");
    }
    line(out, "END:VCALENDAR");
    return out.toString();
}
```

A client can also add a booking straight to their phone's calendar. The app keeps the ids of the events it wrote, so moving a booking moves its own event and a cancellation removes it:

```
/// Adds `a` to the phone's default calendar with an alarm `alarmMinutes`
/// ahead, or moves the event added for it before. Answers whether it is
/// there now.
public static void save(final AppointmentDto a, final String title, final int alarmMinutes,
        final Answer<Boolean> done) {
    authorize(CalendarAccess.EVENTS_WRITE_ONLY, ok -> {
        if (!ok.booleanValue()) {
            done.answer(Boolean.FALSE);
            return;
        }
        ZoneId zone = ZoneId.systemDefault();
        CalendarEvent event = new CalendarEvent()
                .setTitle(title)
                .setLocation(a.online() ? a.meetingUrl() : a.locationName())
                .setDescription(a.icsUrl() == null ? "" : a.icsUrl())
                .setStart(CalendarDateTime.instant(Instant.ofEpochMilli(a.start()), zone))
                .setEnd(CalendarDateTime.instant(Instant.ofEpochMilli(a.end()), zone))
                .setAvailability(CalendarEvent.Availability.BUSY)
                .putProviderData("slate.appointment", a.id());
```

```
        String known = eventOf(a.id());
        int bar = known.indexOf('|');
        if (bar >= 0) {
            event.setCalendarId(bar > 0 ? known.substring(0, bar) : null);
            event.setId(known.substring(bar + 1));
        }
        if (alarmMinutes > 0 && source().getCapabilities().supports(CalendarCapability.ALARMS)) {
            event.addAlarm(new CalendarAlarm().setTimeBefore(Duration.ofMinutes(alarmMinutes)));
        }
        source().saveEvent(event, CalendarMutationScope.THIS_INSTANCE)
                .ready(saved -> later(() -> {
                    if (saved != null && saved.getId() != null) {
                        String calendar = saved.getCalendarId() == null ? ""
                                : saved.getCalendarId();
                        Preferences.set(EVENT_PREFIX + a.id(), calendar + "|" + saved.getId());
                        index(a.id(), true);
                    }
                    done.answer(Boolean.TRUE);
                }))
                .except(failed -> later(() -> done.answer(Boolean.FALSE)));
    });
}
```

66.9. Deposits

A deposit is a part of the price, authorized on the card about six days before the appointment (at once when booking is closer than that) and taken when a client cancels late or doesn't come. Payments go through the same `PaymentProvider` as the other samples:

```
public interface PaymentProvider {
    /// `simulated` or `stripe`: what the app is told, so it knows how to add a
    /// card.
    String name();

    /// Opens the processor's record of a customer and returns its reference.
    String createCustomer(String username, String displayName) throws IOException;

    /// Deletes the processor's record of a customer, and the cards saved to it
    /// with it. A record that is already gone is deleted: this is asked again
    /// when the first answer was lost.
    void forgetCustomer(String customer) throws IOException;

    /// Begins saving a card to `customer`. `setupId` is the server's own id
    /// for the attempt, for the processor to hand back.
    Setup startCardSetup(String customer, String setupId) throws IOException;

    /// Finishes a setup and returns the card it saved.
    ///
    /// @param reference what [#startCardSetup] returned as the setup's reference
    /// @param typed the card as typed into the app, for a processor whose setup
    ///     is not hosted; ignored by one whose setup is
    /// - `PaymentDeclinedException`: when the card was refused or the setup was
    ///   not finished
```

```
    Card finishCardSetup(String customer, String reference, CardDto typed) throws IOException;

    /// Takes a saved card off `customer`, so that it can't be charged again.
    /// A card that is already off, or gone, is detached: this is asked again
    /// when the first answer was lost.
    ///
    /// @param token what [#finishCardSetup] returned as the card's token

66.11. Tests

```
cd scripts/slate
# The server's tests on the JVM, then compiled to a native binary
mvn -Dcodename1.platform=backend -pl shared,backend test -Dcn1.backend.compiledTests=true
# The same tests on PostgreSQL or MySQL
CN1_TEST_DATABASE_URL="postgres://user:password@localhost:5432/db?sslmode=disable" \
  ../ci/sample-server-tests-on-database.sh .
# The app against a running server, in the simulator
./run-e2e.sh
./run-e2e.sh --native
# The app in a headless browser, served by the server
./run-web-e2e.sh
```

The slot engine’s rules are tested one at a time, against the engine alone, and again end to end

through the booking service. `run-e2e.sh` starts the server and drives the app in the simulator as a client, a provider and an owner. `sample-server-tests-on-database.sh` runs the server tests against PostgreSQL or MySQL. CI runs all them, in `.github/workflows/slate.yml`.

66.12. Making it yours

- **Your business.** Replace `DemoBusiness` with your locations, services, people and resources, or create them from the owner's screens on an empty database:

```
/// The business a server starts with.
///
/// Everywhere, the business row itself, since nothing can be booked without
/// one: named, in `slate.timezone`, with the rules a small business would
/// start from. On a development profile also everything a demo needs -- two
/// locations twenty minutes apart, a handful of services of the vertical
/// `slate.demo.vertical` names (`SALON`, `TUTOR`, `TRAINER`, `CONSULTANT` or
/// `CLINIC`), three providers with a working week, the rooms or chairs, four
/// weeks of history and a few bookings to come.
///
/// The bookings to come are made through [Bookings] like any client's, so the
/// demo starts with nothing the slot engine would not have allowed. The
/// `test` profile gets the business and no bookings: each test books its own.
```

- **Your vertical.** A row in `Verticals` and, for the demo, a set of services.
- **Your brand.** Colors and shapes are in `common/src/main/css/theme.css`, text in `common/src/main/l10n`.
- **What it leaves out.** Slate books single appointments. Packages and memberships, gift cards, reviews, recurring appointments, intake forms beyond the one question a service can ask, tips and staff commission aren't included; each is a table and a screen on top of the booking rules, which stay as they are.
- **Your rules.** Every gap rule is a column of the business that the owner edits and previews; the engine is where a new rule goes, with a reason to report.

66.13. Before it's a product

The sample is complete as a demonstration. A product needs at least:

- **Recurring events in ICS calendars.** A published calendar's repeating events (`RRULE`) aren't expanded; only single events count as busy. Google and Microsoft expand them on their side, so those are right.
- **Encrypted calendar credentials.** Refresh tokens and ICS addresses are stored as they are. Encrypt them at rest, with a key outside the database, and let a provider revoke them.
- **Safe fetching of calendar addresses.** The server fetches whatever ICS address a provider types. Restrict it to public `https` addresses, refuse private and loopback networks, and cap the size and time of each fetch.

- **Stricter concurrency on the daily rules.** Cells make a double booking impossible, but a provider's daily cap, their breaks and travel time, and a client's bookings per day are checked by the engine before the claim. Two bookings placed in the same instant for different times can both pass. The hold narrows the window; a product that must never exceed them takes a lock per provider and client day.
- **Tested late cancellation and no-show fees.** Taking a deposit is simulated and hasn't been tested against a real processor's capture and refund flows.
- **A real payment processor and PCI scope.** Wire `PaymentProvider` to your processor and test it with its test keys. Keep card entry on the processor's hosted page, confirm your PCI DSS self-assessment, and add receipts, tax, refunds and disputes.
- **Reviewed translations.** The non-English bundles are machine translations; have them reviewed before release.
- **Operations.** Monitoring, backups that have been restored in a test, a support process, and a channel between server instances before you run more than one.

Device and platform services

Chapter 67. Push notifications

For new integrations, Codename One push uses a typed message envelope and an explicit client binding. Your main application class doesn't implement a push interface. Existing applications using `PushCallback` can keep that integration; see Migrate an existing push server before changing their payload format. The same application code receives messages from Android, iOS, Huawei devices, and supported web browsers.

You can use the managed BuildCloud service or install an adapter for custom native push. A custom-provider adapter is a low-level escape hatch: it bypasses BuildCloud registration and delivery completely, so your server owns tokens, credentials, targeting, retries, and provider errors.

That choice reroutes both halves of the journey, registration and delivery, and leaves the application code alone. The rest of this chapter fills in each box.

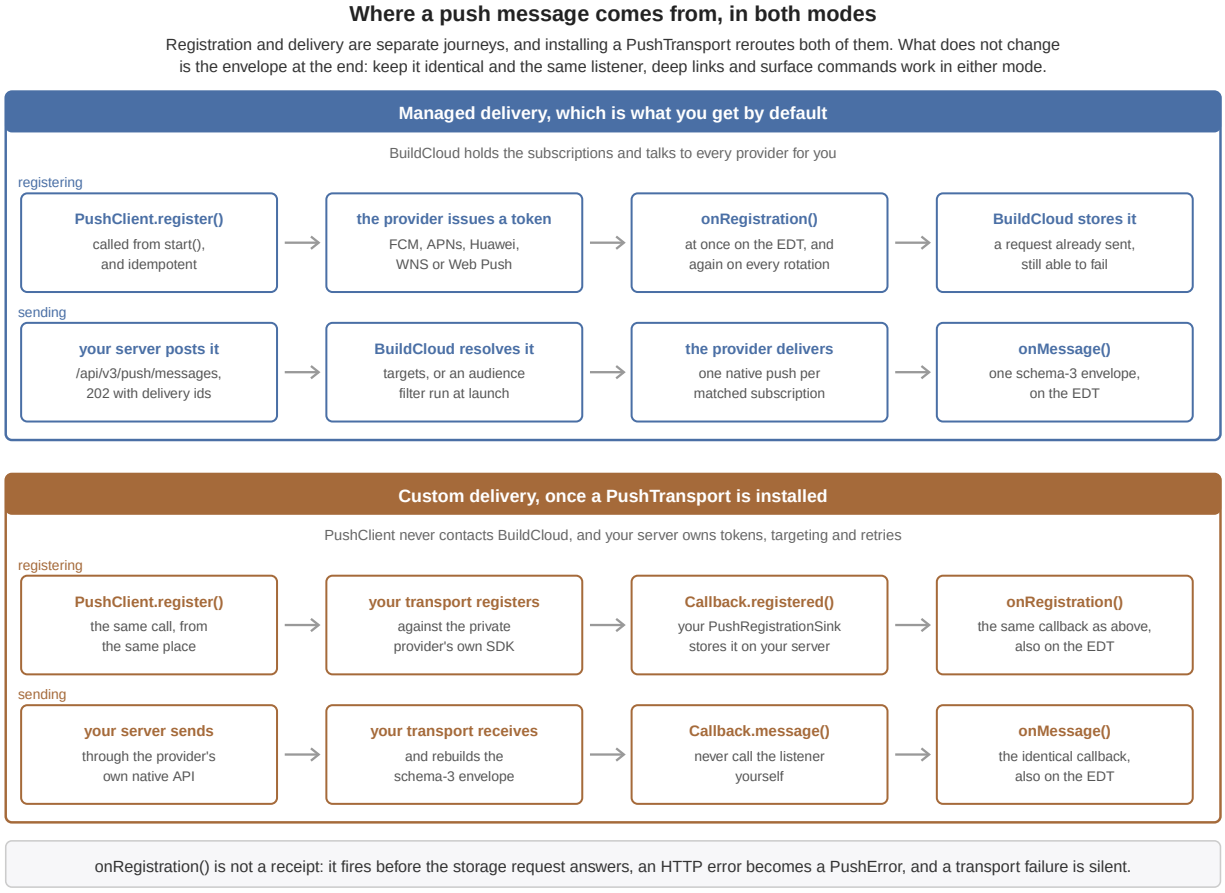

Figure 356. Registration and delivery, managed and custom

67.1. Create and configure an application

Open the Codename One Console [https://cloud.codenameone.com/console/] in the organization that owns the application. Create one Push application for each logical application and environment. Keep production and staging separate so credentials, audiences, and analytics remain isolated.

1. Open **Push** > **Settings**. Enter a name under **Applications** and select **Create application**.
2. Use the **Selected application** picker at the top of the Push page to select that application.

Settings can also list applications registered by the classic API. If the application isn't among those loaded, use **Load more** in Settings, then return to the picker.

3. Open the Android or iOS provider tab under **Native push providers**, paste the credential JSON described below, and save it.
4. Check **Configured** in Settings or **Ready** under **Push** > **Overview** > **Channel readiness** for the same selected application. These labels mean a credential is stored; a real test send is still needed to verify provider authentication and device delivery.

Use the following identifiers for their separate purposes:

Value	Where to find it	Where to use it
Application UUID	**Push** > **Overview** > **Server API** > **Copy ID**	The `appId` field in a V3 server send. It isn't the mobile package name, Apple bundle ID, or client binding key.
Client binding key	**Push** > **Overview** > **Client binding**	`PushClient.builder()` and client registration. It can't authorize a server send.
Server API key	**Account** > **Server API keys**	`Authorization: Bearer` or `X-API-Key` on your server. Create it with the `push` scope; the classic push token is a separate credential.

Select any readiness card, including a green **Ready** card, to open Settings on that provider's tab.

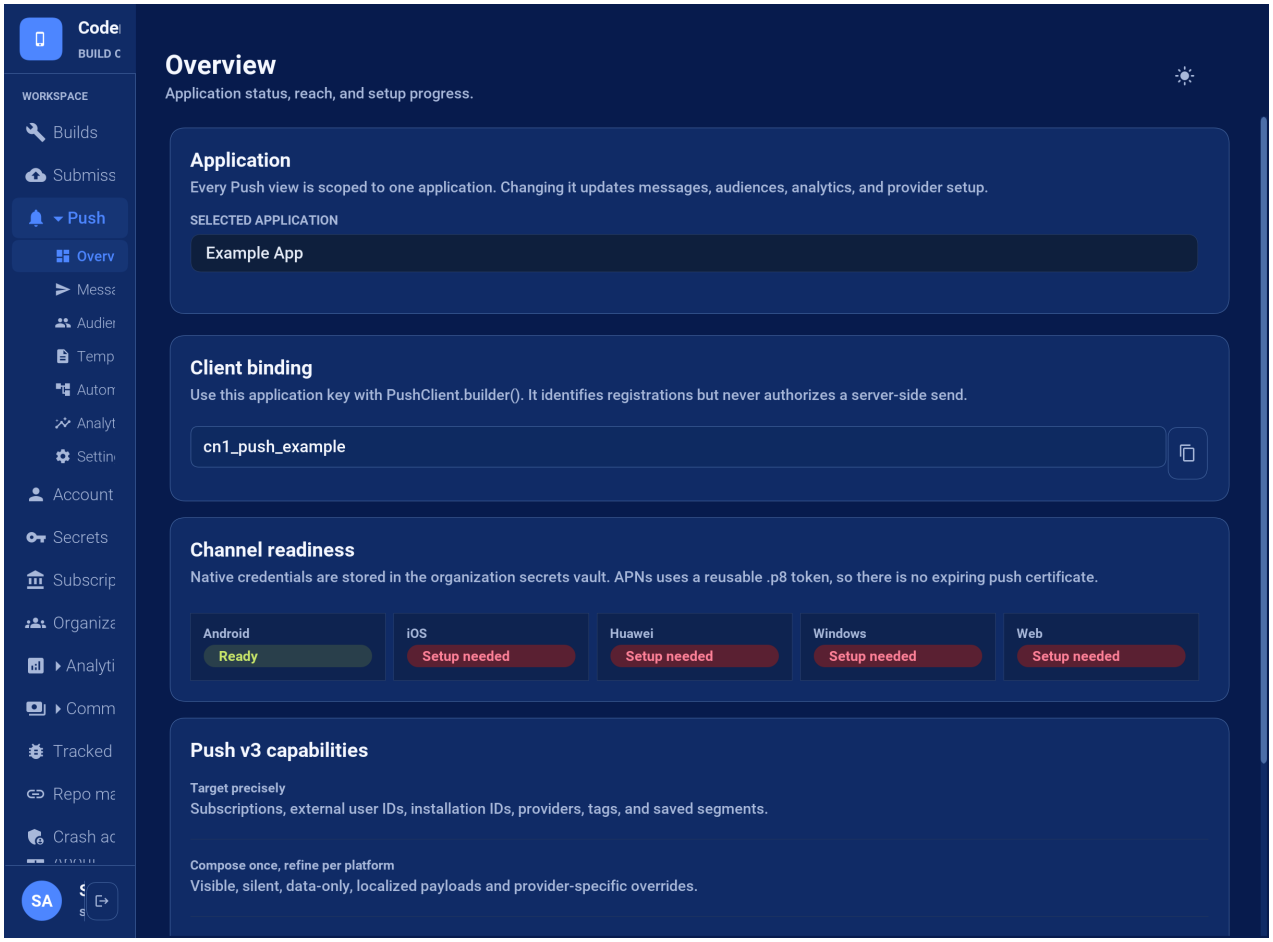

Figure 357. Push Overview shows the client binding and provider readiness cards

67.1.1. Android: Firebase service-account JSON

1. In the Firebase project used by the installed Android app, open **Project settings** > **Service accounts** and select **Generate new private key**.
2. Open the downloaded service-account JSON file locally and copy the complete JSON object.
3. In **Push** > **Settings** > **Native push providers** > **Android**, paste it into **Credential JSON** and select **Save Firebase Cloud Messaging credential**.

The server credential contains `project_id`, `client_email`, and `private_key`. Android's `google-services.json` configures the mobile app and can't authenticate server sends. Keep the service-account private key on the server; don't bundle it into the app or paste it into a support thread.

67.1.2. iOS: APNs key and credential JSON

Create an APNs authentication key in Apple Developer Certificates, Identifiers & Profiles [https://developer.apple.com/help/account/capabilities/communicate-with-apns-using-authentication-tokens/]. Download its `.p8` file and note the key ID and your Apple team ID. Use the bundle ID of the installed app as `topic`.

The Console's **Credential JSON** field expects a JSON object containing those values. It doesn't accept the raw `.p8` file by itself. Replace the placeholders in this example:

```
{
  "teamId": "YOUR_APPLE_TEAM_ID",
  "keyId": "YOUR_APNS_KEY_ID",
  "topic": "com.example.app",
  "environment": "production",
  "privateKey": "-----BEGIN PRIVATE KEY-----\nYOUR_COMPLETE_P8_KEY_CONTENTS\n-----END PRIVATE KEY-----\n"
}
```

`privateKey` contains the entire `.p8` text, including the BEGIN/END lines. Within the JSON string, encode each line break as `\n`; literal line breaks inside a quoted JSON value are invalid. Use `environment: "production"` for App Store and TestFlight installations, and `"sandbox"` for development-signed installations. The bundle ID, Apple team, environment, and device token must belong to the same app installation.

In **Push** > **Settings** > **Native push providers** > **iOS**, paste the completed object and select **Save Apple Push Notification service credential**. Token authentication uses the APNs signing key instead of an expiring push certificate.

67.1.3. Other providers and saved status

- **Huawei**: save the AppGallery Connect application ID and client secret. Add `agconnect-services.json` to the project.
- **Windows / WNS**: save the Package SID and client secret associated with the Store identity.
- **Web Push**: save the VAPID public and private keys and subject.

The managed backend includes WNS delivery for explicit Windows targets. It doesn't revive or

generate bindings for the unsupported UWP port.

Credentials are encrypted in the BuildCloud secrets vault and are write-only. The input is cleared after saving and stays blank when you return to the page. Check the saved-status label for the same selected application instead of expecting the secret to reappear. If the status says **Not configured** or **Status unavailable**, check the selected application and organization and report any error. Rotate a credential by saving its replacement.

67.1.4. Prepare a new client build

Cloud builds detect `PushClient` usage and generate the typed native bootstrap automatically. On Android, include `google-services.json`, `agconnect-services.json`, or both. A build with both configurations uses FCM when Google Play Services are available on the device and falls back to Huawei Push Kit otherwise. No provider-selection build hint is required. Devices without Google Play Services or HMS Core, such as GrapheneOS and LineageOS, can receive through UnifiedPush with the Web Push credential; see Android without Google Play Services. The `android.messagingService=fcm` and `android.messagingService=huawei` hints remain available only when an application intentionally needs to force one provider.

iOS enables push support automatically when `PushClient` is referenced; set `ios.includePush=false` only when an installed custom-provider adapter intentionally owns registration.

The Console displays an application key. This key identifies an application during device registration; it isn’t a server API key and doesn’t authorize sending messages. Keep send API keys on your server.

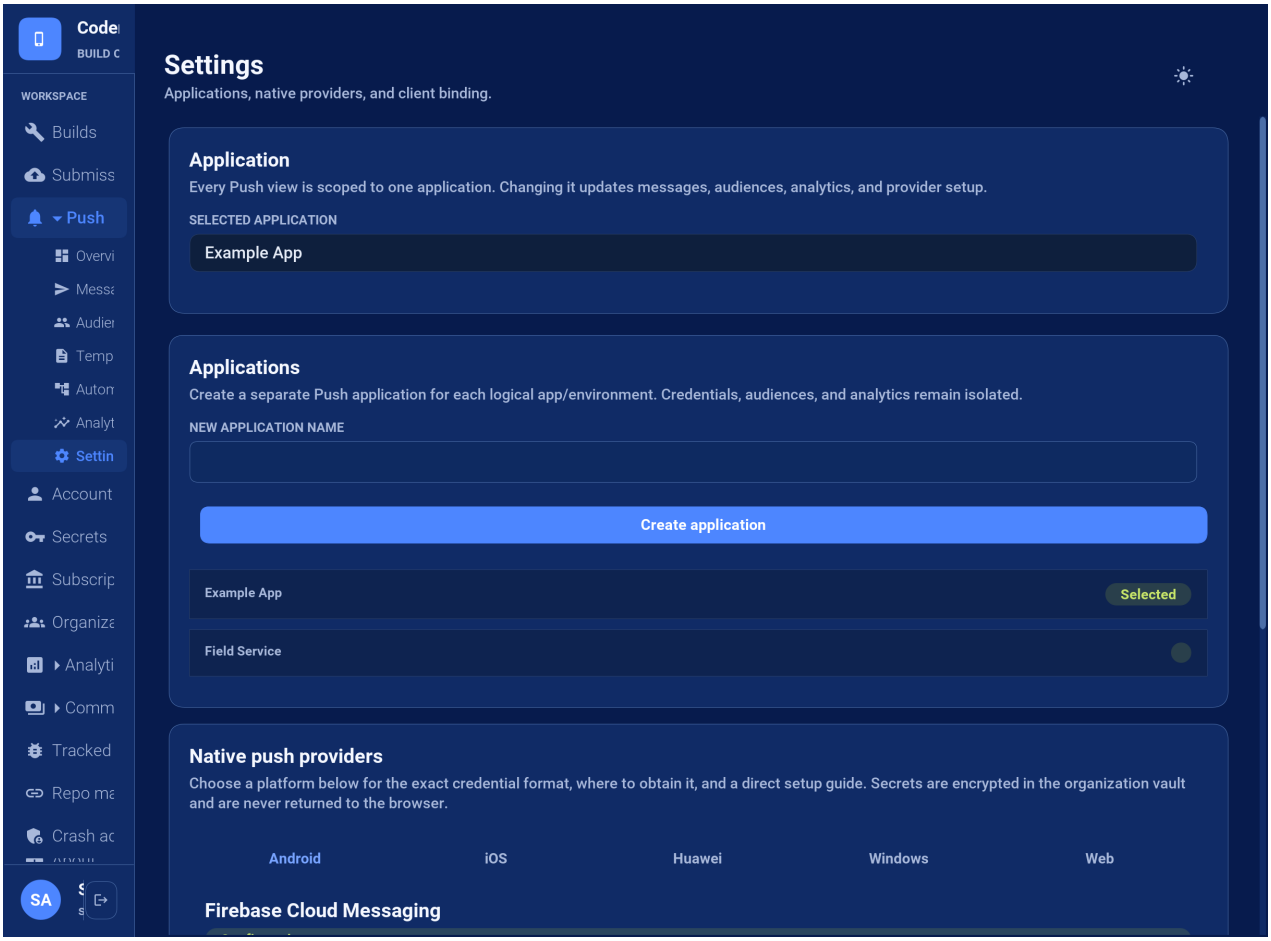

Figure 358. Provider Settings explains each credential and links to the provider console

67.2. Bind the client

Create one `PushClient` in `init()`, retain it in a field on the main application class, and call `register()` from `start()` after showing any permission rationale required by your UX:

```
private PushClient push;

public void init(Object context) {
    push = PushClient.builder("cn1_push_application_key")
            .listener(new PushListener() {
                @Override
                public void onRegistration(PushSubscription subscription) {
                    Log.p("Push ready on " + subscription.getTransportId());
                }

                @Override
                public void onMessage(PushMessage message) {
                    if (message.getDeepLink() != null) {
                        Log.p("Route to " + message.getDeepLink());
                    }
                }

                @Override
                public void onError(PushError error) {
```

```
                    Log.p(error.getCode() + ": " + error.getMessage());
                }
            })
            .build();
}

public void start() {
    push.register();
}

public void stop() {
    // Keep the subscription and listener active while the app is paused.
}

public void disableNotifications() {
    // Use only for an explicit user opt-out.
    push.unregister();
}
```

`start()` can run more than once during one process lifetime. `register()` is idempotent, so the example can call it on every start without creating duplicate native registrations. Don't call `unregister()` from `stop()`: it removes the device subscription. Call it only for an explicit user opt-out or account-removal workflow.

Registration is asynchronous. With managed delivery, the framework registers the native token with BuildCloud automatically. `PushSubscription` exposes the transport identifier, opaque native token, platform, installation ID, expiry, and capability list for diagnostics. Application code shouldn't parse the token or use it as a user identity.

On Android, the native bootstrap can obtain and persist an FCM or Huawei token before `start()` installs the `PushClient` callback. `register()` replays that persisted token after activating the listener and then asks the provider to refresh it, so the documented `init()`/`start()` lifecycle doesn't lose early registration.

67.2.1. Listener lifecycle and early messages

`PushClient.Builder.listener()` is mandatory, and `build()` fails immediately if it's missing. The client retains that listener until deregistration completes. Codename One doesn't locate listeners with reflection or `Class.forName()`: the application must build, retain, and register the client explicitly. Only one `PushClient` can be active in a process; a second client reports an `active_client` error instead of replacing the first listener.

Every `PushListener` and `PushRegistrationSink` callback runs on the Codename One EDT:

- `onRegistration()` runs after initial native registration and can run again when a provider rotates its token. Replace the previous server-side token for that installation.
- `onMessage()` receives one parsed schema-3 envelope. A foreground notification can arrive immediately. A visible background notification normally arrives after the user opens it.
- `onError()` reports registration and envelope errors. Use `PushError.getCode()` for decisions;

diagnostic text isn't a stable contract.

Native ports preserve a cold-start notification until the runtime can deliver it. If the runtime starts before the application calls `register()`, `PushClient` keeps a bounded process-local queue and replays it after activation. If the application never registers its client, it has provided no listener and can't expect application callbacks. Silent/background execution remains subject to each OS's power and scheduling rules, so refresh authoritative state whenever the application resumes.

67.3. Build a message

`PushMessage` is the canonical message model on both sides of the wire:

```
PushMessage message = PushMessage.builder()
        .title("Order shipped")
        .body("Order 4815 is on its way")
        .deepLink("myapp://orders/4815")
        .imageUrl("https://example.com/orders/4815.png")
        .collapseKey("order-4815")
        .ttlSeconds(3600)
        .data("orderId", "4815")
        .build();
```

Common fields have consistent meanings on every provider. Add provider-specific settings under the `platform` object only when the common model isn't sufficient. Unknown settings are ignored by unrelated providers.

```
{
  "schema": 3,
  "title": "Order shipped",
  "body": "Order 4815 is on its way",
  "deepLink": "myapp://orders/4815",
  "collapseKey": "order-4815",
  "ttl": 3600,
  "data": { "orderId": "4815" },
  "platform": {
    "apns": { "badge": 3, "sound": "default", "interruptionLevel": "time-sensitive" },
    "fcm": { "channelId": "orders", "priority": "high" },
    "huawei": { "channelId": "orders", "importance": "HIGH" },
    "wns": { "type": "toast" },
    "web": { "urgency": "high" }
  }
}
```

Don't place secrets or irreplaceable data in a notification. Providers, operating systems, and lock-screen UI may retain or expose payloads.

67.4. Send from a server

Open **Account** > **Server API keys**, enter a key name, select the `push` scope, and select **Create server key**. Copy the key when it's shown; it won't be displayed again. Keep it on your server. Authenticate with `Authorization: Bearer YOUR_SERVER_API_KEY` or `X-API-Key: YOUR_SERVER_API_KEY`; the existing classic push token won't authenticate V3 requests.

Copy the selected application's UUID from **Push** > **Overview** > **Server API** > **Copy ID**. Put that UUID in `appId`, then submit a typed message and one or more provider targets to `POST /api/v3/push/messages`:

```
curl -X POST https://cloud.codenameone.com/api/v3/push/messages \
  -H 'Authorization: Bearer YOUR_SERVER_API_KEY' \
  -H 'Content-Type: application/json' \
  -d '{
    "appId": "APPLICATION_ID",
    "targets": [
      {"provider":"fcm", "token":"OPAQUE_DEVICE_TOKEN"},
      {"provider":"apns", "token":"OPAQUE_DEVICE_TOKEN"}
    ],
    "message": {
      "schema":3,
      "title":"Order shipped",
      "body":"Order 4815 is on its way",
      "data":{"orderId":"4815"}
    }
  }'
```

A successful admission returns HTTP `202` with durable delivery IDs. Invalid targets are deactivated when the provider identifies them as permanent failures.

The complete request, response, authentication, error, target, and message schemas are in the Push sending OpenAPI 3.0 specification [https://cloud.codenameone.com/openapi/push-v3.yaml]. Import that file into Swagger UI, an OpenAPI code generator, or an API client instead of reproducing DTOs from this chapter.

A Chapter 35, *Server-side backend* doesn't need to build this request: `CloudPush` sends a typed message, Live Activity commands included, as Section 36.5, "Sending push notifications" describes.

Use the Console for operator-driven messages, stored audiences, campaigns, analytics, and automations.

67.5. Migrate an existing push server

There are two migration paths. Choose one wire format for each request:

Path	Endpoint and request	Authentication and installed apps
Keep the classic API	`https://cloud.codenameone.com/push/push`, with the existing form-encoded fields	Keep the classic `token`, provider credentials, and installed `PushCallback` apps.
Move the server to V3	`https://cloud.codenameone.com/api/v3/push/messages`, with a JSON body	Use a server API key with `push` scope, the application UUID, saved provider credentials, and `message.classic` for installed `PushCallback` apps.

For the classic path, change only the host of the existing `/push/push` URL. Keep fields such as `token`, `device`, `type`, `body`, `auth`, `cert`, `certPassword`, and `production`. Don't post these form fields to `/api/v3/push/messages`. A Java URL string must contain the plain URL, without Markdown brackets or parentheses.

For a server-only V3 migration, configure credentials for the same Firebase project and Apple bundle ID/environment as the installed apps. Keep existing device keys and select the explicit classic payload:

```
{
  "appId": "YOUR_APPLICATION_UUID",
  "targets": [
    {"provider": "fcm", "token": "cn1-fcm-YOUR_ANDROID_DEVICE_TOKEN"},
    {"provider": "apns", "token": "cn1-ios-YOUR_IOS_DEVICE_TOKEN"}
  ],
  "message": {
    "schema": 3,
    "classic": {"type": 1, "body": "Hello"}
  }
}
```

Send this JSON with the same headers as the V3 curl example above. Replace each target with a real device key for that provider. Existing `cn1-fcm-`, `cn1-gcm-`, and `cn1-ios-` prefixes are accepted. Keep the numeric push `type` and body encoding used by your existing sender; the example uses type 1 for a simple message.

`message.classic` produces the fields consumed by installed `PushCallback` clients. It doesn't require `platform.fcm`/`platform.apns` overrides, a `PushClient` integration, or a new mobile release. Don't combine `classic` with the ordinary V3 message fields. Use ordinary V3 messages for clients that have adopted `PushClient`.

Before changing production traffic, send to installed Android and iOS test apps. Verify foreground delivery, background delivery, notification taps, and any other push types your application uses.

67.5.1. Interpret the response

HTTP `202` means the request was admitted to the durable queue. Its JSON response contains `deliveryIds` and `quota`; it doesn't mean the provider or device has accepted the message yet. Use

delivery feedback and analytics for later outcomes.

- **401**: check the server API key, its `push` scope, and the authentication header. A classic push token or client binding key isn't a V3 server key.
- **400**: read the JSON error, check that `appId` is the selected application UUID, and check the request or credential format. For the classic endpoint, `credential URL returned HTTP 404` means a URL supplied in `auth` or `cert` couldn't be fetched. Firebase `auth` can also contain the complete service-account JSON directly.
- **406 after a notification arrives**: this isn't a successful API response, and changing the message format or resending can duplicate the notification. Report the UTC request time, endpoint, response body, and `CF-RAY` header when present, without including credentials or device tokens. The expected successful V3 response remains `202` with delivery IDs.

67.6. Learn which sends failed

A notification is acknowledged when it's admitted, not when it arrives. Both wire APIs answer before any provider has been asked — the classic endpoint replies `queued` — so the verdict lands seconds later, after your request has already returned. Nothing in the response can tell you that a device key is dead, and a dead key stays in your database being sent to.

Delivery feedback closes that. Configure an HTTPS endpoint and BuildCloud posts a signed digest of the outcomes since the last one, once a day. It's available on Pro and above, and it's configured per organization rather than per application: callers on the classic API register an application per send, so there is nothing stable there to attach a setting to.

Open **Push** > **Settings** > **Delivery feedback**, enter the endpoint, enable the daily digest, and select **Send test event**. The test posts one synthetic event through the same signing and sending path as a real digest and reports what your endpoint answered, so a broken receiver is visible immediately rather than a day later. The signing secret is on the same card.

67.6.1. What arrives

Failures are itemized and successes are counted. A busy application produces thousands of accepted deliveries a day and nothing can be done about any of them, so listing them would bury the handful of events that matter.

```
{
  "version": 1,
  "organization": "9f1c2f7a-2f6e-4a5b-9d71-3f0a7c1d5e22",
  "generatedAt": 1790179200000,
  "window": {"from": 1790092800000, "to": 1790179200000},
  "summary": {
    "fcm":  {"ACCEPTED": 7412, "FAILED": 1},
    "apns": {"ACCEPTED": 3310},
    "web":  {"DEAD": 1}
  },
  "events": [
    {
```

```
      "deliveryId": "6f0f6f1e-9a1e-4f2a-9a7a-6d5f5f6a1b02",
      "device": "cn1-fcm-fH9c...Qk",
      "token": "fH9c...Qk",
      "provider": "fcm",
      "status": "FAILED",
      "reason": "INVALID_TARGET",
      "attempts": 1,
      "at": 1790178322418,
      "detail": "{\"error\":{\"code\":404,\"status\":\"NOT_FOUND\"}}"
    },
    {
      "deliveryId": "d2b1a0c4-1f77-4a4d-9d0e-2c5b7a91f3aa",
      "device": "cn1-web-https://push.example.com/sub/9?p256dh=KEY&auth=AUTH",
      "endpoint": "https://push.example.com/sub/9",
      "provider": "web",
      "status": "DEAD",
      "reason": "TRANSIENT_FAILURE",
      "attempts": 6,
      "at": 1790178901004,
      "detail": "gave up after repeated 503 responses"
    }
  ],
  "truncated": false,
  "eventsOmitted": 10722
}
```

`reason` is the provider-independent verdict, and it decides what you do:

`INVALID_TARGET`	The provider rejected the key. Delete it from your database; it will never work again.
`PERMANENT_FAILURE`	The provider refused the message or the credential. Fix the send, keep the key.
`TRANSIENT_FAILURE`	Retried until the attempt budget ran out. `status` is `DEAD`. The key may still be good.

Store the canonical provider and bare `token` (or web-push `endpoint`) in separate columns alongside the original key returned by `Push.getPushKey()`. The full key has a `cn1-<provider>-` prefix, so comparing it directly with the digest's bare token matches no row. Normalize `gcm` to `fcm` and `ios` to `apns` during registration and backfill existing rows before enabling cleanup. For web push, store the subscription endpoint in its own column. Match feedback on the provider and this normalized target, scoped to the organization. Keep the full original key for sending.

67.6.2. Semantics to build against

- **A digest is at-least-once.** Deduplicate on `deliveryId` when present. For classic events without it, use a key built from the provider, token or endpoint, and event timestamp `at`. A refused digest is resent, and a network failure can deliver one whose response never arrived.
- **Only 2xx acknowledges the window.** It advances the watermark and that window is never

sent again, so answer 2xx after your writes are durable, not before. Anything else, including a timeout, keeps the window for the next attempt.

- `truncated` **means more is waiting.** A digest is capped, and the next page follows in the same run rather than a day later. Expect several digests in quick succession after a bad day.
- **A failing endpoint is retried, then disabled.** Failures are retried on a shorter cadence than the daily digest; after several consecutive failures the endpoint is disabled and the reason appears on the Settings card. Re-enabling it clears the count.
- `eventsOmitted` **counts accepted deliveries**, which appear only in `summary`.
- **One digest can span applications.** The endpoint belongs to the organization, so a receiver that keeps a device store per application correlates on `deliveryId` — the id the v3 send returned — or on the device key itself, which providers issue per application. A classic send returns no delivery id, so for those the key is the correlation.

67.6.3. Verify the signature

Every request carries `X-CN1-Signature: t=<unix-millis>,v1=<hex>`, where the hex is HMAC-SHA256 over `<t>.<raw body>` keyed with your signing secret. The timestamp is inside the signed material, so a captured digest can be rejected by age as well as shown to come from BuildCloud.

Three things are easy to get wrong, and each one fails without a symptom or fails open:

1. **Sign the bytes you received.** Any middleware that parses JSON and re-serializes it produces a different byte string that never verifies.
2. **Compare in constant time.** A comparison that returns on the first differing byte leaks enough timing to recover a valid signature.
3. **Reject old timestamps.** Without an age bound the signature alone permits replay forever.

67.6.4. A Codename One backend receiver

The Chapter 35, *Server-side backend* takes the raw request when a handler needs the exact body, which is what signature verification requires:

```
@RestController
@RequestMapping("/push")
public class PushFeedback {

    /**
     * Your organization-scoped durable store. Store provider and bare token (or
     * web endpoint) alongside the original push key; backfill existing rows before
     * enabling cleanup. Both operations belong in ONE transaction: a marker
     * written before the deletion commits turns a retry into a silent skip,
     * and a deletion without a marker is applied twice.
     */
    public interface DeviceStore {
        boolean alreadyApplied(String eventKey);

        // provider + target match normalized registration columns, NOT Push.getPushKey().
        // Enforce a unique eventKey and delete in the same transaction.
```

```
        void removeTargetAndMarkApplied(String eventKey, String provider, String target)
                throws Exception;
    }

    private final DeviceStore store;

    /** The signing secret shown in Push > Settings. */
    private final String secret;

    /**
     * Both are injected: the store is your bean implementing DeviceStore, and
     * the secret is read from cn1.push.callbackSecret, which the environment
     * variable CN1_PUSH_CALLBACKSECRET overrides.
     */
    public PushFeedback(DeviceStore store,
                        @Value("${cn1.push.callbackSecret}") String secret) {
        this.store = store;
        this.secret = secret;
    }

    /** Reject a digest whose timestamp is older than this, to bound replay. */
    private static final long MAX_AGE_MS = 5 * 60 * 1000L;

    @PostMapping("/feedback")
    public HttpServer.Response feedback(HttpServer.Request request) throws Exception {
        String body = request.getBody();
        if (!verified(request.getHeader("X-CN1-Signature"), body, secret)) {
            // Anything but 2xx keeps the window at the sender and resends it,
            // which is what you want while a secret rotation is half-applied.
            return new HttpServer.Response(401, "text/plain",
                    "bad signature".getBytes(StandardCharsets.UTF_8));
        }
        Map digest = Json.parseObject(body);
        List events = (List) digest.get("events");
        if (events != null) {
            for (Object entry : events) {
                Map event = (Map) entry;
                if (!"INVALID_TARGET".equals(event.get("reason"))) {
                    continue;
                }
                String provider = (String) event.get("provider");
                String target = (String) event.get("token");
                if (target == null || target.length() == 0) {
                    target = (String) event.get("endpoint");
                }
                if (provider == null || provider.length() == 0
                        || target == null || target.length() == 0) {
                    throw new IllegalArgumentException("Missing push target");
                }
                String deliveryId = (String) event.get("deliveryId");
                String eventKey;
                if (deliveryId != null && deliveryId.length() > 0) {
                    eventKey = "delivery:" + deliveryId;
                } else {
```

```
                Object at = event.get("at");
                if (at == null) {
                    throw new IllegalArgumentException("Missing classic event timestamp");
                }
                eventKey = "classic:" + provider + ":" + target.length()
                        + ":" + target + ":" + at;
            }
            if (!store.alreadyApplied(eventKey)) {
                store.removeTargetAndMarkApplied(eventKey, provider, target);
            }
        }
    }
    // 2xx acknowledges that this window is durably applied: it advances the
    // sender's watermark and the window is never sent again. Answer it
    // after the writes above have committed, not alongside them.
    return new HttpServer.Response(200, "text/plain",
            "ok".getBytes(StandardCharsets.UTF_8));
}

// throws, because String.getBytes(Charset) is a CHECKED throw in the
// ParparVM class library even though it is not one on a JVM.

        // Crypto, not javax.crypto: this class is recompiled against the
        // ParparVM class library by cn1:backend-package, and that library has
        // no JCE. equalsConstantTime is here for the same reason a hand-written
        // loop would be -- an early exit on the first differing byte lets a MAC
        // be forged one byte at a time.
        byte[] expected = Crypto.hmacSha256(secret.getBytes(StandardCharsets.UTF_8),
                (timestamp + "." + body).getBytes(StandardCharsets.UTF_8));
        return Crypto.equalsConstantTime(expected, decodeHex(provided));
    }

    private static byte[] decodeHex(String value) {
        if (value.length() % 2 != 0) {
            return new byte[0];
        }
        byte[] out = new byte[value.length() / 2];
        for (int i = 0; i < out.length; i++) {
            int high = Character.digit(value.charAt(i * 2), 16);
            int low = Character.digit(value.charAt(i * 2 + 1), 16);
            if (high < 0 || low < 0) {
                return new byte[0];
            }
            out[i] = (byte) ((high << 4) | low);
        }
        return out;
    }
}
```

67.6.5. A long-running Node server

The same three rules, with the raw-body trap in the form it usually takes:

```
// Express. Verify before any JSON middleware touches the body: the signature
// covers the bytes we sent, and express.json() hands you an object whose
// re-serialisation is not byte-identical, so it never verifies.
const express = require('express');
const crypto = require('crypto');

const app = express();
const SECRET = process.env.CN1_PUSH_CALLBACK_SECRET;
const MAX_AGE_MS = 5 * 60 * 1000;

function verifySignature(header, body) {
  const parts = Object.fromEntries((header || '').split(',')
      .map(p => [p.slice(0, p.indexOf('=')).trim(), p.slice(p.indexOf('=') + 1).trim()]));
  const expected = Buffer.from(
      crypto.createHmac('sha256', SECRET).update(`${parts.t}.${body}`).digest('hex'), 'utf8');
  const provided = Buffer.from(parts.v1 || '', 'utf8');
  return expected.length === provided.length
      && crypto.timingSafeEqual(expected, provided)
      && Math.abs(Date.now() - Number(parts.t)) <= MAX_AGE_MS;
}
```

```
// Store provider + bare token/web endpoint alongside the original push key.
// Backfill existing registrations before enabling cleanup. The durable store
// is scoped to this endpoint's organization.
function cleanupTarget(event) {
  const provider = event.provider;
  const target = event.token || event.endpoint;
  if (typeof provider !== 'string' || !provider
      || typeof target !== 'string' || !target) {
    throw new Error('Missing push target');
  }
  let eventKey;
  if (typeof event.deliveryId === 'string' && event.deliveryId) {
    eventKey = `delivery:${event.deliveryId}`;
  } else {
    if (!Number.isSafeInteger(event.at)) {
      throw new Error('Missing classic event timestamp');
    }
    eventKey = `classic:${provider}:${target.length}:${target}:${event.at}`;
  }
  return {eventKey, provider, target};
}

app.post('/push/feedback', express.raw({type: 'application/json'}), async (req, res) => {
  const body = req.body.toString('utf8');
  if (!verifySignature(req.get('X-CN1-Signature'), body)) {
    return res.sendStatus(401);       // not 2xx, so the same window is resent
  }

  try {
    for (const event of JSON.parse(body).events || []) {
      // Digests are at-least-once, so the deduplication marker and the
      // deletion have to commit together: a marker stored first turns a retry
      // into a silent skip, and a deletion without one is applied twice.
      if (event.reason === 'INVALID_TARGET') {
        const {eventKey, provider, target} = cleanupTarget(event);
        // Enforce eventKey uniqueness and commit marker + removal together.
        await removeTargetIfNotApplied(eventKey, provider, target);
      }
    }
  } catch (failure) {
    // Let it be resent rather than acknowledging work that did not land.
    return res.sendStatus(500);
  }

  // 2xx only now: it advances our watermark and this window is never sent again.
  res.sendStatus(200);
});
```

67.6.6. A serverless function

A function behind an HTTP gateway differs in two ways that are silent when they are wrong: the gateway may hand you the body base64-encoded, and there is no process to keep deduplication state in.

```
// A serverless function behind an HTTP gateway. Two things differ from a
// long-lived server, and both are silent when they are wrong.
const crypto = require('crypto');

const SECRET = process.env.CN1_PUSH_CALLBACK_SECRET;
const MAX_AGE_MS = 5 * 60 * 1000;

function verifySignature(header, body) {
  const parts = Object.fromEntries((header || '').split(',')
      .map(p => [p.slice(0, p.indexOf('=')).trim(), p.slice(p.indexOf('=') + 1).trim()]));
  const expected = Buffer.from(
      crypto.createHmac('sha256', SECRET).update(`${parts.t}.${body}`).digest('hex'), 'utf8');
  const provided = Buffer.from(parts.v1 || '', 'utf8');
  return expected.length === provided.length
      && crypto.timingSafeEqual(expected, provided)
      && Math.abs(Date.now() - Number(parts.t)) <= MAX_AGE_MS;
}

exports.handler = async (event) => {
  // 1. The gateway may hand you the body base64-encoded, and it decides that
  //    by sniffing content rather than by anything you control. Hashing the
  //    encoded form verifies nothing and fails closed on every digest.
  const body = event.isBase64Encoded
      ? Buffer.from(event.body, 'base64').toString('utf8')
      : event.body;

  // Header names arrive lower-cased from some gateways and not from others.
  const headers = event.headers || {};
  const signature = headers['x-cn1-signature'] || headers['X-CN1-Signature'];
  if (!verifySignature(signature, body)) {
    return {statusCode: 401, body: 'bad signature'};
  }

  // 2. There is no process to keep state in, so deduplication and the device
  //    table both have to be the database. A warm container that remembers
  //    delivery ids is an optimisation, never the correctness mechanism.
  // applyDurably must use the same provider + target normalization and
  // deliveryId/classic-event fallback as the long-running receiver above.
  await applyDurably(JSON.parse(body).events || []);

  // Return after the writes, not alongside them: a function that answers 200
  // and is frozen before its writes flush has told us to advance the watermark
  // over a window nobody stored.
  return {statusCode: 200, body: 'ok'};
};
```

67.6.7. A Spring server

`byte[]` rather than a mapped type, for the reason above: what Jackson parses and re-serializes is a different byte string.

```
@RestController
```

```
public class PushFeedbackSpring {

    private static final long MAX_AGE_MS = 5 * 60 * 1000L;

    // An injected collaborator, NOT a method on this class. Spring's
    // transaction management is proxy-based, so a call from one method of this
    // bean to another of its own never passes through the interceptor, and a
    // @Transactional there would do nothing at all -- without saying so.
    private final PushFeedbackApplier applier;
    private final byte[] secret;

    public PushFeedbackSpring(PushFeedbackApplier applier,
            @Value("${cn1.push.callback.secret}") String secret) {
        this.applier = applier;
        this.secret = secret.getBytes(StandardCharsets.UTF_8);
    }

    // byte[], not a mapped type: the signature covers the bytes as sent, and
    // anything Jackson parses and re-serialises is a different byte string that
    // never verifies.
    @PostMapping(path = "/push/feedback", consumes = MediaType.APPLICATION_JSON_VALUE)
    public ResponseEntity<String> feedback(
            @RequestHeader(name = "X-CN1-Signature", required = false) String signature,
            @RequestBody byte[] raw) throws Exception {
        String body = new String(raw, StandardCharsets.UTF_8);
        if (!verified(signature, body, secret)) {
            // Anything but 2xx keeps the window at the sender and resends it.
            return ResponseEntity.status(HttpStatus.UNAUTHORIZED).body("bad signature");
        }
        JsonNode digest = new ObjectMapper().readTree(body);
        for (JsonNode event : digest.path("events")) {
            applier.apply(event);
        }
        // 2xx advances the sender's watermark, so it is returned only after
        // every event above has committed.
        return ResponseEntity.ok("ok");
    }

    static boolean verified(String header, String body, byte[] secret) throws Exception {
        if (header == null) {
            return false;
        }
        long timestamp = 0;
        String provided = null;
        for (String part : header.split(",")) {
            int equals = part.indexOf('=');
            if (equals < 1) {
                continue;
            }
            String name = part.substring(0, equals).trim();
            String value = part.substring(equals + 1).trim();
            if ("t".equals(name)) {
                timestamp = Long.parseLong(value);
            } else if ("v1".equals(name)) {
                provided = value;
```

```
            }
        }
        if (provided == null
                || Math.abs(System.currentTimeMillis() - timestamp) > MAX_AGE_MS) {
            return false;                       // bound replay by age
        }
        Mac mac = Mac.getInstance("HmacSHA256");
        mac.init(new SecretKeySpec(secret, "HmacSHA256"));
        byte[] expected = mac.doFinal(
                (timestamp + "." + body).getBytes(StandardCharsets.UTF_8));
        // MessageDigest.isEqual is the JDK's constant-time comparison. Never
        // Arrays.equals or String.equals here: both return at the first
        // differing byte, and that timing is enough to forge a signature.
        return MessageDigest.isEqual(expected, HexFormat.of().parseHex(provided));
    }
}

@Component
class PushFeedbackApplier {

    private final DeviceStore store;

    PushFeedbackApplier(DeviceStore store) {
        this.store = store;
    }

    /**
     * One transaction per event: the deduplication marker and the deletion have
     * to commit together. A marker written first turns a retry into a silent
     * skip; a deletion without one is applied twice.
     */
    @Transactional
    public void apply(JsonNode event) {
        if (!"INVALID_TARGET".equals(event.path("reason").asText(null))) {
            return;
        }
        String provider = event.path("provider").asText(null);
        String target = event.path("token").asText(null);
        if (target == null || target.isEmpty()) {
            target = event.path("endpoint").asText(null);
        }
        if (provider == null || provider.isEmpty() || target == null || target.isEmpty()) {
            throw new IllegalArgumentException("Missing push target");
        }
        String deliveryId = event.path("deliveryId").asText(null);
        String eventKey;
        if (deliveryId != null && !deliveryId.isEmpty()) {
            eventKey = "delivery:" + deliveryId;
        } else {
            String at = event.path("at").asText(null);
            if (at == null) {
                throw new IllegalArgumentException("Missing classic event timestamp");
            }
            eventKey = "classic:" + provider + ":" + target.length() + ":" + target + ":" + at;
        }
```

```
        if (store.alreadyApplied(eventKey)) {
            return;
        }
        store.removeTarget(provider, target);
        store.markApplied(eventKey);
    }
}
```

67.6.8. A MicroProfile or Jakarta REST server

The same shape with `@HeaderParam` and a `byte[]` entity, taking the secret from MicroProfile Config:

```
@Path("/push")
@ApplicationScoped
public class PushFeedbackMicroProfile {

    // Injected, not a method on this bean: CDI interceptors are proxy-based
    // exactly like Spring's, so this.apply(...) would never reach the
    // @Transactional interceptor and the guarantee would be silently absent.
    @Inject
    PushFeedbackCdiApplier applier;

    // MicroProfile Config, so the secret arrives the same way as every other
    // deployment value rather than as a constant in the source.
    @Inject
    @ConfigProperty(name = "cn1.push.callback.secret")
    String secret;

    // byte[] entity, for the reason it is byte[] everywhere else: a provider
    // that binds this to a POJO reads the bytes, and the re-serialised form no
    // longer matches the signature.
    @POST
    @Path("/feedback")
    @Consumes(MediaType.APPLICATION_JSON)
    public Response feedback(@HeaderParam("X-CN1-Signature") String signature, byte[] raw)
            throws Exception {
        String body = new String(raw, StandardCharsets.UTF_8);
        // The verification is protocol, not framework: HMAC-SHA256 over
        // "<t>.<raw body>", constant-time compare, timestamp inside the window.
        if (!PushFeedbackSpring.verified(signature, body,
                secret.getBytes(StandardCharsets.UTF_8))) {
            return Response.status(Response.Status.UNAUTHORIZED).entity("bad signature").build();
        }
        try (JsonReader reader = Json.createReader(new StringReader(body))) {
            JsonObject digest = reader.readObject();
            JsonValue events = digest.get("events");
            if (events != null) {
                for (JsonValue value : events.asJsonArray()) {
                    applier.apply(value.asJsonObject());
                }
            }
        }
        return Response.ok("ok").build();
    }
```

```
}

@ApplicationScoped
class PushFeedbackCdiApplier {

    @Inject
    DeviceStore store;

    /** Marker and deletion in one transaction, as in the Spring receiver. */
    @Transactional
    public void apply(JsonObject event) {
        if (!"INVALID_TARGET".equals(event.getString("reason", null))) {
            return;
        }
        String provider = event.getString("provider", null);
        String target = event.getString("token", null);
        if (target == null || target.isEmpty()) {
            target = event.getString("endpoint", null);
        }
        if (provider == null || provider.isEmpty() || target == null || target.isEmpty()) {
            throw new IllegalArgumentException("Missing push target");
        }
        String deliveryId = event.getString("deliveryId", null);
        String eventKey;
        if (deliveryId != null && !deliveryId.isEmpty()) {
            eventKey = "delivery:" + deliveryId;
        } else {
            String at = (event.get("at") == null ? null : event.get("at").toString());
            if (at == null) {
                throw new IllegalArgumentException("Missing classic event timestamp");
            }
            eventKey = "classic:" + provider + ":" + target.length() + ":" + target + ":" + at;
        }
        if (store.alreadyApplied(eventKey)) {
            return;
        }
        store.removeTarget(provider, target);
        store.markApplied(eventKey);
    }
}
```

67.6.9. Any other stack

The contract is a signed JSON POST, so a receiver in Go, Python, PHP, Ruby or a JVM framework is the same three steps: HMAC-SHA256 over `<t>.<raw body>`, constant-time compare against `v1`, reject a `t` outside your age window. Then apply each event no more than once, and answer 2xx after it’s stored.

67.7. Build audiences in the Console

Managed audiences are application-scoped. They don’t contain copied device tokens. A saved segment stores a dynamic filter, and BuildCloud resolves that filter against active subscriptions when a campaign launches.

Your authenticated server assigns an external user ID and tags to an installation with `PUT /api/v3/push/apps/{appId}/installations/{installationId}`. Tags should be stable application facts such as `subscription=active`, `region=emea`, `role=technician`, or `testUser=true`. Don't let an untrusted client grant itself a privileged tag.

```
{
  "externalUserId": "customer-4815",
  "tags": {
    "subscription": "active",
    "region": "emea",
    "testUser": "false"
  }
}
```

Open **Push** > **Audience**. The tag and value pickers contain values discovered from current active subscriptions for the selected application. Choose an optional platform, choose one tag rule, enter a segment name, and select **Save segment**. The new segment appears immediately under **Saved segments** with its current recipient estimate. It also becomes available in the Messages recipient picker.

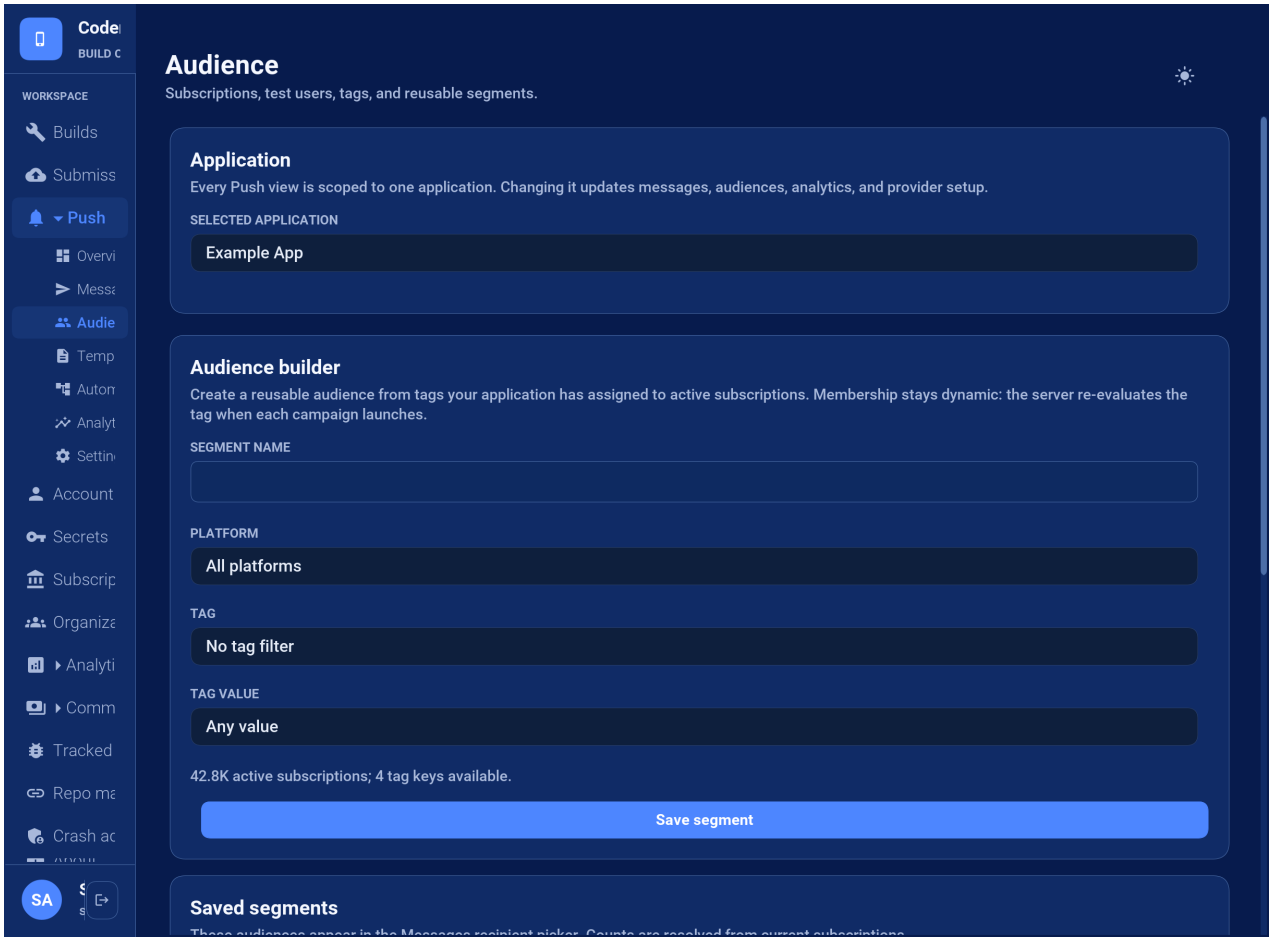

Figure 359. Audience uses discovered tag values and shows every saved segment

Segments are evaluated at send time. Changing a subscription's tags changes future membership without editing the segment. A count is an estimate of the current state; registrations, subscription removals, and tag updates can change it before admission.

For a safe rollout, tag internal devices with `testUser=true`, create a test-user segment, and send the message there first. Create the production segment only from server-controlled tags.

67.8. Send a message from the Console

Open **Push** > **Messages** and complete the three numbered sections:

1. **Audience**: choose **All subscribed devices** or a saved segment. The Console displays the current recipient estimate. Individual provider tokens aren't entered in this workflow.
2. **Message**: enter a notification title and message. A visible notification requires message text. For a silent notification, enable **Silent / data-only notification** and provide an additional-data key and value. The Console builds valid JSON; operators don't paste JSON into the primary composer.
3. **Delivery**: choose how long providers may retain an undelivered message. Console messages use safe cross-platform defaults and enter the durable queue immediately.

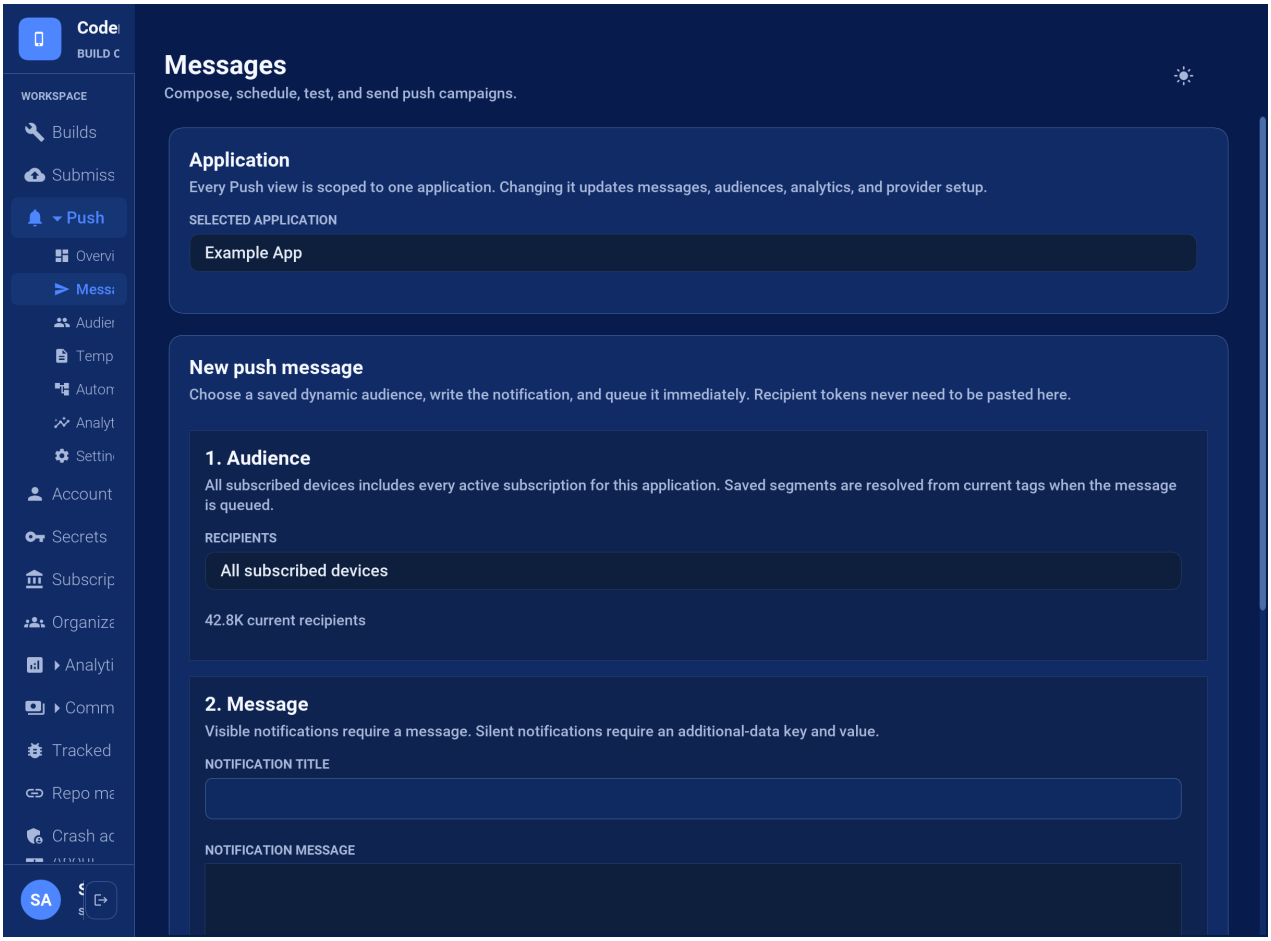

Figure 360. The restrictive message composer accepts a saved audience and typed fields

Select **Queue message** only after checking the audience name and estimate. BuildCloud creates the campaign, resolves the segment, and admits the recipients to the durable delivery queue. The provider may accept a notification that the device never displays, so inspect **Push** > **Analytics** for provider acceptance and failures without treating acceptance as device delivery.

67.9. Event automations

An automation is an enabled rule containing `trigger.event`, a schema-3 `message`, an optional `audience`, and an optional `delaySeconds`. If no audience is stored in the rule, the event must identify an `externalUserId` or `installationId`. Text fields in the message can insert event properties with `${event.propertyName}`.

```
{
  "enabled": true,
  "trigger": {"event": "order.ready"},
  "delaySeconds": 0,
  "message": {
    "schema": 3,
    "title": "Order update",
    "body": "Order ${event.orderId} is ready"
  }
}
```

Your server triggers enabled rules with `POST /api/v3/push/apps/{appId}/events` using a `push`-scoped API key:

```
{
  "name": "order.ready",
  "externalUserId": "customer-4815",
  "properties": {"orderId": "4815"}
}
```

Immediate matches enter the durable delivery queue. Delayed matches become scheduled campaigns, so restarts don't lose them. Automations are intentionally push rules, not a general-purpose customer journey or analytics product.

67.10. Widgets and live surfaces

A push can publish widget content or update a live activity before the regular listener receives the message. The `surface` object uses one of these operations:

```
{
  "schema": 3,
  "silent": true,
  "surface": {
    "operation": "widget",
    "kind": "order-status",
    "timeline": "{...serialized widget timeline...}"
  }
}
```

For a live activity use `live-update` or `live-end` with `id`, serialized `state`, and optional `dismissImmediately`. Unsupported surfaces are ignored. A surface command runs when the Codename One runtime receives the envelope. On platforms that don't start application code for a background push, the native queue preserves the command and applies it on the next start or resume. Applications must therefore refresh stale surface state during foreground activation too.

67.11. Use an application-owned push server

A custom server is a low-level alternative to managed push; it doesn't reuse the BuildCloud protocol at a different endpoint. A CN1Lib implements `PushTransport` around the private provider's native SDK. It obtains native registration material, reports token rotation, and forwards incoming data as the canonical schema-3 JSON envelope. A matching `PushRegistrationSink` stores and removes the subscription on your server:

```
// companyTransport is supplied by the native CN1Lib.
// listener is the application's normal, non-null PushListener.
PushClient client = PushClient.builder("private-app-id")
        .transport(companyTransport)
        .registrationSink(new PushRegistrationSink() {
            @Override
            public void registered(PushSubscription value) {
                Log.p("Send the subscription to the company server");
            }

            @Override
            public void unregistered(PushSubscription value) {
                Log.p("Remove the subscription from the company server");
            }
        })
        .listener(listener)
        .build();
```

When a `PushTransport` implementation is present, `PushClient` never contacts BuildCloud. Your implementation owns these responsibilities:

- `getId()` returns a stable provider ID that your server understands.
- `isSupported()` checks whether the SDK can operate on this device.
- `register()` invokes `Callback.registered()` with a `PushSubscription`, then reports later token rotations through the same callback.
- `unregister()` removes the provider subscription and invokes `Callback.unregistered()` when complete.
- Incoming native messages call `Callback.message()` with one complete schema-3 envelope. Don't call the application listener directly and don't invent a second payload format.
- Registration or transport failures call `Callback.failed()`. The callback is thread-safe; `PushClient` moves application-facing callbacks to the EDT.

The registration sink should asynchronously insert or update the subscription by `installationId` on your server and replace its token when it rotates. The server then sends through your provider's native API. It must preserve the schema-3 envelope so the same `PushListener`, deep-link handling, and surface commands work in managed and custom-server modes.

The application still follows the normal lifecycle: retain one client, call `register()` from `start()`, and reserve `unregister()` for an actual opt-out. This custom integration doesn't introduce reflection or automatic listener discovery.

67.12. Testing delivery behavior

Hosted CI has no installed application, OS push daemon, permission state, or physical device, so it can't prove provider-to-device delivery. Codename One tests at the lowest controllable boundary instead. `PushClientTransportTest` injects a fake native transport and covers:

- foreground, background, force-stopped, and cold-start delivery;
- notification tap, action, dismissal, and deep-link routing;
- permission granted, denied, and later changed in system settings;
- token rotation, reinstall, expiry, logout, and multiple installations per user;
- silent delivery and simulated constrained-state replay;
- collapse keys, TTL expiry, Unicode, maximum payloads, images, and provider errors;
- queued widget and live-activity updates replayed at the native/runtime seam;
- retry idempotency and dead-letter behavior.

The JavaScript contract executes the real service-worker source with mocked browser clients and notification APIs. BuildCloud has a separate local suite using mocked provider HTTP responses for compatibility translation, credentials, durable queue behavior, retries, and automations. Physical-device sends are optional release diagnostics rather than a CI or nightly requirement. Provider acceptance isn't proof of device delivery.

Chapter 68. Notifications and Background Execution

Codename One exposes a cross-platform API for rich local notifications, runtime notification permission, notification channels, constraint-aware background work, foreground services, deferrable background processing, receiving content shared from other apps, and push topic subscriptions. Each capability degrades on platforms that can't support it — calls become documented no-ops rather than errors — and the JavaSE simulator implements them so you can exercise the flows without a device.

Because these features build on platform-specific behavior, every section below lists the support per platform. In the matrices: **Yes** = fully supported, **Partial** = supported with documented limitations, **No-op** = the call is accepted but does nothing, **Sim** = exercised in the simulator.

68.1. Notification permission

On iOS, and on Android 13+ (`POST_NOTIFICATIONS`), an app must obtain permission before its notifications are shown. Request it through `Display`:

```
NotificationPermissionRequest req = new NotificationPermissionRequest()
        .provisional(true)      // iOS: deliver quietly without an explicit prompt
        .timeSensitive(true);   // iOS: allow the time-sensitive interruption level

Display.getInstance().requestNotificationPermission(req, result -> {
    if (result.isGranted()) {
        // schedule notifications
    }
    AuthorizationLevel level = result.getAuthorizationLevel();
});
```

`NotificationPermissionResult.getAuthorizationLevel()` returns an `AuthorizationLevel` enum (`NOT_DETERMINED`, `DENIED`, `AUTHORIZED`, `PROVISIONAL`, `EPHEMERAL`). The values are ordered from least to most permissive, so `isGranted()` is "more permissive than `DENIED`." The callback is delivered on the EDT.

Request option	iOS	Android	Simulator
alert / sound / badge	Yes	Implied by POST_NOTIFICATIONS	Granted
provisional	Yes (iOS 12+)	No-op	Granted
timeSensitive	Yes (iOS 15+, needs entitlement)	No-op	Granted
critical	Yes (needs Apple entitlement)	No-op	Granted

Request option	iOS	Android	Simulator
carPlay / announcement	Yes	No-op	Granted

The `timeSensitive` and `critical` options require an Apple capability on the App ID. Enable injection of the matching entitlement with the `ios.timeSensitiveNotifications=true` and `ios.criticalAlerts=true` build hints (they're opt-in because an entitlement the provisioning profile doesn't carry breaks code signing).

68.2. Local notifications

`LocalNotification` is scheduled through `Display.scheduleLocalNotification(…)` as before; the bean has been extended with fluent, backward-compatible setters:

```
LocalNotification n = new LocalNotification()
        .setChannelId("messages")                // Android channel (see below)
        .setGroup("chat-42")                      // bundle related notifications
        .setProgress(100, 40)                     // determinate progress bar (Android)
        .setTimeSensitive(true);                  // break through Focus / elevated importance
n.setId("msg-42");
n.setAlertTitle("New message");
n.setAlertBody("Tap to reply");
n.addAction("open", "Open");
n.addInputAction("reply", "Reply", "Type a message", "Send");  // inline quick reply
Display.getInstance().scheduleLocalNotification(n, System.currentTimeMillis() + 1000,
        LocalNotification.REPEAT_NONE);
```

When the user taps an action, the selected action id (and any quick-reply text) are delivered through `com.codename1.push.PushContent` — `getActionId()`, `getActionTitle()` and `getTextResponse()` — before your `LocalNotificationCallback.localNotificationReceived(id)` runs, so push and local notification actions are handled identically.

Capability	iOS	Android	Simulator
title / body / badge / sound	Yes	Yes	Sim (panel)
image attachment	Yes (UNNotificationAttachment)	Yes (BigPicture)	Sim (thumbnail)
action buttons	Yes (UNNotificationAction)	Yes	Sim (buttons)
quick-reply input action	Yes (UNTextInputNotificationAction)	Yes (RemoteInput)	Sim (text field)
grouping	Yes (thread identifier)	Yes (group + summary)	Partial
progress (ongoing)	No-op	Yes	Sim (progress bar)

Capability	iOS	Android	Simulator
full-screen intent	No-op	Yes (needs permission, see hints)	No-op
time-sensitive	Yes (iOS 15+)	Approximated (category + priority)	Sim
messaging / conversation style	Partial	Yes (MessagingStyle)	Sim
custom view	Notification content extension	RemoteViews	Sim (render)

68.2.1. Resource names for sound, image and action icons

These string parameters are platform **resource names**, not numeric ids (Codename One has no `R.drawable` constants). They're resolved at runtime per platform:

Parameter	What to provide	Android resolution	iOS resolution
`alertSound` / channel sound	a file whose name starts with `notification_sound`, bundled in the app	`res/raw/<name>` via `android.resource://` URI	`UNNotificationSound` from the app bundle
`alertImage`	image path placed in the app root	loaded from `assets/`	`UNNotificationAttachment` from the bundle
`Action` icon	a drawable name bundled in `android/src/main/resources`	`getResources().getIdentifier(name, "drawable", pkg)`	not displayed

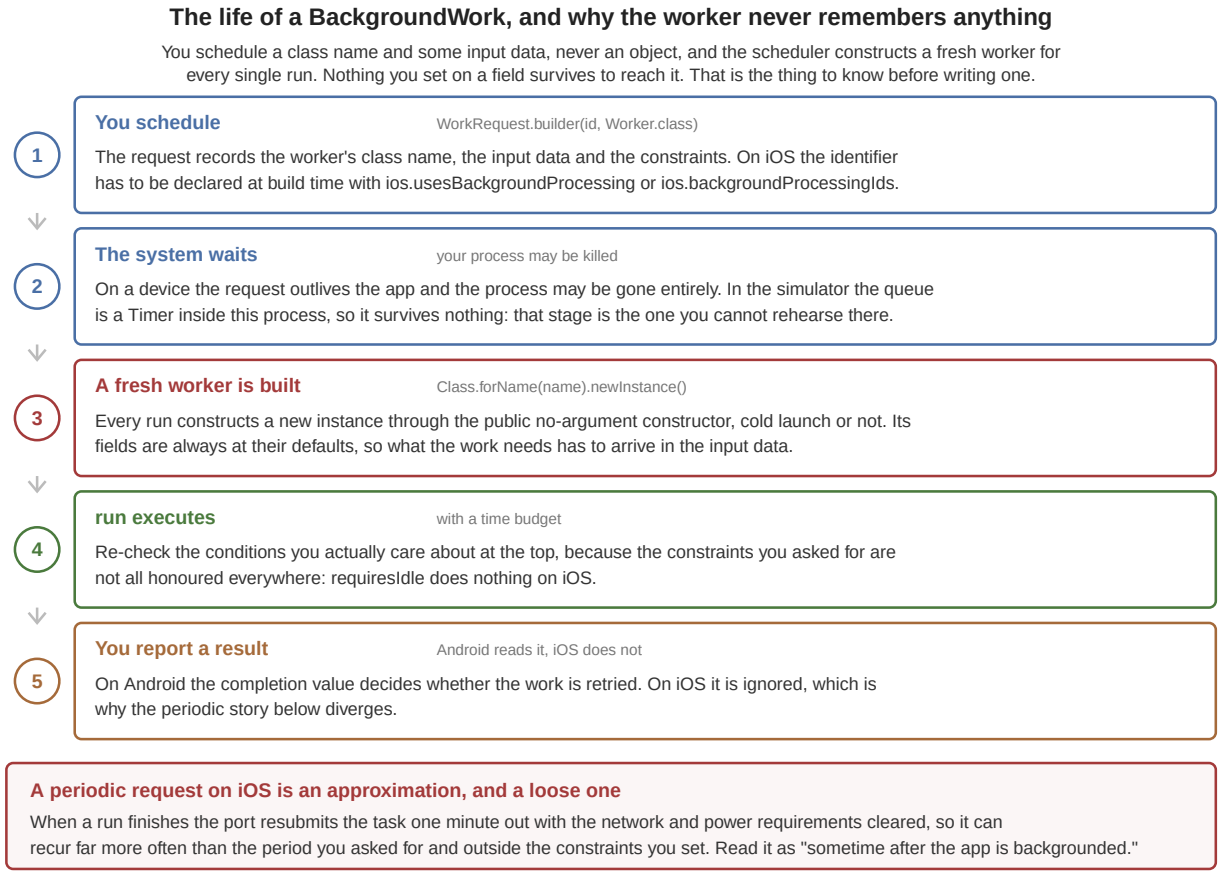
The file extension is optional for the action icon and is ignored. iOS notification action buttons don't render icons, so the icon value is ignored there.

68.3. Notification channels (Android O+)

Channels let the user control importance, sound, vibration, lights, lock screen visibility and badge display for a group of notifications. Build and register one at startup, then reference it from a notification with `setChannelId(…)`:

```
new NotificationChannelBuilder("messages", "Messages")
        .description("Incoming chat messages")
        .importance(NotificationChannelBuilder.IMPORTANCE_HIGH)
        .sound("/notification_sound_ping.mp3")
        .enableVibration(true)
        .lightColor(0xff0000)
        .register();
```

Channels are an Android concept. On iOS and the simulator `register()` is a no-op (the simulator stores the channel so its name can be shown in the notification panel); the channel id you assign is still carried so the notification behaves consistently.



68.4. Constraint-aware background work

`BackgroundWork` schedules deferrable work that the OS runs when its constraints are met. Implement `BackgroundWorker` in a class with a public no-argument constructor. You schedule the class, never an instance: the request records its name, and the scheduler constructs a fresh worker for every run, even when the process was never killed. Its fields are always at their defaults, so pass state through the input data:

```
/// The platform may rebuild this after the app process was killed, so it
/// needs a public no-argument constructor and can rely on nothing from the
/// foreground app -- state arrives through the input data.
public static class SyncWorker implements BackgroundWorker {
    public void performWork(String id, java.util.Map<String, String> inputData,
            long deadline, com.codename1.util.Callback<Boolean> onComplete) {
        // the real work goes here; inputData carries whatever the request
        // was scheduled with, because no foreground state survives
        String account = inputData.get("account");
        boolean ok = account != null;
        // TRUE for done. FALSE asks for a retry on Android; the iOS port
        // ignores the value, so do not rely on it to recover from failure
        onComplete.onSucess(Boolean.valueOf(ok));
    }
}

void scheduleSync() {
    // on iOS the id must appear in BGTaskSchedulerPermittedIdentifiers, and
    // it gets there only if you ask: ios.usesBackgroundProcessing=true
    // declares <packageName>.processing, which is what this derives
    String taskId = Display.getInstance().getProperty("package_name", "") + ".processing";
    WorkRequest req = WorkRequest.builder(taskId, SyncWorker.class)
            .setRequiresNetwork(true)
            .setRequiresCharging(true)
            .setPeriodic(6 * 60 * 60 * 1000L)
            .putInputData("account", "primary")
            .build();
    BackgroundWork.schedule(req);
}
```

iOS needs the identifier declared at build time before `BGTaskScheduler` will accept the request, and nothing detects `BackgroundWork` on the classpath for you. Set `ios.usesBackgroundProcessing=true`, which declares `<packageName>.processing` — the id the sample derives — or list your own ids with `ios.backgroundProcessingIds`. Without one of those the scheduling call is rejected on the device.

	iOS	Android	Simulator
backend	BGTaskScheduler (iOS 13+)	JobScheduler	Timer
requiresNetwork / unmetered	Yes	Yes	Toggle in Simulate menu
requiresCharging	Yes (requiresExternalPower)	Yes	Toggle
requiresIdle / batteryNotLow	No-op	Yes	Toggle
periodic	Approximated (resubmit)	Yes (>= 15 min)	Yes

The iOS approximation of a periodic request doesn't carry the request forward. After a run completes, the port resubmits the task with an earliest date one minute out and with both the network and power requirements cleared, so the work can recur far more often than the period you asked for and outside the constraints you set. Treat a periodic request on iOS as "sometime after the app is next backgrounded," and re-check the conditions you care about at the top of the worker. The completion value is Android-only for the same reason: the iOS port resubmits periodic work whichever value you report, and never resubmits one-shot work, so a `FALSE` there doesn't buy you a retry.

`BackgroundTask.scheduleProcessing(id, earliestBeginDate, requiresNetwork, requiresPower, runnable)` is a one-shot variant for occasional maintenance work. On iOS the identifiers must be declared via the `ios.backgroundProcessingIds` build hint (comma separated, default `<packageName>.processing`); the build also adds the `processing` UIBackgroundMode and links `BackgroundTasks.framework` automatically.

68.5. Foreground service (Android)

`ForegroundService` runs a long task while a persistent notification is shown. The first argument names a channel, but the Android service currently routes its notification through the app-wide channel — `android.NotificationChannel.id`, defaulting to `cn1-channel` — so the id here doesn't place the notification in a channel of its own today:

```
ForegroundService svc = ForegroundService.start("downloads", "Downloading", "Please wait",
        null, service -> {
            for (int i = 0; i <= 100; i++) {
                service.updateNotification("Downloading", i + "%");
                // ... do a chunk of work ...
            }
        });
// auto-stops when the task returns, or call svc.stop()
```

	Android	iOS	Simulator
persistent-notification service	Yes	No (best-effort background window + notification)	Sim (status indicator)

When the app references `ForegroundService` the build registers the service and injects `FOREGROUND_SERVICE` plus the per-type `FOREGROUND_SERVICE_<TYPE>` permission (Android 14). Override the type with the `android.foregroundServiceType` build hint (default `dataSync`).

68.6. Receiving shared content

Override `onReceivedSharedContent(SharedContent)` on your `Lifecycle` subclass to receive text, URLs, files or images shared into your app from other apps:

```
public class MyApp extends Lifecycle {
    public void onReceivedSharedContent(SharedContent content) {
        for (SharedContent.Item item : content.getItems()) {
            if (item.getType() == SharedContent.TYPE_IMAGE) {
                // your own import; the path is a FileSystemStorage path
                importImage(item.getFilePath());
            }
        }
    }
}
```

	Android	iOS	Simulator
receive shared content	Yes (SEND / SEND_MULTIPLE)	Yes (share extension + App Group)	Sim ("Send shared content")

On Android, declare the accepted MIME types with the `android.shareFilter` build hint (comma separated, for example `text/plain,image/*`); the build registers the share-receiver activity. On iOS this reuses the share-extension authoring pipeline; set the `ios.shareAppGroup` build hint to the App Group the extension writes to. File and image items are copied into Codename One `FileSystemStorage` so your code is platform neutral.

68.7. Push topics

`Push.subscribeToTopic("news")` / `unsubscribeFromTopic("news")` subscribe the device to a fan-out topic.

	Android	iOS
topic subscribe / unsubscribe	Yes (Firebase Cloud Messaging)	No-op (raw APNs has no topics; fan out server-side)

Server-side topic delivery is handled by the Codename One push server.

68.8. Simulator

The JavaSE simulator implements all the above so you can develop without a device. Use the **Simulate → Notifications and Background** menu to toggle the background constraints (network / charging / idle / battery), run scheduled work immediately, inspect registered channels, and inject shared content. Posted notifications appear in a panel at the top right; tapping an action (or submitting a quick-reply) routes back through your callback exactly as on device.

Chapter 69. Calendar integration

The `com.codename1.calendar` package provides scheduling rather than just an "add event" shortcut. It represents calendars, events, task/reminders, recurrence, attendees, alarms, free/busy intervals, attachments, conference links, paging, incremental synchronization, and explicit edit conflicts.

The API is capability based. Don't branch on the platform name. Ask the source what it can do:

```
LocalCalendarSource local = LocalCalendarSource.getInstance();
CalendarCapabilities capabilities = local.getCapabilities();

if (capabilities.supports(CalendarCapability.READ_EVENTS)) {
    local.requestAuthorization(CalendarAccess.EVENTS_READ_ONLY).ready(status -> {
        if (status == CalendarAuthorizationStatus.FULL) {
            local.queryEvents(new CalendarQuery()
                    .setCalendarId("primary")
                    .setStartTime(Instant.now()))
                 .ready(page -> page.getItems().forEach(System.out::println));
        }
    });
}
```

`LocalCalendarSource` is implemented with Android's Calendar Provider and Apple EventKit on iOS and macOS. The simulator supplies an isolated, in-memory source so tests never modify the developer's real calendar. A port that has no local calendar service returns an empty capability set. Online sources and `.ics` import/export remain available on every port, including JavaScript and Linux.

Target	Built-in local source	Portable alternatives
Android	Calendar Provider events	Google, Microsoft, CalDAV, and `.ics`
iOS and macOS	EventKit events and reminders	Google, Microsoft, CalDAV, and `.ics`
Codename One simulator	Isolated in-memory source	Google, Microsoft, CalDAV, and `.ics`
Win32, native macOS desktop, Linux, and JavaScript	No built-in local source; the capability set is empty	Google, Microsoft, CalDAV, and `.ics`

This API is a clean replacement for the old `CN1Calendar` integration. New code shouldn't mix objects or identifiers from the two APIs.

To show what a source holds by the day, the week or the month, and let the user drag an event to another time, give a `CalendarScheduleModel` to a `Scheduler`. See Scheduling and Gantt charts.

69.1. Creating an event

All-day values use `CalendarDateTime.allDay(LocalDate)`. Timed values use `ZonedDateTime` (or the `Instant` and `ZoneId` convenience factory). Alarms use `Duration`, and query ranges and absolute timestamps use `Instant`. The API uses `java.time` instead of defining parallel date, time-zone, or duration types. Keeping all-day and timed values separate avoids shifting an all-day event when it crosses a time-zone boundary.

```
CalendarEvent event = new CalendarEvent()
        .setCalendarId(calendarId)
        .setTitle("Architecture review")
        .setStart(CalendarDateTime.instant(start, ZoneId.of("Europe/Paris")))
        .setEnd(CalendarDateTime.instant(end, ZoneId.of("Europe/Paris")))
        .setRecurrence(new CalendarRecurrenceRule()
                .setFrequency(CalendarRecurrenceRule.Frequency.WEEKLY)
                .addDayOfWeek(2))
        .addAttendee(new CalendarAttendee()
                .setName("Ari")
                .setEmail("ari@example.com"))
        .addAlarm(new CalendarAlarm().setTimeBefore(Duration.ofMinutes(15)));

local.saveEvent(event, CalendarMutationScope.ALL).ready(saved -> {
    Log.p("Created " + saved.getId());
});
```

The `version` returned by a source is an optimistic-concurrency token. Pass the returned object to `saveEvent()` or its version to a delete method. A stale token produces `CalendarError.CONFLICT` instead of overwriting a newer server edit.

69.2. Online sources

Online sources work on all ports and use the application's OAuth client. They never embed a client secret and never persist credentials implicitly.

```
OidcClient.discover("https://accounts.google.com").ready(oidc -> {
    oidc.setClientId(clientId)
        .setRedirectUri(redirectUri)
        .setScopes(GoogleCalendarSource.SCOPE_CALENDAR,
                   GoogleCalendarSource.SCOPE_TASKS)
        .authorize().ready(tokens -> {
            CalendarSource google = new GoogleCalendarSource(
                    new OidcCalendarTokenProvider(oidc, tokens));
            CalendarManager.getInstance().registerSource(google);
        });
});
```

`GoogleCalendarSource` covers Google Calendar and Google Tasks. `MicrosoftCalendarSource` covers

Microsoft Graph calendars and Microsoft To Do. Both expose provider paging and delta tokens through `CalendarPage` and retry once with a refreshed token after HTTP 401.

For CalDAV, pass the account's calendar-home URL and an authentication strategy:

```
CalendarSource caldav = new CalDavCalendarSource(
        "work", "Work CalDAV", calendarHomeUrl,
        CalDavAuthentication.digest(username, password));
```

`CalDavAuthentication.basic()`, `bearer()`, and `digest()` are supported. Prefer Bearer or Digest over Basic unless Basic is protected by HTTPS. Calendar discovery filters collections by their advertised `VEVENT` and `VTODO` component support. Check the result of each asynchronous operation as servers can restrict individual collections further.

69.3. Import and export

`ICalendarCodec` reads and writes RFC 5545 `VEVENT`, `VTODO`, `VALARM`, attendees, recurrence rules, URI attachments, conference URIs, all-day values, and time zones. Unknown `X-` properties are retained in provider data.

```
String ics = ICalendarCodec.writeEvent(event);
CalendarEvent imported = ICalendarCodec.readEvent(ics);
```

69.4. Change notifications and offline synchronization

The cross-platform guarantee is intentionally pull based:

- Local sources can emit `CalendarChange` through `addChangeListener()` when the operating system reports a local store change.
- Online providers return a sync/delta token. Store it and pass it in the next `CalendarQuery`. The API doesn't register provider webhooks.

Listeners run on the Codename One EDT. Treat a `RESET` change as an instruction to query again; it doesn't promise one callback per underlying OS edit.

Offline mutation storage is opt-in. Supply a `CalendarCache` to `CalendarSyncEngine`, queue edits, and call `sync()` yourself or from the platform's background-work callback. `StorageCalendarCache` stores calendar data and pending mutations, never credentials. Conflicts remain paused until the application chooses `KEEP_LOCAL`, `KEEP_REMOTE`, or `MERGED`.

```
CalendarSyncEngine sync = new CalendarSyncEngine(
        google, new StorageCalendarCache("google-account-1"));
sync.queueEventSave(event, CalendarMutationScope.ALL);
sync.sync().ready(result -> {
    for (CalendarConflict conflict : result.getConflicts()) {
        // Present both versions, then call resolveConflict(...).
```

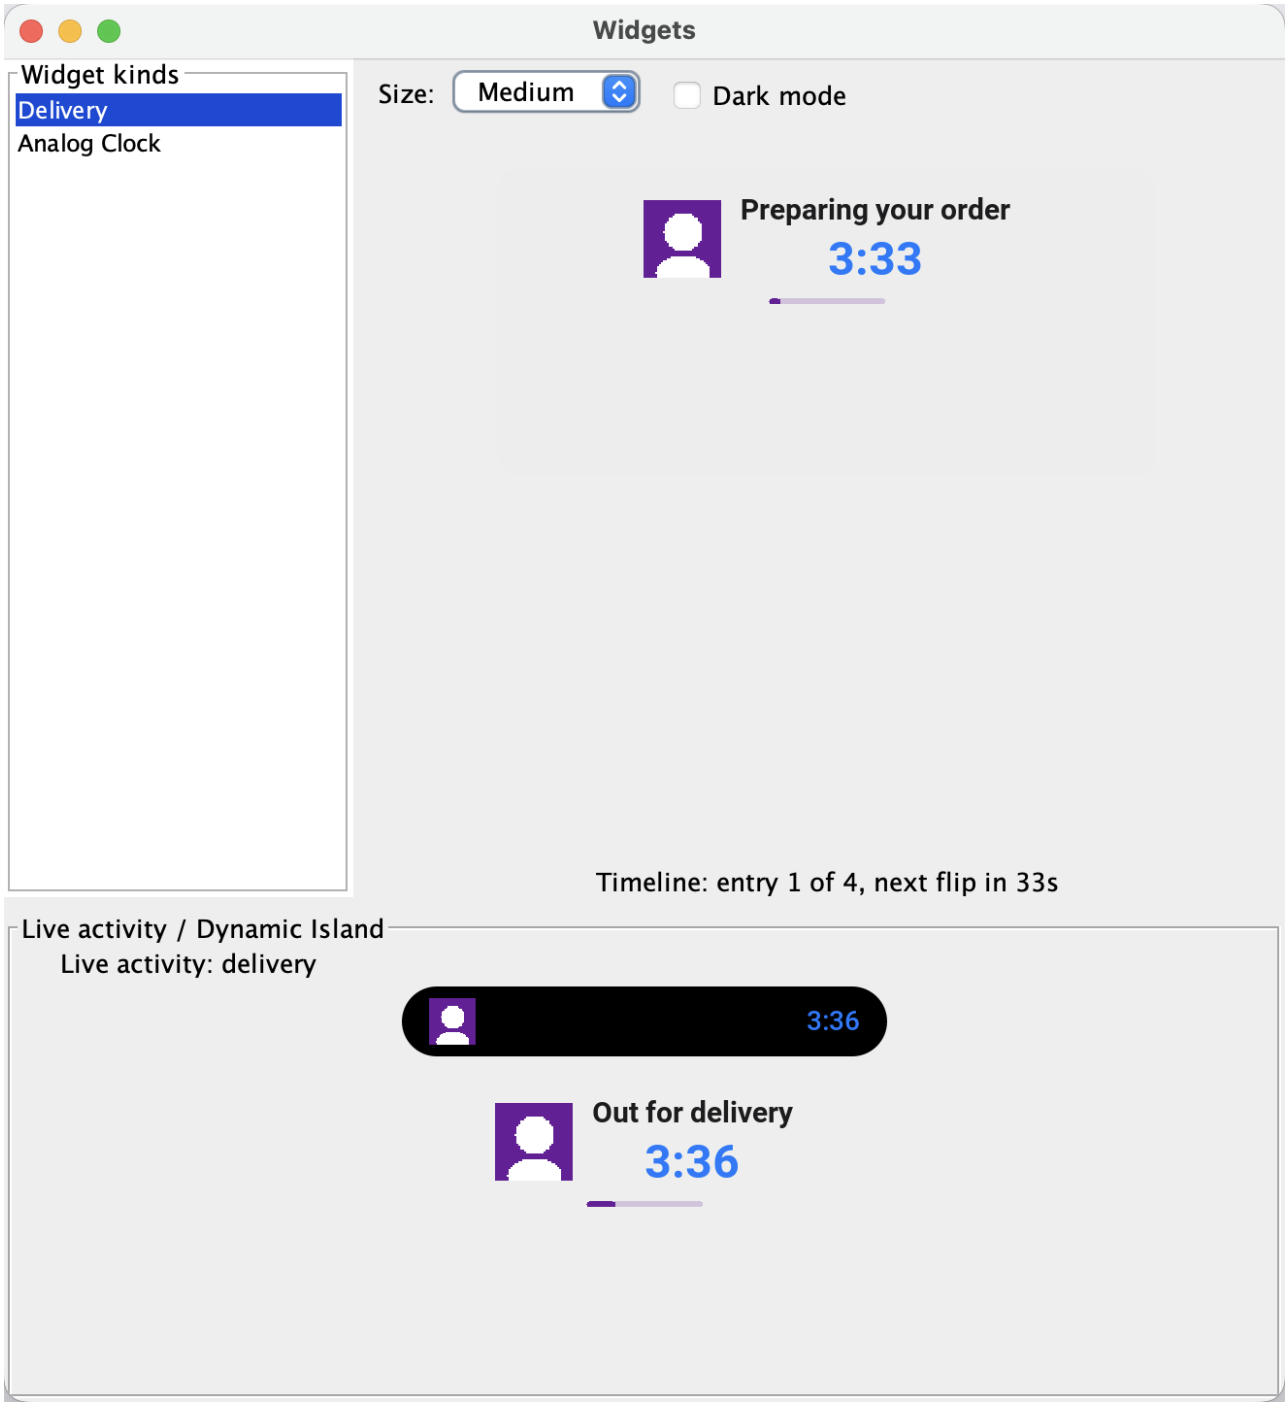
```
    }
});
```

69.5. Permissions and build hints

Calling `LocalCalendarSource.getInstance()`, `CalendarManager.getLocalSource()`, `CalendarManager.getSources()`, or `Display.getLocalCalendarSource()` is the builder signal for local calendar integration. Android builds add `READ_CALENDAR` and `WRITE_CALENDAR`; iOS and macOS builds add EventKit and calendar/reminder privacy strings. You can replace the default user-facing strings with:

```
ios.NSCalendarsFullAccessUsageDescription=Explain why events are needed
ios.NSCalendarsWriteOnlyAccessUsageDescription=Explain why creating events is needed
ios.NSRemindersFullAccessUsageDescription=Explain why reminders are needed
```

The built-in Win32 source currently reports unavailable. An application-supplied native integration can explicitly opt into the standard MSIX `uap:appointments` capability with:



```
windows.msix=true
windows.calendar.restrictedCapability=true
```

Always check `getCapabilities()` and `getAuthorizationStatus()` at runtime. Manifest declarations make a request possible; they don't mean the user or provider granted it.

Chapter 70. External Surfaces: Widgets and Live Activities

Home-screen widgets and live activities answer the same developer question: how to keep a live piece of information outside the app. Codename One models both as one concept — an external surface — under the `com.codename1.surfaces` package. A **widget** is persistent, user-placed and content-driven: the weather, the next meeting, the delivery status on the home screen. A **live activity** is transient, app-started and progress-driven: the delivery that's out right now, a running timer, a live score on the iOS lock screen and Dynamic Island, an ongoing Android notification, a floating desktop pill. Both share the same layout model, serialization, state mechanism, and action model.

The simulator renders every surface you publish in a dedicated preview window, so the full loop runs on your desktop with no device:

70.1. The dead-process rule

Surfaces render while your app process may not be running. Everything you hand this API is therefore turned into plain data at publish time: layouts serialize to a compact JSON descriptor, images are encoded to named PNG blobs, and "callbacks" are string action ids that open the app and reach your handler on the EDT. Layout text embeds `${key}` placeholders resolved from a per-entry state map, so a content change is a cheap re-publish of data, not a new layout.

This rule explains everything unusual about the API. You can't attach a listener to a widget — the process that renders it may have nothing to call back into. You can't hand it a `Component` — there is no Codename One renderer on the other side. What you can do is describe the surface declaratively and let each platform's native renderer (SwiftUI on iOS, `RemoteViews` on Android, a rasterizer on desktop) draw it.

70.2. Getting started

The build injects the native plumbing (a WidgetKit extension and App Group on iOS, widget receivers on Android) when your bytecode references `com.codename1.surfaces`. Apps that never touch the package get none of it, and on ports without surface support every entry point is an inert no-op.

Platform widget galleries are compiled into the native app, so widget kinds must be known at build time. Declare them in a `surfaces.json` resource (in `src/main/resources` of a Maven project, next to your icons):

```
{
  "liveActivities": true,
  "kinds": [
    {
      "id": "delivery_status",
      "name": "Delivery",
      "description": "Track your order",
      "iosFamilies": ["systemSmall", "systemMedium"],
      "androidMinWidthDp": 180,
      "androidMinHeightDp": 60
    },
    {
      "id": "analog_clock",
      "name": "Analog Clock",
      "description": "A vector clock face",
      "iosFamilies": ["systemSmall"],
      "androidMinWidthDp": 110,
      "androidMinHeightDp": 110
    }
  ]
}
```

The `id` values must match `[a-z]`. The `families` list accepts the portable names (`small`, `medium`, `large`, `lockscreen`, and the four `watch` complication families) as well as the WidgetKit spellings (`systemSmall`, `systemMedium`, `systemLarge`, `accessoryRectangular`); when omitted, all three home-screen sizes are offered. `iosFamilies` is the older spelling of the same key and still works — it predates there being a second platform that cared — and is read only when `families` is absent. The `androidMinWidthDp` / `androidMinHeightDp` / `androidResizeMode` fields fill the Android provider metadata. An optional top-level `appGroup` pins the iOS App Group id, and `"liveActivities": true` enables the live activity plumbing.

At runtime, mirror the manifest by registering each kind in your app's `init()`:

```
Surfaces.registerWidgetKind(new WidgetKind("delivery_status")
        .setDisplayName("Delivery")
        .setDescription("Track your order")
        .addSupportedSize(WidgetSize.SMALL)
```

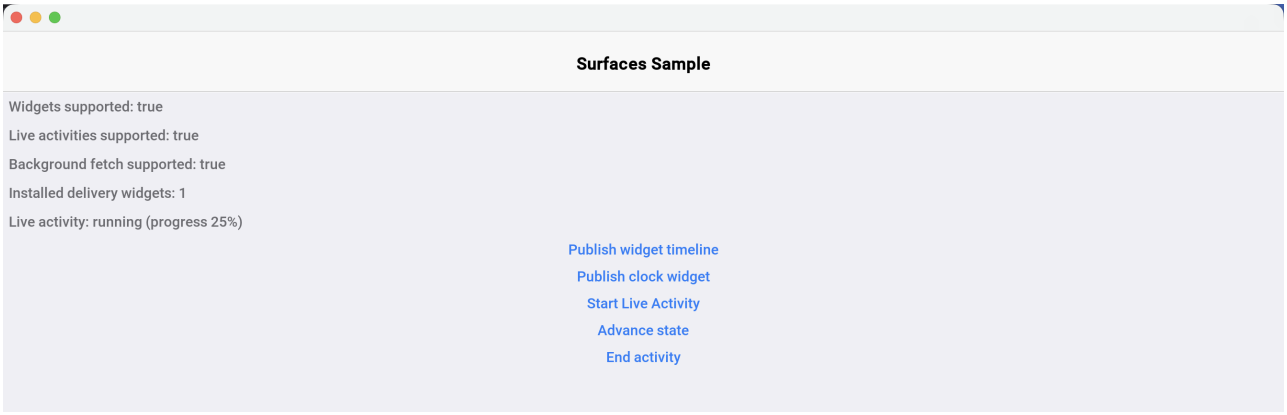
```
        .addSupportedSize(WidgetSize.MEDIUM));
```

A widget renders a **timeline**: a shared layout plus dated entries whose state maps fill the layout's `${key}` placeholders. The OS flips entries on schedule without waking your app. This publishes a delivery tracker that advances through four states:

```
long now = System.currentTimeMillis();
long eta = now + 4 * 60000L;
WidgetTimeline timeline = new WidgetTimeline()
        .setContent(buildDeliveryLayout())
        .addEntry(new Date(now), deliveryState("Preparing your order", eta, 0.1f))
        .addEntry(new Date(now + 60000L), deliveryState("Out for delivery", eta, 0.4f))
        .addEntry(new Date(now + 3 * 60000L), deliveryState("Arriving now", eta, 0.9f))
        .addEntry(new Date(eta), deliveryState("Delivered", eta, 1f))
        .setReloadPolicy(WidgetTimeline.RELOAD_AT_END);
Surfaces.publish("delivery_status", timeline);
```

The layout itself is a small tree of nodes with shared styling (padding, background, corner radius, alignment, weight, size, action):

```
private SurfaceNode buildDeliveryLayout() {
    Map<String, Object> params = new HashMap<>();
    params.put("orderId", "CN1-12345");
    return new SurfaceColumn().setSpacing(6).setPadding(12)
            .add(new SurfaceRow().setSpacing(10)
                    .add(new SurfaceImage(courierAvatar)
                            .setSize(40, 40).setCornerRadius(20))
                    .add(new SurfaceColumn().setSpacing(2).setWeight(1)
                            .add(new SurfaceText("${status}")
                                    .setFontSize(15)
                                    .setFontWeight(SurfaceFontWeight.SEMIBOLD)
                                    .setMaxLines(1))
                            .add(new SurfaceDynamicText(
                                    SurfaceDynamicText.STYLE_TIMER_DOWN, "eta")
                                    .setFontSize(24)
                                    .setFontWeight(SurfaceFontWeight.BOLD)
                                    .setColor(SurfaceColor.ACCENT))))
            .add(new SurfaceProgress(SurfaceProgress.STYLE_LINEAR)
                    .setValueState("progress")
                    .setColor(SurfaceColor.rgb(ACCENT_COLOR)))
            .setAction("open_order", params);
}



private Map<String, Object> deliveryState(String status, long eta, float progress) {
    Map<String, Object> state = new HashMap<>();
    state.put("status", status);
    state.put("eta", eta);
    state.put("progress", progress);
```

```
    return state;
}
```

Three things in this layout carry the model's weight. `SurfaceText` renders `${status}` from the entry state, so updates ship a tiny state map instead of a layout. `SurfaceDynamicText` with `STYLE_TIMER_DOWN` is a countdown the OS animates on its own clock — the ETA ticks every second with zero app wake-ups. `SurfaceProgress` reads its value from the `progress` state key. The `setAction` call at the root makes a tap anywhere on the widget open the app and deliver the `open_order` action.

`Surfaces.publish(…)` is callable from any thread and never blocks on the EDT, which matters for background refresh later in this chapter.

A complete runnable example lives in `Samples/samples/SurfacesSample` together with its `surfaces.json`:

70.2.1. Previewing in the simulator

Open **Widgets** > **Widgets Preview** in the simulator. The window lists your registered kinds, renders the published timeline of the selected kind at any size in light or dark mode, flips timeline entries on schedule, and ticks countdowns exactly as a home-screen widget would. The four watch complication families are listed too, at the accessory families' own sizes and clipped round where a watch face clips them — worth seeing, because a face shows nothing a circular complication draws into its corners. What it previews is the node tree, not the per-platform lowering, so a complication that looks right there can still arrive on a Wear OS face as one number. The mock Dynamic Island at the bottom renders running live activities. Clicks map through to your action handler, and a desktop (non-simulator) build renders the same publishes as floating widget windows pinned from a tray icon.

70.3. The node catalog

The catalog is kept small: a set of nodes every platform can render natively. Android app widgets (`RemoteViews`) are the constrained platform, so the catalog is designed to that floor and degrades as follows:

Node	iOS (SwiftUI)	Android (RemoteViews)	Notes
`SurfaceColumn` / `SurfaceRow`	`VStack` / `HStack`	`LinearLayout`	Weight maps to `layout_weight`
`SurfaceBox`	`ZStack`	`FrameLayout`	Child alignment via a 9-way enum
`SurfaceText`	`Text`	`TextView`	Android maps light/regular/medium weights to regular, semibold/bold to bold
`SurfaceDynamicText` timer	`Text(date, style:)`	`Chronometer`	Ticks natively on both
`SurfaceDynamicText` time	`Text(date, style: .time)`	`TextClock`	Native on both
`SurfaceDynamicText` date/relative	Native	Static text	Android refreshes it on the next update only
`SurfaceImage`	`Image`	`ImageView`	Named PNG blobs, content-hash dedup
`SurfaceProgress` linear	`ProgressView`	`ProgressBar`	Value 0..1 or a state key
`SurfaceProgress` circular	`Gauge`	Falls back to linear	Android widgets lack determinate circular progress
`SurfaceProgress` date interval	Native animation	Frozen at each refresh	iOS-only nicety
`SurfaceVector`	SwiftUI `Canvas`	Bitmap rendered in-process	Large vector nodes cost bitmap budget on Android
`SurfaceSpacer`	`Spacer`	Weighted `View`	Flexible gap
Corner radius	`clipShape`	Background drawable	May render square below Android 12
Node action	`Link` / `widgetURL`	`setOnClickPendingIntent`	Small iOS widgets honor only the root action

Descriptors are limited to 8 nesting levels. Keep payloads (JSON plus images) comfortably under 200kb — the iOS widget extension runs in about 30mb of memory, and Android parcels rendered widgets over a 1mb binder transaction.

70.4. Vector widgets

`SurfaceVector` covers the widgets the template catalog can't express — clocks, gauges, dials — with a retained list of vector drawing operations (fills, strokes, lines, arcs, text, rotation groups) replayed

natively by every renderer. Rotation groups can read their angle from a state key, which turns a static drawing into a data-driven one.

The classic example is an analog clock. The face is resolution independent — the `200x200` view box scales to whatever size the widget gets:

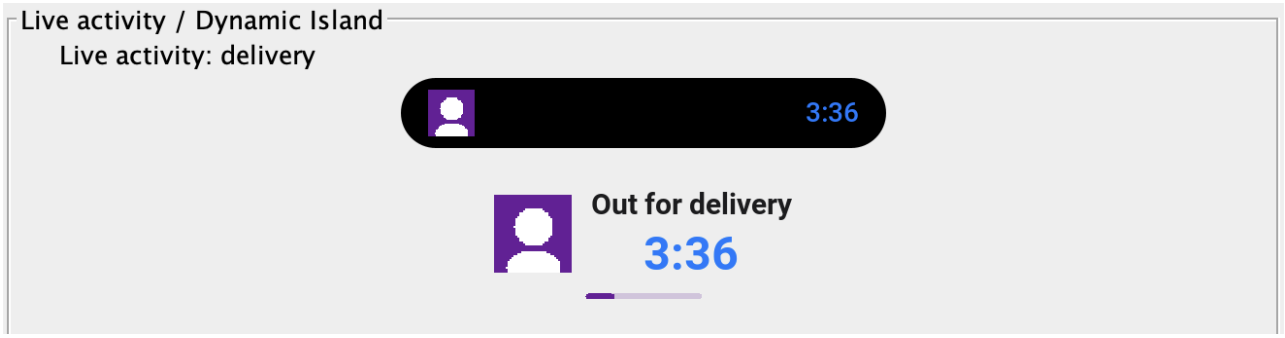
```
private SurfaceNode buildClockFace() {
    SurfaceVector face = new SurfaceVector(200, 200)
            .fillEllipse(100, 100, 96, 96, SurfaceColor.rgb(0xfffafafa, 0xff1c1c1e))
            .strokeEllipse(100, 100, 96, 96, 4, SurfaceColor.rgb(ACCENT_COLOR));
    for (int hour = 0; hour < 12; hour++) {
        boolean quarter = hour % 3 == 0;
        face.beginRotation(hour * 30f, 100, 100)
                .line(100, 10, 100, quarter ? 24 : 18, quarter ? 5 : 3, SurfaceColor.LABEL)
                .endRotation();
    }
    face.beginRotation("hourAngle", 100, 100)
            .line(100, 100, 100, 52, 8, SurfaceColor.LABEL)
            .endRotation()
            .beginRotation("minuteAngle", 100, 100)
            .line(100, 100, 100, 26, 5, SurfaceColor.rgb(ACCENT_COLOR))
            .endRotation()
            .fillEllipse(100, 100, 6, 6, SurfaceColor.rgb(ACCENT_COLOR));
    return face;
}
```

Angles use the clock convention: degrees, 0 at 12 o’clock, clockwise positive. The face publishes once; 60 per-minute timeline entries carry only the two angle values, and the OS flips them on schedule. The clock stays correct for an hour with zero app wake-ups:

```
WidgetTimeline timeline = new WidgetTimeline()
        .setContent(buildClockFace())
        .setReloadPolicy(WidgetTimeline.RELOAD_AT_END);
Calendar c = Calendar.getInstance();
c.set(Calendar.SECOND, 0);
c.set(Calendar.MILLISECOND, 0);
long minuteStart = c.getTimeInMillis();
int baseMinutes = c.get(Calendar.HOUR_OF_DAY) * 60 + c.get(Calendar.MINUTE);
for (int m = 0; m < 60; m++) {
    int totalMinutes = baseMinutes + m;
    Map<String, Object> state = new HashMap<>();
    // clock convention: degrees, 0 = 12 o'clock, clockwise positive
    state.put("minuteAngle", totalMinutes % 60 * 6f);
    state.put("hourAngle", totalMinutes % 720 * 0.5f);
    timeline.addEntry(new Date(minuteStart + m * 60000L), state);
}
Surfaces.publish("analog_clock", timeline);
```

70.5. Live activities

A live activity is started explicitly from the app and updated by pushing fresh state. The descriptor carries the main content (the lock screen presentation on iOS, the notification layout on Android) plus the Dynamic Island regions: `setCompactLeading` / `setCompactTrailing` for the pill shown around the camera cutout, `setMinimal` for the detached circle when several activities run, and `setExpandedLeading` / `setExpandedTrailing` / `setExpandedCenter` / `setExpandedBottom` for the long-press expanded card.



```
long eta = System.currentTimeMillis() + 4 * 60000L;
LiveActivityDescriptor descriptor = new LiveActivityDescriptor("delivery")
        .setContent(buildDeliveryLayout())
        .setCompactLeading(new SurfaceImage(courierAvatar)
                .setSize(24, 24).setCornerRadius(12))
        .setCompactTrailing(new SurfaceDynamicText(
                SurfaceDynamicText.STYLE_TIMER_DOWN, "eta")
                .setFontSize(14).setColor(SurfaceColor.ACCENT))
        .setExpandedCenter(new SurfaceText("${status}")
                .setFontSize(16).setFontWeight(SurfaceFontWeight.SEMIBOLD))
        .setExpandedBottom(new SurfaceProgress(SurfaceProgress.STYLE_LINEAR)
                .setValueState("progress")
                .setColor(SurfaceColor.rgb(ACCENT_COLOR)))
        .setTint(SurfaceColor.rgb(ACCENT_COLOR));
activity = LiveActivity.start(descriptor,
        deliveryState("Out for delivery", eta, 0.25f));
```

The returned handle is inert (`isActive()` returns `false`) on platforms without live activity support, so no platform checks are needed. Updates and the final state are plain state maps interpolated into the descriptor persisted at start time:

```
activity.update(deliveryState("Arriving now", eta, 0.9f));
// ... and when the delivery completes:
```

```
activity.end(deliveryState("Delivered", System.currentTimeMillis(), 1f));
```

The simulator preview renders the running activity as a mock Dynamic Island pill plus the expanded card:

On iOS the activity appears on the lock screen and, on supported devices, inside the Dynamic Island (ActivityKit requires iOS 16.1 or newer). On Android it lowers to an ongoing notification that renders the same content; on Android 13 and newer the first `start(…)` prompts for the notification permission, which the build declares for you, and `isSupported()` reports false once the user has turned that prompt down twice or has switched notifications off for the app. On desktop it appears in the simulator preview or as a floating window.

70.6. Actions and cold start

Every interactive node carries a string action id plus an optional parameter map, set with `setAction(id, params)`. Tapping the surface opens the app and delivers a `SurfaceActionEvent` to the single handler registered with `Surfaces.setActionHandler(…)`:

```
Surfaces.setActionHandler(evt -> {
    if ("open_order".equals(evt.getActionId())) {
        String orderId = (String) evt.getParams().get("orderId");
        showOrderForm(orderId);
    } else {
        Dialog.show("Surface Action", "Action " + evt.getActionId()
                + " from " + evt.getSource()
                + ", cold start: " + evt.isColdStart(), "OK", null);
    }
});
```

Actions are delivered on the EDT. When the tap launches a dead app, the event is queued across the cold start and delivered once your handler registers — which is why the registration belongs in `init()`. `SurfaceActionEvent.isColdStart()` tells you which path you are on, `getSource()` identifies the surface (widget kind or activity type), and `getParams()` returns the parameter map serialized with the action.

70.7. Updating from the background

Surfaces are updated from the running app in this release; push-driven updates are planned. Three

mechanisms keep content fresh without keeping the app open:

Timelines carry the future with them. Publish entries covering the hours ahead and the OS flips them on schedule — the clock above stays correct for an hour without a single wake-up. `WidgetTimeline.RELOAD_AT_END` (the default) asks the platform to request fresh content when the entries run out.

Background fetch re-publishes data. Implement `com.codename1.background.BackgroundFetch`, register with `Display.setPreferredBackgroundFetchInterval(int)`, and re-publish inside the callback — publishing is data-only file IO, safe from any thread and from a UI-less process:

```
public void performBackgroundFetch(long deadline, Callback<Boolean> onComplete) {
    // fetch fresh data, then re-publish the timeline
    publishDeliveryTimeline();
    onComplete.onSucess(Boolean.TRUE);
}
```

The completion callback must be invoked, or iOS stops granting fetch time. On iOS, background fetch also needs the `fetch` background mode:

```
codename1.arg.ios.background_modes=fetch
```

On Android, the widget pulls the app. When a provider renders an exhausted `RELOAD_AT_END` timeline (or no timeline at all) it starts the background fetch service directly — throttled to once per 15 minutes per kind, and only when the app declares background fetch. The iOS widget extension can't wake the app arbitrarily: an exhausted timeline makes WidgetKit re-read the persisted document, so publish timelines with enough future entries to bridge the gap between fetches. The simulator simulates background fetch with a timer that fires while the app is paused (**Simulate** > **Pause App**).

70.8. Per-platform notes

70.8.1. iOS

The build generates a `CN1Widgets` WidgetKit extension target into the Xcode project and shares published timelines with it through an App Group container. The App Group id defaults to `group.<your package name>`; override it with the `appGroup` field in `surfaces.json` or the `ios.surfaces.appGroup` build hint. The extension's deployment target defaults to 16.1 (ActivityKit's floor) without raising your app's own deployment target — on older iOS versions the extension never runs and `Surfaces.areWidgetsSupported()` returns `false`.

Signing follows the generic app extension rules: the extension needs its own App ID (`<your package>.CN1Widgets`) with the App Groups capability and, for cloud device builds with manual signing, its own provisioning profile. Either place the `.mobileprovision` under `common/src/main/resources` or supply a URL with the `ios.appext.CN1Widgets.provisioningURL` build hint. With automatic (managed) signing and in local `ios-source` builds no extra configuration is

needed — Xcode provisions the extension target as usual.

Like the app itself (`codename1.ios.debug.provision` / `codename1.ios.release.provision`), the extension needs a *development* profile for debug device builds and a *distribution* profile for release builds. Qualify any extension provisioning key with `debug` or `release` after the `ios.` segment and the build picks the variant matching the build target, falling back to the unqualified key when no matching variant is set:

- Build hints: `codename1.arg.ios.debug.appext.CN1Widgets.provisioningURL` and `codename1.arg.ios.release.appext.CN1Widgets.provisioningURL`
- Local profile paths in `codenameone_settings.properties`: `codename1.ios.debug.appext.CN1Widgets.provision` and `codename1.ios.release.appext.CN1Widgets.provision`

The Certificate Wizard populates both `provision` variants automatically when it sets up widget extension signing (the development profile requires at least one registered device). An unqualified key alone still works and is used for both build types.

Widget taps deep link back into the app through the `cn1surface://` URL scheme, which the build registers automatically.

70.8.2. Android

Widgets are rendered through `RemoteViews` by generated per-kind providers; no Android-specific build hints are needed, and the per-kind sizing metadata comes from `surfaces.json`. Timeline entry flips are scheduled with inexact alarms (a 30-second window) to avoid the exact-alarm permission by default; apps that need to-the-second flips can opt in with the `android.surfaces.exactAlarms` build hint. Second-precision countdowns still tick natively through `Chronometer`. Live activities lower to ongoing notifications, which on Android 13 and newer require the `POST_NOTIFICATIONS` runtime permission: the build declares it for you when `surfaces.json` sets `"liveActivities": true`, and the first `LiveActivity.start(…)` raises the system prompt, blocking the calling thread until the user answers. Codename One raises it at most twice across an install — Android stops showing the dialog after two refusals anyway — and spends an attempt only on a request it managed to issue. Android reports a dismissed dialog exactly as it reports a refusal, so dismissing one does cost an attempt, but one rather than the whole budget. Start the first activity while your app is in the foreground: there is no UI to prompt from in a background service or push handler, so a start from one before the permission is granted is refused without spending an attempt. `LiveActivity.isSupported()` is the programmatic signal once the answer has settled — a spent budget or, for an app that never declared the permission, a missing manifest entry — and `adb logcat -s CN1Surfaces` explains every refusal, reporting each settled reason once. A grant from anywhere counts — these prompts, push registration, `Display.requestNotificationPermission(…)` or the system settings — because the live permission state is always checked first. The approximations listed in the node catalog table apply: font weights collapse to regular/bold, circular progress falls back to linear, relative dates refresh only on entry flips, and vector nodes render as bitmaps.

70.8.3. Apple Watch

A kind declaring a `WATCH_*` family gets a second WidgetKit extension, `CN1WatchWidgets`, embedded in

the watch app rather than the phone app. It needs watchOS 10 (`watchNative.surfaces.deploymentTarget` overrides the floor), and it shares the App Group identifier with the phone — though the container behind it is watch-local, which is why the watch publishes its own timelines. Under manual signing the extension's bundle id, `<your.package>.watchkitapp.CN1WatchWidgets`, needs its own provisioning profile; the generic `ios.appext.CN1WatchWidgets.provisioningURL` hint supplies it.

70.8.4. Wear OS

A watch-bearing kind gets a `ComplicationDataSourceService`, and the `WATCH_RECTANGULAR` family additionally gets a `TileService`. Both are generated into the Wear module — the single APK in a standalone build, the `wear` module in a companion one — and pull in the `androidx.wear` complication and Tile libraries, which are AndroidX-only and raise that module's `minSdkVersion` to 26. The phone module's floor is untouched.

The node catalog maps as follows. A complication is the lossy one: the face asks for a typed value and composes it itself.

Node	Complication	Tile
`SurfaceText` / `SurfaceDynamicText`	First two nodes only, as text and title	Rendered, but a countdown is frozen and refreshed on timeline flips
`SurfaceImage` / `SurfaceVector`	First node only, as a monochrome glyph the face tints	Rendered as an inline image resource
`SurfaceProgress`	Becomes the ranged value	**Renders natively as an arc** — better than the phone widget, which degrades a circular bar to linear
`SurfaceRow` / `SurfaceColumn` / `SurfaceBox`	Traversal order only; there is no layout to honour	Rendered
Padding, background, alignment, weight, colour	Dropped — the face owns its design	Rendered
Actions	Root action only, as the complication tap	**Per-node actions work** — better than a small iOS widget

Everything a complication drops is logged once per render; `adb logcat -s CN1Surfaces` shows what a face is actually displaying.

70.8.5. Desktop, Windows, and Linux

In a desktop build the app shows a tray icon whose menu pins a floating widget per kind: a frameless, always-on-top window rendering the published timeline, with clicks dispatched to your action handler. Window positions and the pinned set persist across runs, and a running live activity docks a pill window at the top of the primary screen. Desktop widgets are process-bound in this release — they exist while the app process runs. On Windows the plain signed executable ships

these layered floating widgets with zero packaging; setting `windows.msix=true` additionally wraps the build in an MSIX package that declares a Windows 11 Widgets Board provider, so your kinds appear in the Win+W board rendered as Adaptive Cards. The MSIX channel is opt-in because it has real distribution prerequisites: a certificate the target machine trusts, the Windows App Runtime redistributable on the target machine, and Windows 11 for the board itself. On Linux the widgets are frameless GTK applet windows; on Wayland compositors that support the layer-shell protocol (KDE Plasma, Sway and the rest of the `wlroots` family) a runtime-loaded `gtk-layer-shell` places widgets above the wallpaper as real desktop applets with persistent positions and drag-to-move, and on GNOME Wayland they degrade to plain floating windows because the compositor controls global positioning and keep-above.

70.9. Build hints

Hint	Default	Purpose
`ios.surfaces.extension`	`true`	Set to `false` to skip the whole iOS lowering: no extension, no App Group, and the surfaces API reports unsupported at runtime
`ios.surfaces.appGroup`	`group.<package>`	The shared App Group id; the `appGroup` field in `surfaces.json` takes precedence
`ios.surfaces.deploymentTarget`	`16.1`	Deployment target of the widget extension (the host app is unaffected)
`ios.surfaces.frequentUpdates`	`false`	Adds `NSSupportsLiveActivitiesFrequentUpdates` for high-frequency live activity updates
`ios.appext.CN1Widgets.provisioningURL`		URL of the extension's provisioning profile for cloud manual-signing builds; used for both debug and release builds unless a qualified variant is set
`ios.debug.appext.CN1Widgets.provisioningURL` / `ios.release.appext.CN1Widgets.provisioningURL`		Build-type-specific variants: the URL of the development profile used by debug device builds and the URL of the distribution profile used by release builds. The variant matching the build target overrides the unqualified hint

Hint	Default	Purpose
`ios.background_modes`		Add `fetch` so background fetch can re-publish timelines on device
`android.surfaces.exactAlarms`	`false`	Schedule widget timeline entry flips with exact alarms; declares `SCHEDULE_EXACT_ALARM` and falls back to the inexact 30-second window when the user revokes the special app access
`watchNative.surfaces.deploymentTarget`	`10.0`	Deployment target of the watchOS complication extension. Can't go below 10.0: the container background every generated widget applies is watchOS 10, so a lower floor fails the build rather than losing the background
`ios.appext.CN1WatchWidgets.provisioningURL`		URL of the watch complication extension's provisioning profile, for cloud manual-signing builds. The `ios.debug.` / `ios.release.` variants work as they do for `CN1Widgets`
`android.surfaces.complicationUpdateSeconds`	`0`	How often the system polls a Wear complication data source. Zero means never: the timeline model is push-driven, so a poll spends watch battery asking a question the app has already answered
`android.wear.complicationsVersion` / `android.wear.tilesVersion` / `android.wear.protoLayoutVersion`	pinned	Override the `androidx.wear` library versions the generated complication and Tile services compile against
`android.watchModule`	`true`	Set to `false` to keep the wearable link without generating a companion Wear module; the phone build is then unchanged

Hint	Default	Purpose
`android.watchVersionCode` / `android.watchVersionCodeOffset`	`+100000000`	The Wear artifact's version code, which must outrank the phone's for Play to pick it on a watch. The offset is wide so the phone's next release can't catch up to a watch code already published
`windows.msix`	`false`	Wrap the Windows build in an MSIX package with a Widgets Board provider
`windows.msix.identityName`	package name	MSIX package identity name
`windows.msix.publisher`	`CN=<display name>`	MSIX identity publisher; must match the signing certificate subject
`windows.msix.version`	`1.0.0.0`	MSIX package version
`windows.msix.pfx` / `windows.msix.password`	executable signing configuration	Certificate used to sign the MSIX package

70.10. Current limitations

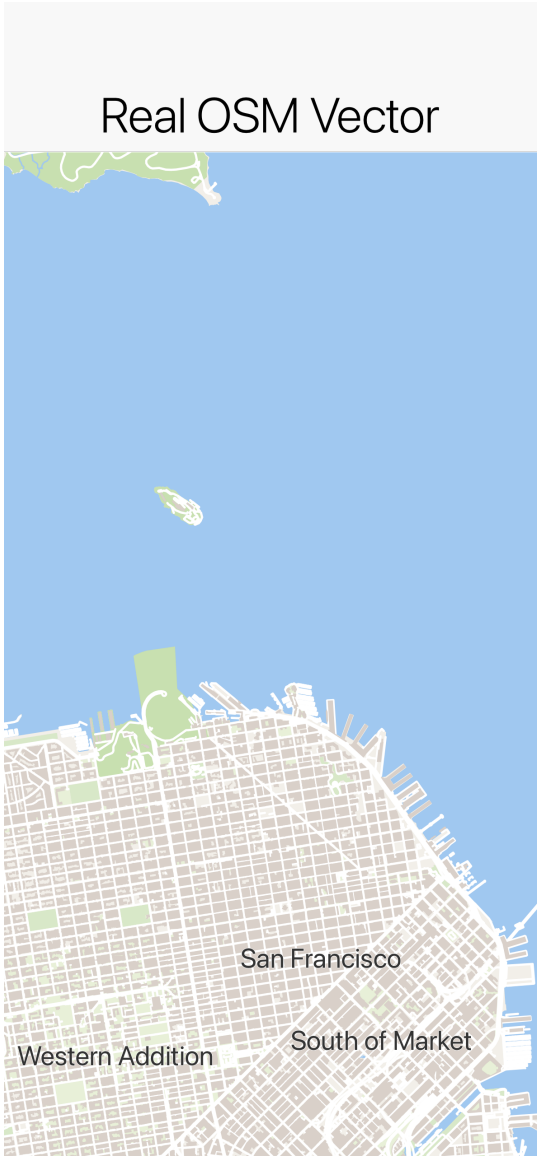
- Updates originate from the app (timelines, background fetch, live activity updates). Server-pushed widget content and ActivityKit push tokens are planned; the wire format already accommodates them.
- The node catalog is intentionally the lowest common denominator — there is no arbitrary per-pixel drawing beyond `SurfaceVector`, and no embedding of regular Codename One components.
- `WidgetSize.LOCKSCREEN` maps to the iOS `accessoryRectangular` family and is ignored on Android in this release.
- A kind declaring only `WATCH_*` families produces no phone surface on either platform — those kinds are hosted by the watch. Declare a phone family alongside them if you want both.
- What a watch face shows is narrower than what you laid out, and on Wear OS much narrower. See the wearables chapter for the per-family mapping and what gets dropped.
- The Widgets Board provider requires the `windows.msix` opt-in and its distribution prerequisites; without it, Windows desktop widgets are floating windows.

Chapter 71. Maps

Codename One ships a modern mapping API in the `com.codename1.maps` package built around two components:

- `MapView` — a **pure-vector** map drawn entirely through the Codename One `Graphics` pipeline. It never embeds a native peer, so it composes cleanly with the rest of your UI (dialogs, lists and overlays draw over it) and behaves identically on every platform, including the simulator and the web.
- `NativeMap` — a map backed by a **native provider** (Apple MapKit, Google Maps, …) when one is wired into the build, and which transparently **falls back to a `MapView`** when no provider is available (the simulator, devices without the selected provider, or builds that didn't opt in).

Both components implement the same `MapSurface` interface, so application code is identical regardless of which one — or which provider — is backing the map.



The legacy tile-based `MapComponent` and the external `codenameone-google-maps` cn1lib are deprecated in favor of this API.

71.1. A first map

The pure-vector `MapView` renders real maps with zero configuration and no API key — by default it shows the free, keyless OpenFreeMap [https://openfreemap.org] vector basemap (real OpenStreetMap data):

```
MapView map = new MapView();
map.moveCamera(new LatLng(37.7749, -122.4194), 12);
form.add(BorderLayout.CENTER, map);
```

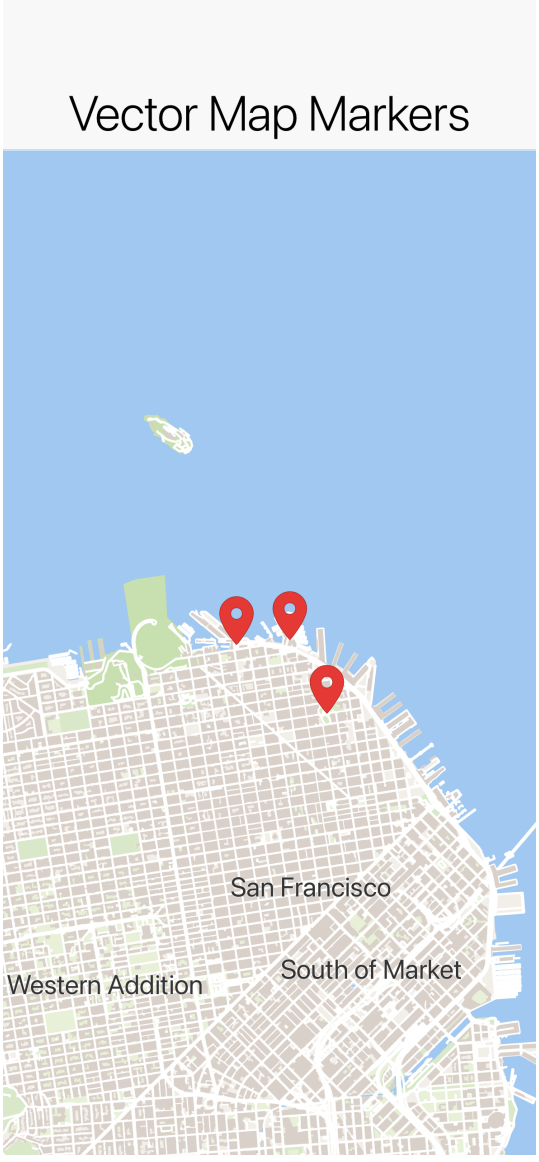
`LatLng` is the immutable WGS84 coordinate value type used throughout the API. The camera is described by a center `LatLng` and a fractional zoom level (the standard slippy-map scale where each whole increment doubles the scale).

71.2. The MapSurface API

Every map — vector or native — exposes the same operations through `MapSurface`:

```
// Camera
map.setCameraPosition(new CameraPosition(new LatLng(48.8566, 2.3522), 11));
map.moveCamera(new LatLng(48.8566, 2.3522), 11);
map.setZoom(13);
map.fitBounds(new MapBounds(new LatLng(48.8, 2.2), new LatLng(48.9, 2.4)), 24);

// Markers
Marker m = map.addMarker(new MarkerOptions(new LatLng(48.8584, 2.2945))
        .icon(pinImage)
        .title("Eiffel Tower")
        .anchor(0.5f, 1.0f)
        .onClick(e -> showDetails()));
map.removeMarker(m);



// Shapes
map.addPolyline(new Polyline(routePoints).setStrokeColor(0xff5722).setStrokeWidth(6));
```

```
map.addPolygon(new Polygon(areaPoints).setFillColor(0x803f51b5).setStrokeColor(0x3f51b5));
map.addCircle(new Circle(new LatLng(48.85, 2.35), 500).setFillColor(0x804caf50));
map.clearMapObjects();

// Coordinate conversion and bounds
Point pixel = map.latLngToScreen(new LatLng(48.85, 2.35));
LatLng coord = map.screenToLatLng(120, 240);
MapBounds visible = map.getVisibleRegion();

// Events
map.addTapListener((surface, location, x, y) -> placeMarker(location));
map.addLongPressListener((surface, location, x, y) -> contextMenu(location));
map.addCameraChangeListener((surface, camera) -> persist(camera));
```

Marker icons are supplied as `EncodedImage` and anchored in normalized `(u, v)` image space (`0.5, 1.0` puts the pin tip on the location). When no icon is given, a marker draws the standard Material Design map pin. Polygon and circle fills accept an `0xAARRGGBB` color so you can make them translucent.

71.3. Routes that follow the road

A polyline joins the coordinates you hand it with **straight** lines — it knows nothing about roads. Passing two endpoints to `addPolyline` therefore draws a single straight segment across the map, which is seldom what a navigation screen wants. Working out the road geometry between two points is a separate job, done by a routing service, and that's what the `com.codename1.maps.routing` package is for:

```
MapView map = new MapView();
form.add(BorderLayout.CENTER, map);

// Draws the driving route along the actual roads and frames it.
Routing.showRoute(map, origin, destination);
```

`Routing.showRoute(…)` fetches the route, draws it and moves the camera to frame it. Like the keyless OpenFreeMap basemap, it works with no API key and no signup: routing runs over OpenStreetMap data through the built-in `OsrmRouteService`.

Routing is asynchronous — the call returns immediately and the line appears when the service answers. Use `Routing.findRoute(…)` when you want the result itself, for example to style the line or show the distance and the estimated time:

```
RouteRequest request = new RouteRequest(origin, destination)
        .addWaypoint(new LatLng(38.8899, -77.0091))
        .setTravelMode(TravelMode.DRIVING);

Routing.findRoute(request, new RouteCallback() {
    @Override
    public void routesFound(java.util.List routes) {
        Route best = (Route)routes.get(0);
        map.addPolyline(best.toPolyline().setStrokeColor(0xff5722).setStrokeWidth(6));
        map.fitBounds(best.getBounds(), CN.convertToPixels(4));
        label.setText((int)(best.getDistanceMeters() / 1000) + " km, "
                + (int)(best.getDurationSeconds() / 60) + " min");
    }

    @Override
    public void routeFailed(String message, Throwable error) {
        label.setText(message);
    }
});
```

A `Route` carries the drawable geometry (`toPolyline()`), the bounds to frame it with, the total distance and duration, and the `RouteLeg`/`RouteStep` breakdown behind a turn-by-turn list. A `RouteRequest` adds waypoints and a `TravelMode` (`DRIVING`, `WALKING`, `CYCLING`).

The default endpoint is OSRM's **public demo server**. It exists for development and

> demos: no SLA, rate limited, and it hosts the car profile, so walking and cycling requests are routed over driving data there. Before shipping, point the service at your own OSRM instance (or any OSRM-compatible endpoint) — nothing else in your code changes:

```
// Your own OSRM instance, or any OSRM-compatible endpoint.
Routing.setService(new OsrmRouteService("https://osrm.example.com"));
```

To route through a different provider entirely — Google Directions, Mapbox Directions, GraphHopper, your own server — implement `RouteService` and install it the same way. Every provider of that kind returns the route as an **encoded polyline**, which `Polyline.fromEncoded(geometry)` turns straight into something drawable (`PolylineCodec` also handles the `polyline6` variant used by Valhalla).

71.4. Tile sources and styles (MapView)

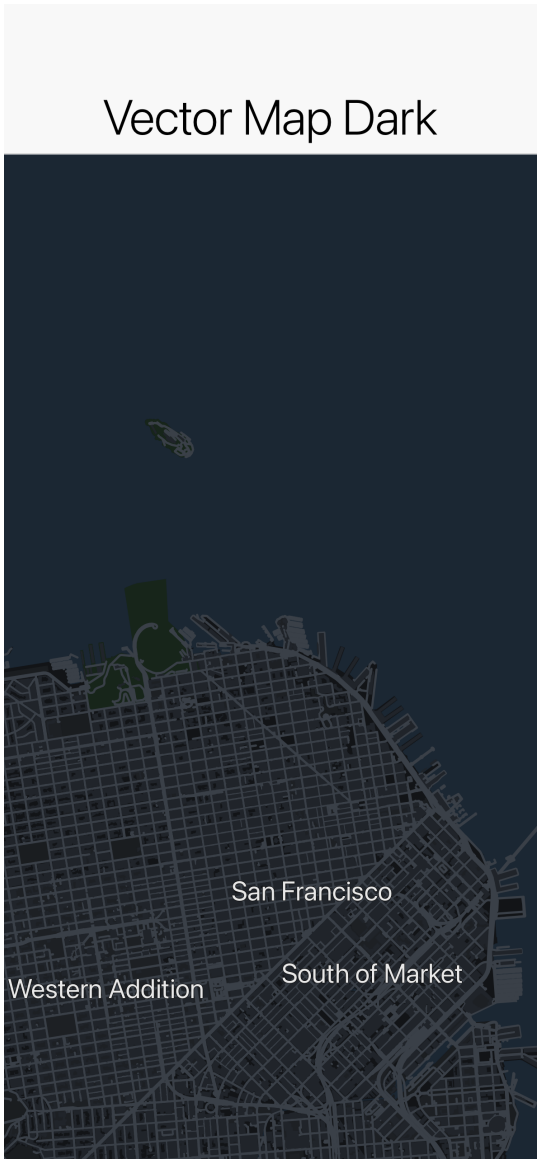
`MapView` pulls its tiles from a pluggable `com.codename1.maps.vector.TileSource`:

- `MvtTileSource` — networked Mapbox Vector Tiles (`.pbf`/`.mvt`). `MvtTileSource.openFreeMap()` is the free, keyless OpenStreetMap-based default (its tile URLs are versioned, so it resolves them from OpenFreeMap's TileJSON automatically). Most other hosted vector basemaps require an API key supplied via `setApiKey(…)` and referenced as `{key}` in the URL template; a TileJSON endpoint (a URL with no `{z}` token) is resolved automatically.
- `RasterTileSource` — networked XYZ image tiles. `RasterTileSource.openStreetMap()` is a keyless raster alternative.
- `BundledTileSource` — tiles bundled into the app as resources, for fully offline maps. The screenshot tests in this repo use this against a small fixture set so the renders are deterministic and network-free; it's not how you ship a real map.
- `DemoTileSource` — a self-contained synthetic tile set (no network), handy for demos and deterministic tests.

71.4.1. Connecting to real map data

For a real app you point `MapView` at a hosted tile service. The simplest keyless option is OpenFreeMap (OpenStreetMap-based vector tiles); for branded styles or higher quotas use a keyed provider such as MapTiler or your own self-hosted Protomaps/TileServer GL endpoint:

```
// Keyless, zero-config vector basemap (OpenStreetMap data via OpenFreeMap):
MapView vector = new MapView(MvtTileSource.openFreeMap(), MapStyle.light());



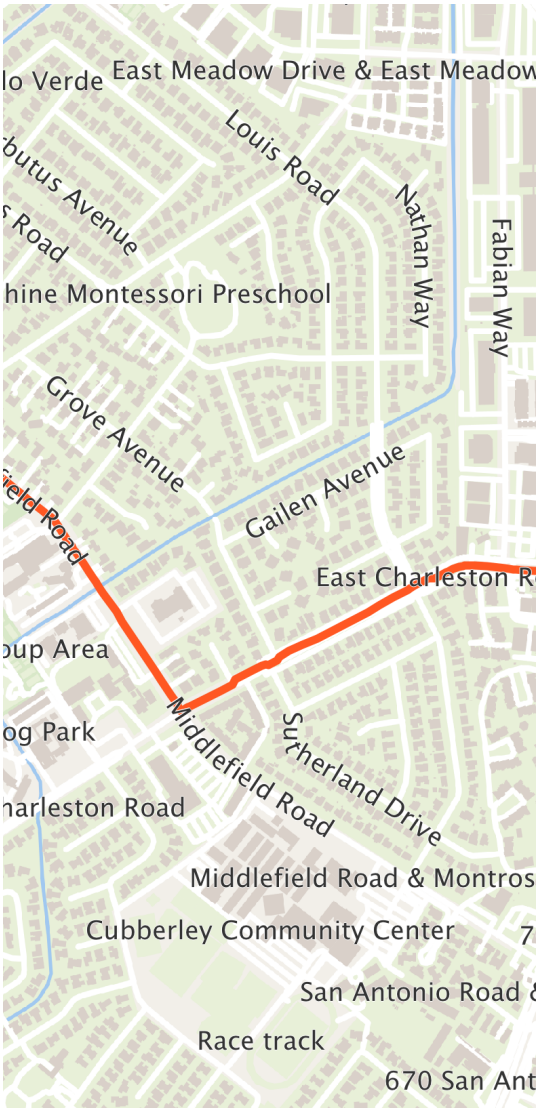
// A keyed hosted provider (e.g. MapTiler). {z}/{x}/{y} are the XYZ tile
// coordinates and {key} is substituted from setApiKey(...):
MapView branded = new MapView(
        new MvtTileSource("https://api.maptiler.com/tiles/v3/{z}/{x}/{y}.pbf?key={key}", 0, 14)
                .setApiKey(apiKey),
        MapStyle.dark());
```

```
// A keyless raster (image-tile) basemap, if you don't need vector styling:
MapView raster = new MapView(RasterTileSource.openStreetMap());
```

If the URL has no `{z}` token it's treated as a TileJSON document and the real tile-URL template (and min/max zoom) are resolved from it automatically, so you can paste a provider's TileJSON URL directly.

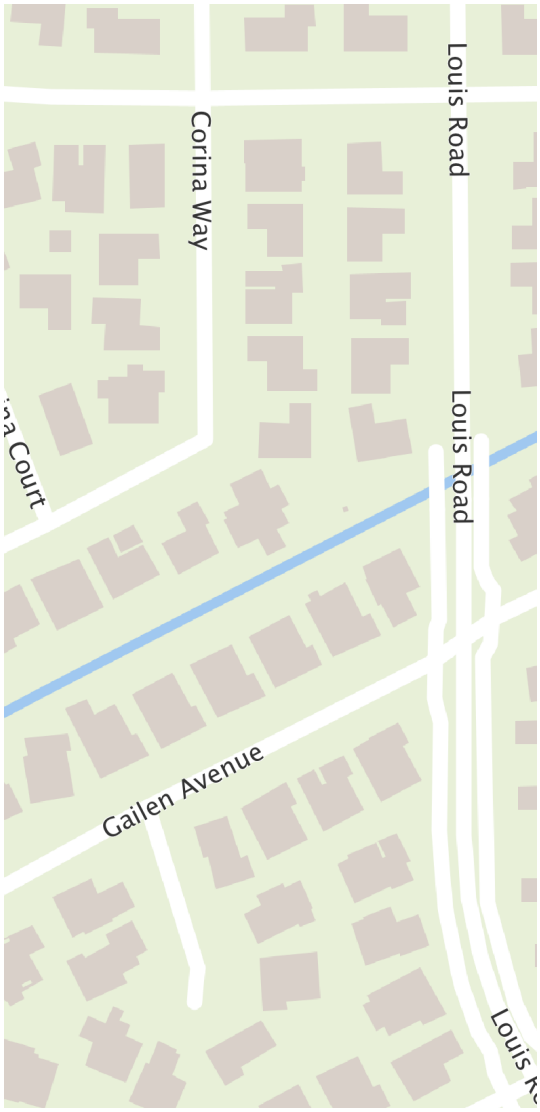
To bundle your own offline tiles instead, drop `.mvt`/`.pbf` files into the app's resources under a `{z}/{x}/{y}` layout and point `BundledTileSource` at them — that's exactly what the test fixtures do.

Vector tiles are painted according to a `MapStyle`. The built-in `MapStyle.light()` and `MapStyle.dark()` cover a usable basemap; `MapStyle.fromJson(json)` parses a subset of the MapLibre GL style specification (`background`/`fill`/`line`/`symbol` layers, zoom-stop interpolation, simple `["==", key, value]` filters).



71.4.2. Street names and street-level zoom

Street names are written along the streets themselves, the way a printed street map shows them. A name follows the line of its road, bends with it on a gentle curve and always reads left to right. A



long road repeats its name at intervals so a name is in view wherever you look along it. A name is left out rather than scrambled where a corner falls under it, where the road is shorter than the name, or where it would overlap another label. Place names and points of interest stay horizontal.

Labels are drawn above the lines and shapes you add and below the markers. A route drawn with `addPolyline` therefore never hides the names of the streets it follows, while pins stay on top of everything:

When you draw on the basemap yourself through `getEngine()`, the engine's `paint` method draws the tiles and their labels together. To put your own drawing between the two, call `paintTiles`, draw, then call `paintLabels`.

A vector map zooms further than the deepest level its tile source serves. OpenFreeMap's data stops at zoom 14, yet the map reaches zoom 20: past zoom 14 the map redraws the zoom 14 geometry at the larger scale, so roads and buildings stay sharp instead of turning into a stretched image. `getMaxZoom()` reports the deepest level the camera can reach: six levels past the source's own, up to zoom 22. A source that serves deeper tiles than that keeps its own deepest level. A raster source stops at its own deepest level, since enlarging an image only blurs it.

Line widths, like text sizes, are in logical pixels and scale with the screen density, so a road is as thick on a high-density phone as on a desktop. The built-in styles keep widening roads as you zoom in to street level. At the deepest zooms a street name can sit a little to the side of its road: the name comes from a simplified copy of the road's line in the tile data, and the difference grows as the map enlarges it.

71.5. Native maps and providers

`NativeMap` renders through a native map SDK when the build wires one in:

```
NativeMap map = new NativeMap(new LatLng(37.7749, -122.4194), 12);
map.addMarker(new MarkerOptions(new LatLng(37.7749, -122.4194)).title("San Francisco"));
form.add(BorderLayout.CENTER, map);

if (!map.isNativeMap()) {
    // Running on the simulator (or a build without a provider) -> vector fallback.
}
```

Which provider (if any) backs the map is decided entirely by **build hints** — the public API never names a provider, so unused providers add nothing to your app's size. Select one with the `maps.provider` build hint (or the per-platform `ios.maps.provider` / `android.maps.provider`):

```
# iOS uses Apple MapKit (a free system framework, no API key, no pod):
codename1.arg.ios.maps.provider=apple

# Android uses Google Maps (pulls Google Play Services Maps):
codename1.arg.android.maps.provider=google

# ...or Huawei Map Kit, for devices without Google Play Services (HMS Core).
# The build pulls com.huawei.hms:maps from Huawei's Maven repo automatically;
# your app still needs the usual HMS onboarding (agconnect-services.json / key):
codename1.arg.android.maps.provider=huawei
```

The built-in providers are Apple MapKit (iOS), Google Maps (Android) and Huawei Map Kit (Android). Huawei Map Kit runs on any Android device with HMS Core installed — not only Huawei hardware — so it's the natural choice for the Android market without Google Play Services. Each reports `isAvailable()` at runtime (Google checks Play Services, Huawei checks HMS Core), and when the selected provider is unavailable `NativeMap` falls back to the pure-vector `MapView`.

When a provider is selected the build server injects that provider's implementation into your app and wires it in; with no provider selected (or when the provider is unavailable at runtime, for example when Google Play Services is missing) `NativeMap` simply renders the vector `MapView` fallback. You can configure the fallback basemap explicitly:

```
NativeMap map = new NativeMap(new LatLng(0, 0), 4, fallbackTileSource, MapStyle.light());
```

71.5.1. Provider API keys

Apple MapKit needs no key. Google Maps requires the usual keys, supplied as build hints:

```
codename1.arg.android.xapplication=<meta-data android:name="com.google.android.maps.v2.API_KEY"
android:value="YOUR_ANDROID_API_KEY"/>
codename1.arg.ios.afterFinishLaunching=[GMSServices provideAPIKey:@"YOUR_IOS_API_KEY"];
```

71.5.2. Cross-platform web maps

A native provider only renders on the platforms that ship its SDK. To show a provider's map **everywhere** — including platforms with no native SDK for it — register a `WebMapProvider`, which hosts the provider's JavaScript SDK inside a `BrowserComponent`. It draws the basemap and not much else, though: the camera getters report zero and markers, shapes, coordinate conversion and gestures are no-ops, so prefer it only where a static map is what you want:

```
// Render Google Maps through its JavaScript SDK on any platform with a browser:
MapProviderRegistry.register(WebMapProvider.google("YOUR_MAPS_JS_API_KEY"));

// Registering only appends to the registry, and a build-injected native
// provider already there wins -- Apple Maps on iOS, for one. Asking for
// the web provider by name is what makes this one render everywhere.
//
// Ask for it only when a basemap is all you need. WebMapProvider draws
// the tiles and little else: the camera getters answer zero, and
// markers, shapes, coordinate conversion and the gesture callbacks are
// no-ops. setZoom() through it reads that zero position and recenters on
// (0, 0). For the operations the MapSurface section shows, leave the
// native provider in front.
MapProviderRegistry.setPreferredProvider("web");

NativeMap map = new NativeMap(new LatLng(41.0, 13.0), 5);
```

Because it needs only a web view, the web provider (id `web`) is the natural last step before the pure-vector fallback in a provider chain. The order is fully customizable from code, so you can express per-platform preferences — for example "try the native Google SDK, then the web map, then the vector `MapView`":

```
MapProviderRegistry.setProviderOrder(new String[]{"google", "web", "vector"});
```

71.6. Choosing between MapView and NativeMap

Use `MapView` when you want a lightweight, dependency-free map that looks the same everywhere and composes with CN1 components. Use `NativeMap` when you want the platform's native map look, gestures and performance, and are willing to opt a provider in through build hints — with the guarantee that it still works (as a vector map) where the provider is unavailable.

Chapter 72. In-Car Experiences (CarPlay & Android Auto)

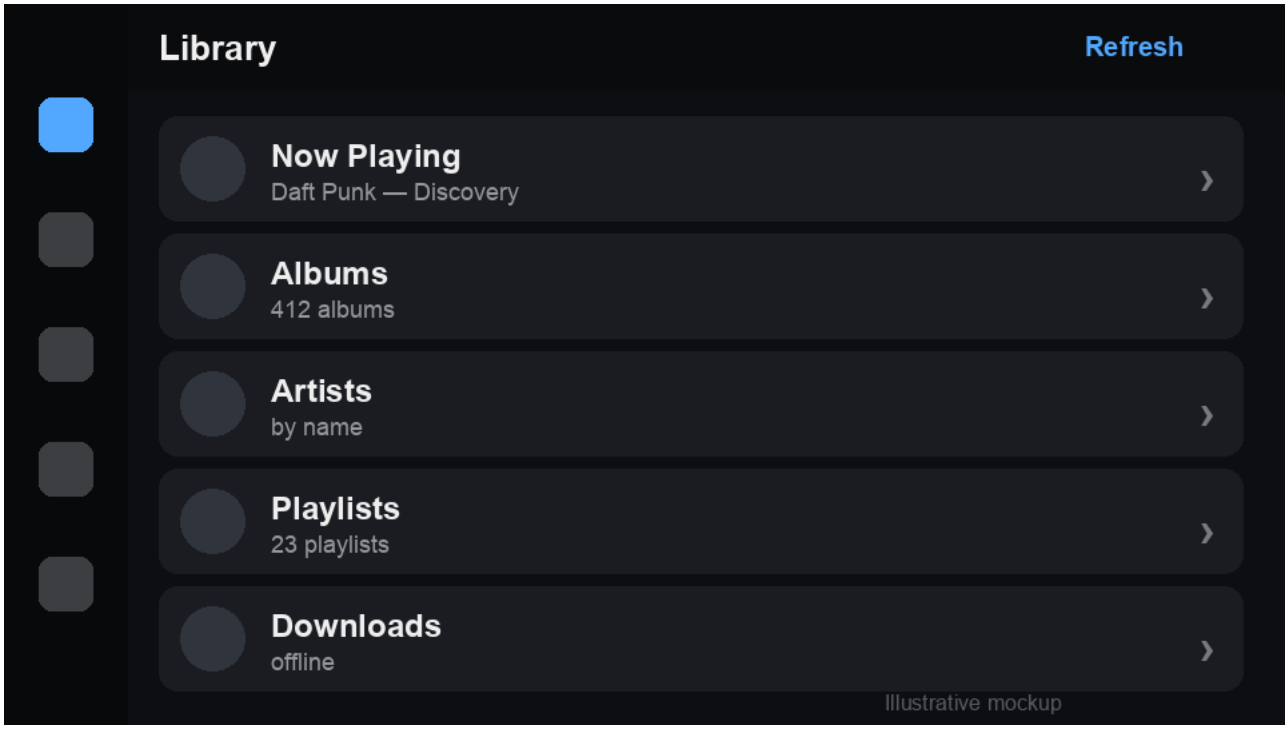
Codename One can project a driver-safe UI onto Apple CarPlay and Google Android Auto from a single portable API under the `com.codename1.car` package. You describe the screens once with a small set of cross-platform templates; Codename One renders them as native `CPTemplate`s on CarPlay and `androidx.car.app` templates on Android Auto.

CarPlay and Android Auto are **template-based** UI systems. Unlike the phone, tablet, or even Apple TV/Android TV (which reuse the normal Codename One renderer), the car platforms don't let an app draw arbitrary pixels or show a regular Codename One `Form`. To minimise driver distraction the system only renders a fixed catalogue of templates — lists, grids, info panes, messages, navigation and now-playing — and grants access per **app category** (audio, communication, navigation, point-of-interest). The `com.codename1.car` API maps the common in-car use cases onto that catalogue. "Seamless" here means seamless integration, lifecycle and build wiring — not running your existing phone UI on the dashboard.

This API is **zero cost when unused**: simply referencing `com.codename1.car` is what tells the build to wire the native plumbing (the CarPlay scene + entitlement on iOS, the `androidx.car.app` dependency + `CarAppService` on Android). Apps that never touch the package get none of it.

72.1. Quick start

Register a single `CarApplication` from your app's `init()` — before a head unit connects — and return a root `CarScreen` that builds a template:



```
public class MyApp {
    public void init(Object context) {
        // ... normal app init ...
        Car.setApplication(new MyCarApplication());
    }
}

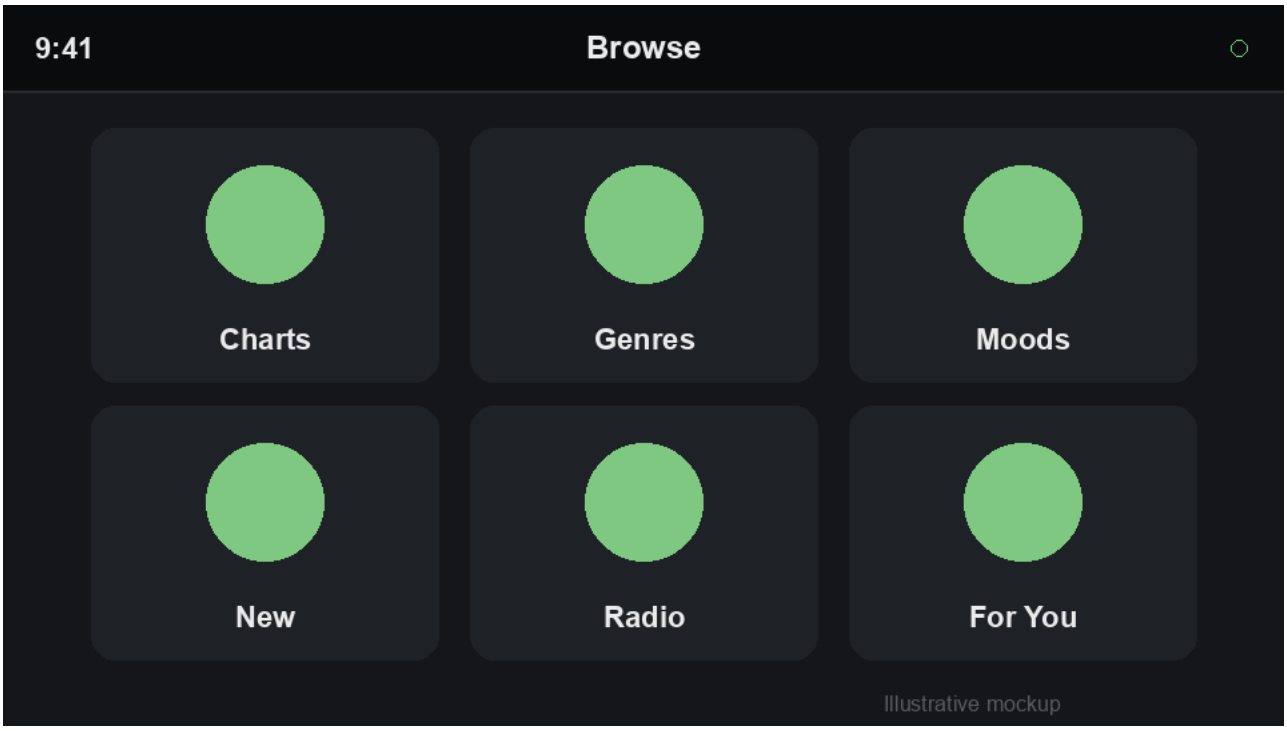
class MyCarApplication extends CarApplication {
    public CarScreen onCreateRootScreen(CarContext context) {
        return new LibraryScreen();
    }
}

class LibraryScreen extends CarScreen {
    protected CarTemplate onCreateTemplate() {
        return new CarListTemplate().setTitle("Library")
            .addRow(new CarRow("Now Playing").setText("Daft Punk - Discovery")
                .setOnAction(ctx -> play()))
            .addRow(new CarRow("Albums").setBrowsable(true)
```

```
                .setOnAction(ctx -> ctx.pushScreen(new AlbumsScreen())))
            .addRow(new CarRow("Playlists").setBrowsable(true)
                .setOnAction(ctx -> ctx.pushScreen(new PlaylistsScreen())));
    }
}
```

That single description renders natively on both platforms:

On the simulator and on any port without in-car projection there is no head unit, so the whole API is an inert no-op and `CN.isCarConnected()` returns `false` — your code never needs platform `if` statements.



72.2. Templates

A `CarScreen` returns exactly one `CarTemplate`. The catalogue mirrors what the head units allow:

Template	Use for	CarPlay	Android Auto
`CarListTemplate`	Sectioned scrolling list of rows (browse, settings)	`CPListTemplate`	`ListTemplate`
`CarGridTemplate`	Image-forward grid (categories, presets, artwork)	`CPGridTemplate`	`GridTemplate`
`CarPaneTemplate`	Detail pane: label/value rows + up to two actions	`CPInformationTemplate`	`PaneTemplate`

Template	Use for	CarPlay	Android Auto
`CarMessageTemplate`	Short message + actions (errors, prompts, messaging)	`CPInformationTemplate`	`MessageTemplate`
`CarNavigationTemplate`	Turn-by-turn surface with a drawable map	`CPMapTemplate`	`NavigationTemplate`
`CarNowPlayingTemplate`	System now-playing surface for audio apps	`CPNowPlayingTemplate`	media now-playing

Rows (`CarRow`), grid items (`CarGridItem`) and actions (`CarAction`) carry a title, optional secondary text, an optional `com.codename1.ui.Image` icon and a `CarActionListener` invoked on the EDT when the element is selected. Mark a row `setBrowsable(true)` when selecting it drills into a deeper screen.

Head units enforce a hard cap on the number of rows/items they display (driver-distraction rules). Query it and trim accordingly:

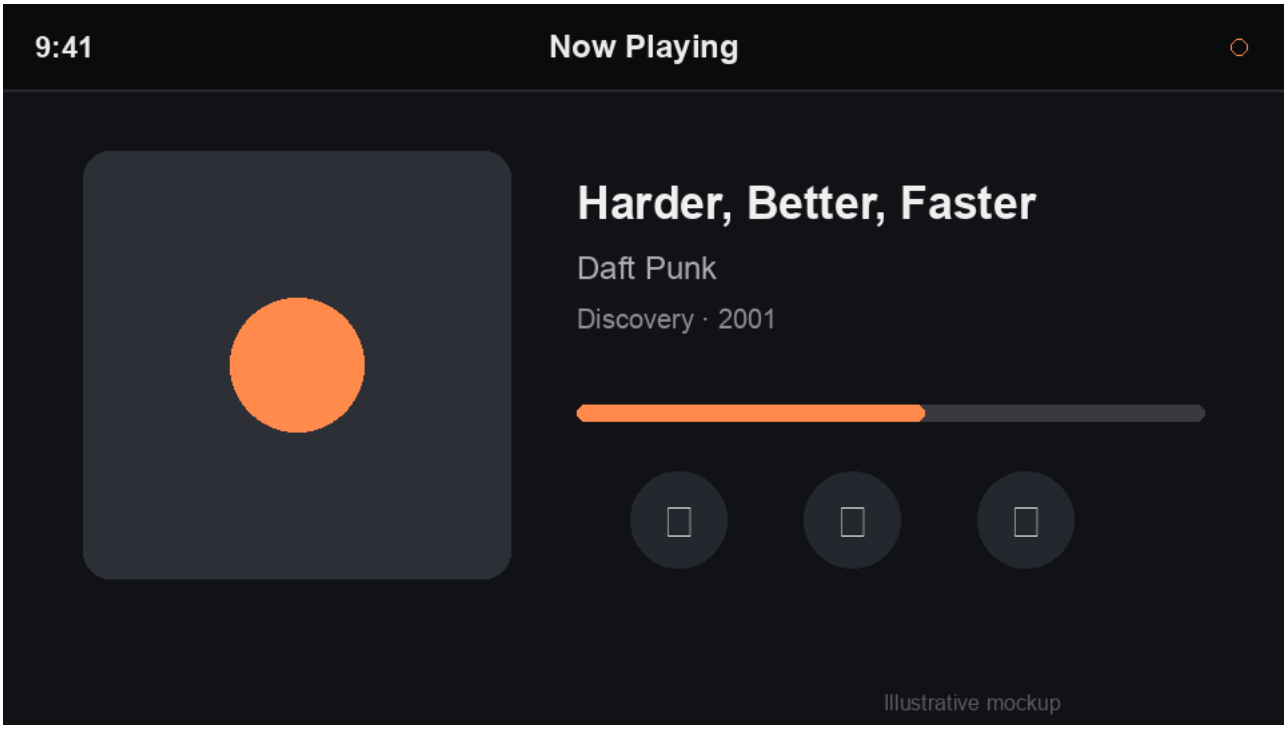
```
int max = context.getListRowLimit(); // 0 when the head unit doesn't say
int count = (max > 0) ? Math.min(items.size(), max) : items.size();
CarListTemplate t = new CarListTemplate().setTitle("Library");
for (int i = 0; i < count; i++) {
    t.addRow(new CarRow(items.get(i)));
}
```

72.3. Screen stack & lifecycle

`CarContext` manages a back stack, mirroring `androidx.car.app`'s `ScreenManager` and CarPlay's `CPInterfaceController`:

```
context.pushScreen(new DetailScreen());  // drill in
context.popScreen();                     // back
screen.invalidate();                     // rebuild this screen's template after a model change
context.showToast("Added to queue");
```

`CarScreen` exposes optional lifecycle hooks — `onCreate()`, `onResume()`, `onPause()`, `onDestroy()` — and `CarApplication` is notified of connection changes via `onCarConnected(CarContext)` / `onCarDisconnected()`. You can also observe connection globally:



```
class CarAwareForm extends Form {
    // Car keeps the listener in a static list, so a screen-scoped observer
    // has to hand back this exact instance or every recreated screen stays
    // reachable and keeps receiving connection callbacks
    private CarConnectionListener connectionListener;

    protected void initComponent() {
        super.initComponent();
        connectionListener = new CarConnectionListener() {
            public void carConnected(CarContext ctx) { startLocationStream(); }
            public void carDisconnected()           { stopLocationStream(); }
        };
        Car.addConnectionListener(connectionListener);
    }

    protected void deinitialize() {
        Car.removeConnectionListener(connectionListener);
        super.deinitialize();
    }
}
```

72.4. Now-playing (audio apps)

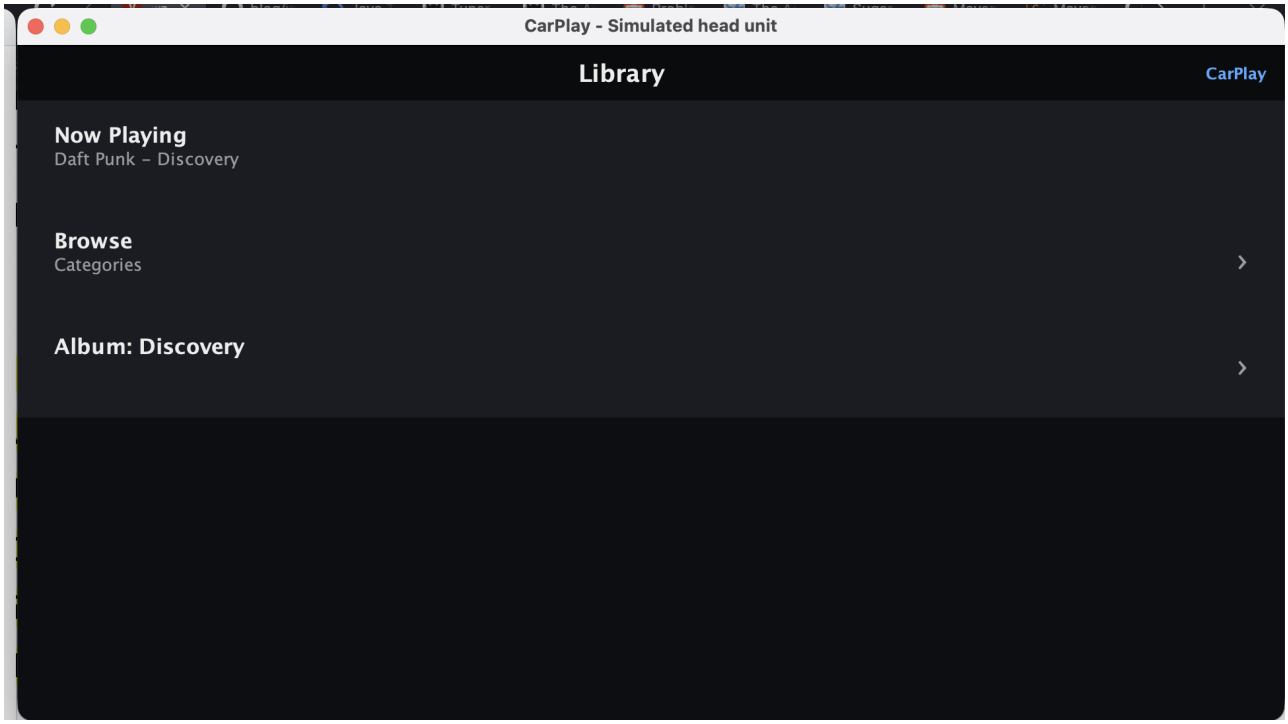
For audio apps the track metadata, artwork, scrubber and transport controls are driven by the platform media session (the Android background audio service / `MPNowPlayingInfoCenter` on iOS), so `CarNowPlayingTemplate` carries no metadata of its own — it routes the head unit to the now-playing surface and lets you add a couple of app-specific buttons (shuffle, like).

72.5. Build configuration

Native wiring is added automatically when your bytecode references `com.codename1.car`. Apple grants CarPlay entitlements — and Android Auto surfaces categories — **per app category**, so declare the categories you ship with these build hints:

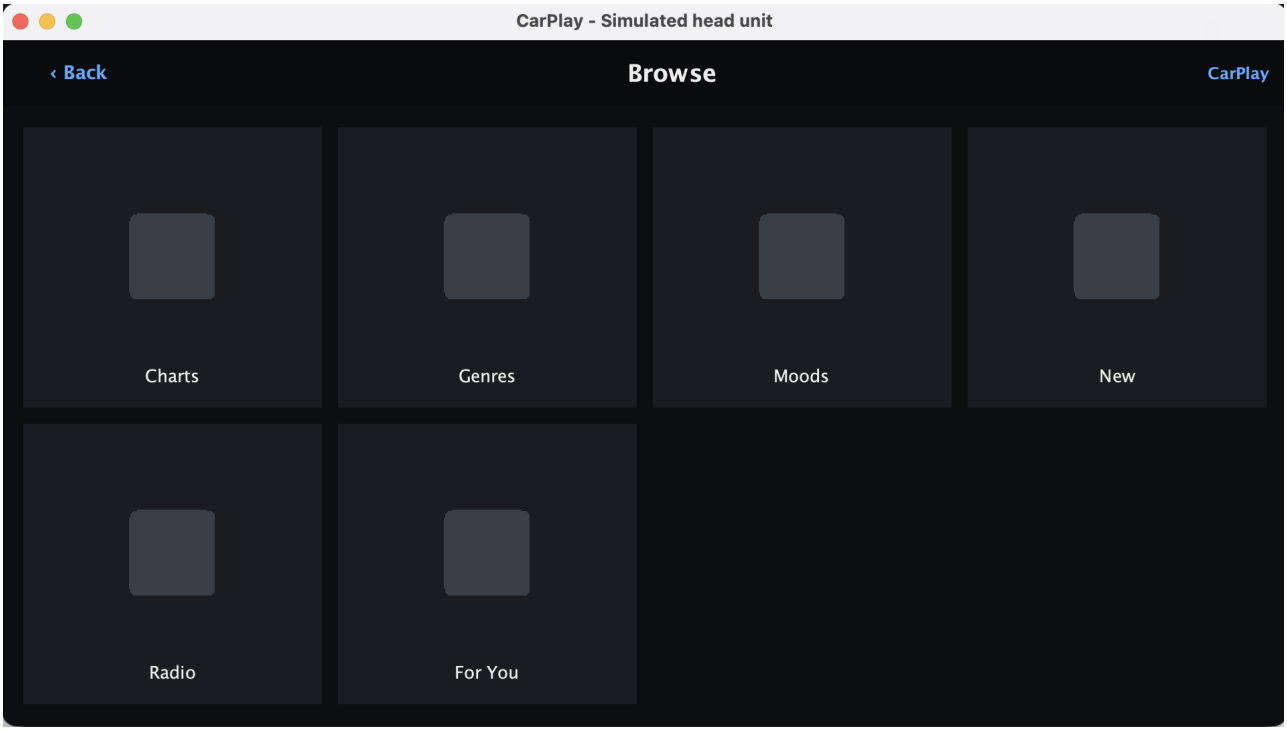
Category	iOS hint	Android hint	Notes
Audio	`ios.carplay.audio=true`	(media browser service)	Default CarPlay entitlement when none specified
Communication	`ios.carplay.messaging=true`	`android.androidAuto.messaging=true`	Read-aloud / voice reply
Navigation	`ios.carplay.navigation=true`	`android.androidAuto.navigation=true`	Adds the drawable map surface + `MAP_TEMPLATES` permission
Point of interest	`ios.carplay.poi=true`	`android.androidAuto.poi=true` (default)	Browse/POI list apps

Optional: `android.carAppVersion` pins the `androidx.car.app` version; `android.androidAuto.minCarApiLevel` sets the minimum car API level.



CarPlay and the restricted Android Auto categories require approval from Apple/Google before they will run outside the simulator/Desktop Head Unit. The build wiring is automatic, but shipping to real cars still needs the relevant CarPlay entitlement on your Apple App ID (request it at developer.apple.com) and acceptance into the Android Auto programme.

72.6. Debugging in the simulator



The fastest way to build and debug an in-car experience is the Codename One simulator. Run your app as usual, then use the **Car** menu:

- **Car** > **Connect CarPlay** or **Car** > **Connect Android Auto** opens a simulated head-unit window that renders your registered `CarApplication` in the matching style. Click rows, grid items and actions to drive navigation (`pushScreen`/`popScreen`) exactly as a real head unit would; the **Back** button pops the stack.
- **Car** > **Disconnect** (or closing the window) ends the session and fires `onCarDisconnected()`.

This needs no iOS/Android toolchain, no entitlement and no head unit — it exercises the same portable template tree and the same `CarActionListener` callbacks (on the EDT) that ship to the device, so you can iterate on your screens in seconds. If you haven't called `Car.setApplication(…)` the menu tells you so. The simulated head unit approximates the two platform styles and the driver-distraction row caps; it's a debugging aid, not a pixel-accurate emulation.

Selecting a browsable row pushes the next screen, just as it would in the car — here a `CarGridTemplate`, reachable via the **Back** button:

72.7. Testing on the real platforms

- **iOS**: run the app in the iOS Simulator, then **I/O** > **External Displays** > **CarPlay** to open the CarPlay window.
- **Android**: install the **Desktop Head Unit (DHU)** from the Android SDK and connect a device/emulator running Android Auto.

A complete runnable example lives in `Samples/samples/CarSample`.

72.8. Limitations

- The navigation map **surface** (`CarSurfaceCallback`) is scaffolded; live map drawing onto the head-unit surface is a work in progress — the navigation template's controls, header and ETA strip are wired.
- Android Auto media browsing is driven by the standard media session; `CarNowPlayingTemplate` routes to it.
- You can't show arbitrary Codename One forms on the head unit — use the template catalogue above.

Chapter 73. Motion Sensors

The `com.codename1.sensors` package exposes the device motion hardware through a single entry point, `MotionSensorManager`, and layers high-level gesture detection on top of the raw sensor stream. The raw sensors are the accelerometer, the gyroscope and the magnetometer. From those readings the framework derives the gravity vector, the linear acceleration and the device orientation, and it recognizes a set of common gestures: shake, flip, tilt, pick up and free fall.

Gesture detection lives in the core rather than in each platform port. Any platform that reports an accelerometer therefore gets the full gesture set, with no per-device work.

73.1. Reading a sensor

`MotionSensorManager.getInstance()` always returns a manager. On a device without motion hardware every sensor reports as unsupported, so application code can call the API without a null check on the manager itself. `getSensor(int)` returns `null` when the requested sensor isn't available on the current device:

```
class SensorForm extends Form {
    private MotionSensor accelerometer;
    private MotionSensorListener listener;

    protected void initComponent() {
        super.initComponent();
        MotionSensorManager m = MotionSensorManager.getInstance();
        accelerometer = m.getSensor(MotionSensorManager.TYPE_ACCELEROMETER);
        if (accelerometer != null) {
            listener = new MotionSensorListener() {
                public void motionReceived(MotionEvent evt) {
                    // x, y and z are in meters per second squared
                    label.setText(evt.getX() + ", " + evt.getY() + ", " + evt.getZ());
                    label.getParent().revalidate();
                }
            };
            accelerometer.addListener(listener);
        }
    }
}
```

Callbacks arrive on the EDT, so the listener can update the UI directly. Sampling is reference counted: the hardware sensor draws power only while at least one listener is registered. Remove the listener once the screen is no longer visible, from the form's `deinitialize()`, so the sensor powers down:

```
// in the same form's deinitialize(), before super.deinitialize()
// getSensor returns null on a device without the hardware
if (accelerometer != null) {
```

```
    accelerometer.removeListener(listener);
}
```

73.2. Sensor types

Each sensor is identified by a `TYPE_*` constant on `MotionSensorManager`. The three hardware sensors map directly to the device. The gravity, linear acceleration and orientation values are derived in the core from the accelerometer (and the magnetometer, for the compass azimuth) when the platform doesn't report them on its own.

Constant	Reading
`TYPE_ACCELEROMETER`	Acceleration including gravity, in meters per second squared.
`TYPE_LINEAR_ACCELERATION`	Acceleration with gravity removed, in meters per second squared.
`TYPE_GRAVITY`	The gravity vector on its own, in meters per second squared.
`TYPE_GYROSCOPE`	Rate of rotation around each axis, in radians per second.
`TYPE_MAGNETOMETER`	The ambient magnetic field, in microtesla.
`TYPE_ORIENTATION`	Azimuth, pitch and roll, in radians.

Readings use a single convention across every port: the x-axis points to the right, the y-axis points up, and the z-axis points out of the screen toward the user, with the device held upright in portrait. At rest, face up, the accelerometer reports about `+9.81` on the z-axis.

73.3. Detecting gestures

Register a `GestureListener` for one of the `GestureEvent.TYPE_*` gestures. The accelerometer powers on for the duration that a gesture listener stays registered:

```
private GestureListener shakeListener;

void listenForShake() {
    shakeListener = new GestureListener() {
        public void gestureDetected(GestureEvent evt) {
            Dialog.show("Shaken", "You shook the device", "OK", null);
        }
    };
    MotionSensorManager.getInstance()
            .addGestureListener(GestureEvent.TYPE_SHAKE, shakeListener);
}

void stopListeningForShake() {
    // the accelerometer stays powered while any gesture listener is registered
    MotionSensorManager.getInstance()
            .removeGestureListener(GestureEvent.TYPE_SHAKE, shakeListener);
}
```

The recognized gestures are:

- `TYPE_SHAKE` — the device was shaken back and forth.
- `TYPE_FLIP_FACE_DOWN` and `TYPE_FLIP_FACE_UP` — the device was turned screen down or screen up.
- `TYPE_TILT_LEFT`, `TYPE_TILT_RIGHT`, `TYPE_TILT_FORWARD` and `TYPE_TILT_BACKWARD` — the device crossed a tilt angle on the roll or pitch axis.
- `TYPE_PICK_UP` — the device was lifted from a resting position.
- `TYPE_FREE_FALL` — the device is falling (near weightlessness was detected).

The detection thresholds suit most apps as shipped, and you can tune them when a gesture needs to be more or less sensitive:

```
MotionSensorManager m = MotionSensorManager.getInstance();
m.setShakeThreshold(15.0);     // require a more vigorous shake
m.setTiltThreshold(0.5);       // tilt angle in radians
m.setSamplingInterval(33);     // sample at about 30Hz for snappier gestures
```

A smaller sampling interval makes gestures more responsive at a higher battery cost. The value is clamped to the range 10ms through 1000ms.

73.4. Device orientation

`TYPE_ORIENTATION` is a derived sensor. Its event carries the azimuth, pitch and roll in radians, available through `getAzimuth()`, `getPitch()` and `getRoll()` on `MotionEvent`. Pitch and roll come from the gravity vector and need only the accelerometer. The azimuth is a compass heading and needs the magnetometer; on a device without one the azimuth stays at zero.

73.5. Platform notes

- **Android** — backed by `android.hardware.SensorManager`. Android already reports its readings in the units and axis convention this API documents, so no conversion takes place.
- **iOS** — backed by CoreMotion (`CMMotionManager`). Add the build hint `ios.NSMotionUsageDescription` with a short sentence describing why the app reads motion data; iOS denies access to the motion hardware without it. The iOS Simulator doesn't expose an accelerometer, so the sensors report as unsupported there. Test motion features on a real device.
- **Other ports** — a port that doesn't implement the sensors returns an unsupported manager, so the API stays safe to call everywhere.

73.6. Testing in the simulator

The simulator can stand in for real hardware. Open **Simulate** > **Motion** / **Gesture Simulation** to show a small control window. The two sliders set the simulated device orientation, which the accelerometer reflects, and the buttons inject the motion needed to fire the shake, flip, pick up and free fall gestures. This lets you wire up and debug a gesture handler on the desktop before

deploying to a device.

Chapter 74. Near-Field Communication (NFC)

Codename One ships an NFC API under `com.codename1.nfc` that covers the three things most apps need: read and write NDEF tags, exchange APDUs with ISO 7816 / MIFARE / FeliCa smart cards, and act as a host-emulated card for a nearby reader/terminal.

A single entry point exposes the platform NFC controller, a typed enum reports the technologies the discovered tag supports, and a typed error enum lets callers react to failures without string matching.

74.1. Quick start: Read an NDEF URI

```
Nfc nfc = Nfc.getInstance();
if (!nfc.canRead()) {
    // no NFC hardware, or it is disabled in system settings
    return;
}
nfc.readNdef(new NfcReadOptions()
        .setNdefOnly(true)
        .setAlertMessage("Hold near the poster"))
   .onResult((NdefMessage msg, Throwable err) -> {
        if (err != null) {
            return;
        }
        String url = msg.getFirstRecord().getUriPayload();
        Display.getInstance().execute(url);
   });
```

`setNdefOnly(true)` picks the fastest iOS Core NFC session (`NFCNDEFReaderSession`) and matches the most common tag layout. For mixed payloads use `readTag(…)` and inspect `tag.getTypes()`.

74.2. Quick start: Write an NDEF URI

NDEF records carry one of the well-known types (`T`, `U`, `Sp`), a MIME media type, an absolute URI, or an external `domain:type`. Use the factory methods on `NdefRecord` rather than constructing raw byte arrays:

Factory	Use for
`createUri(String)`	URI records — launches the associated app on tap
`createText(String lang, String text)`	Human-readable text
`createMime(String mimeType, byte[] payload)`	Binary payloads (vCard, JSON, …)

Factory	Use for
`createExternal(String domain, String type, byte[] payload)`	Custom vendor types
`createApplicationRecord(String pkg)`	Android Application Record (AAR)

74.3. Tag-technology APIs

Beyond NDEF, the discovered `Tag` exposes accessors for the underlying technologies:

```
nfc.readTag(new NfcReadOptions()
        .setTechFilter(TagType.ISO_DEP)
        .setIsoSelectAids(myAid))
   .onResult((Tag tag, Throwable err) -> {
        if (err != null) return;
        IsoDep iso = tag.getIsoDep();
        if (iso == null) return;
        iso.transceive(myCommandApdu).onResult((byte[] resp, Throwable e) -> {
            if (ApduResponse.isSuccess(resp)) {
                byte[] body = ApduResponse.body(resp);
                // application-specific parsing
            }
        });
   });
```

Each accessor returns `null` when the tag doesn't advertise the corresponding technology, so always null-check before calling.

On iOS the AIDs handed to `setIsoSelectAids` must also be listed in `Info.plist` under `com.apple.developer.nfc.readersession.iso7816.select-identifiers`. Core NFC only discovers an application the app declared up front, and the builders can't read a runtime argument, so inject that key with `ios.plistInject` too. The `nfc.hce.iso7816.select-identifiers` entitlement the builders do set is the host-card-emulation key, which is a different thing.

Accessor	Android	iOS	Notes
`getIsoDep()`	yes	yes	ISO 7816 — EMV, ePassport, smart cards
`getMifareClassic()`	yes	—	Apple doesn't expose MIFARE Classic on iOS
`getMifareUltralight()`	yes	yes	NTAG21x, Ultralight C
`getNfcA()`	yes	yes (limited)	Raw ISO 14443-3A
`getNfcB()`	yes	—	Raw ISO 14443-3B (Android-only)

Accessor	Android	iOS	Notes
`getNfcF()`	yes	yes	FeliCa (Suica / PASMO / ICOCA)
`getNfcV()`	yes	—	ISO 15693 (Android-only)

For FeliCa on iOS, set the system codes in `NfcReadOptions`:

```
NfcReadOptions options = new NfcReadOptions()
    .setTechFilter(TagType.NFC_F)
    .setFelicaSystemCodes("0003", "8008");
nfc.readTag(options);
```

The builders can't derive that from the call — the codes are a runtime argument they never see. iOS wants them in `Info.plist`, so inject the key at build time:

```
codename1.arg.ios.plistInject=<key>com.apple.developer.nfc.readersession.felica.systemcodes</key><array><string>0003</string><string>8008</string></array>
```

Seeing `com.codename1.nfc` on the classpath gets you CoreNFC, a default `NFCReaderUsageDescription` and the `com.apple.developer.nfc.readersession.formats` entitlement automatically. These system codes are the one part you supply.

74.4. Quick start: Host card emulation

Host Card Emulation (HCE) lets the device pretend to be a contactless smart card. A nearby reader (Android phone, payment terminal, access control gate) sends ISO 7816 APDUs and your app responds. Subclass `HostCardEmulationService` and register the instance:

```
class MyService extends HostCardEmulationService {
    @Override
    public String[] getAids() {
        return new String[] { "F0010203040506" };
    }
    @Override
    public byte[] processCommand(byte[] apdu) {
        if (apdu.length > 1 && apdu[1] == (byte) 0xA4) {
            // SELECT -- terminal has just routed an APDU to our AID
            return ApduResponse.withStatus(
                    new byte[] { 'O', 'K' },
                    ApduResponse.swSuccess());
        }
        return ApduResponse.swInsNotSupported();
    }
}
```

```
Nfc.getInstance().registerHostCardEmulationService(new MyService());
```

Set the AIDs as a build hint so they appear in the platform routing tables:

```
android.hceAids=F0010203040506
android.hceCategory=other
```

The Maven plugin and BuildDaemon generate `apduservice.xml` on Android, register the `CodenameOneHostApduService` in the manifest, and inject the iOS HCE entitlement so the same code path works on both platforms.

iOS HCE (`CardSession`) requires iOS 17.4+ and, as of 2026, is EU-only. The Codename One plugin still injects the entitlement when you reference the class, but `canHostEmulate()` will report `false` on non-EU devices.

74.5. Permissions and build hints

The Codename One build pipeline automatically detects NFC usage. Apps that never touch `com.codename1.nfc` see no manifest / plist change.

Reference	Android injected	iOS injected
`com.codename1.nfc.*`	`android.permission.NFC` + `<uses-feature android:name="android.hardware.nfc">`	`NFCReaderUsageDescription`, `com.apple.developer.nfc.readersession.formats=TAG\nNDEF`, CoreNFC.framework
`com.codename1.nfc.HostCardEmulationService`	`BIND_NFC_SERVICE` permission, `android.hardware.nfc.hce` feature, `<service>` entry, generated `res/xml/apduservice.xml`	`com.apple.developer.nfc.hce` and `…hce.iso7816.select-identifiers` entitlements

Override any of the defaults with the matching build hint:

Build hint	Default	Notes
`ios.NFCReaderUsageDescription`	"Hold near an NFC tag to continue"	Localise this — Apple rejects builds that ship the default copy
`ios.entitlements.com.apple.developer.nfc.readersession.formats`	`TAG\nNDEF`	Multi-line entitlement value
`android.hceAids`	(none)	Comma-separated; required for HCE on Android
`android.hceCategory`	`other`	`payment` for EMV-conformant apps
`android.hceRequireUnlock`	`false`	Force lock screen unlock before APDU routing

Build hint	Default	Notes
`ios.hceAids`	falls back to `android.hceAids`	iOS HCE AID list

74.6. Simulator support

The JavaSE simulator implements `Nfc` via a virtual tag you can edit and tap from the `Simulate → NFC` submenu:

Menu item	Effect
Hardware Available / NFC Enabled / HCE Available	Toggle what `isSupported()` / `canRead()` / `canHostEmulate()` return
Next read outcome	Pick `DISCOVER_TAG`, `USER_CANCELED`, `TAG_LOST`, `TIMEOUT`, or `READ_ONLY` for the next `readTag()` call
Tap virtual tag	Fire the configured outcome on any pending read or registered listener
Set virtual tag URI…	Replace the virtual tag's NDEF payload with a URI record
Set virtual tag text…	Replace the virtual tag's NDEF payload with a text record
Tag is read-only	Lock the virtual tag so the next write fails with `READ_ONLY`
Send APDU to HCE service…	Hex-entry dialog that dispatches the bytes to your registered `HostCardEmulationService` and shows the response
Deactivate HCE field	Fires `onDeactivated(DEACTIVATION_LINK_LOSS)` on the registered service

All toggles persist between simulator runs (under `NfcSim.*` user preferences) so you can drive tests deterministically.

74.7. Platform behaviour

Platform	NDEF read	NDEF write	Tag tech	HCE	Notes
Android	yes	yes	full set	yes	`NfcAdapter.enableReaderMode` (API 19+); `HostApduService` (API 19+)
iOS	yes (iOS 11+)	yes (iOS 13+)	ISO 7816, FeliCa, MIFARE Ultralight	iOS 17.4+ EU-only	MIFARE Classic and NFC-B/V not exposed by Apple

Platform	NDEF read	NDEF write	Tag tech	HCE	Notes
JavaSE simulator	yes (virtual tag)	yes (virtual tag)	configurable	yes (synthetic APDUs)	Drive everything from the Simulate → NFC menu
Desktop deploy / JavaScript	no	no	no	no	Fallback base class — every method completes with `NfcError.NOT_AVAILABLE`

Always gate user-facing affordances on `canRead()` (for tag operations) or `canHostEmulate()` (for HCE). `isSupported()` only reports whether the hardware is present.

Chapter 75. Bluetooth

Codename One ships a first-class Bluetooth API under `com.codename1.bluetooth` that covers both Bluetooth Low Energy roles and classic Bluetooth: scan for and connect to BLE peripherals (the GATT client), act as a BLE peripheral (a local GATT server plus advertising), stream bytes over L2CAP connection-oriented channels, and exchange RFCOMM streams with classic serial devices.

`Bluetooth.getInstance()` is the single entry point and never returns `null` — ports without Bluetooth return a fallback whose operations fail fast with `BluetoothError.NOT_SUPPORTED`, so calling code needs no platform-specific `if`. Every callback of the API — `AsyncResource` results, scan sightings, connection events, notifications, adapter state changes — is delivered on the EDT; the only exceptions are the blocking RFCOMM/L2CAP streams, which must be consumed off the EDT.

Capability	Android	iOS / macOS	Simulator (mock)	Simulator (native backend)	JavaScript
BLE central (scan, GATT client)	yes	yes	yes	yes	browser chooser only
BLE peripheral (GATT server + advertising)	yes	yes (not tvOS/watchOS)	yes	—	—
L2CAP channels	yes (Android 10+)	yes (iOS 11+)	yes	—	—
Classic RFCOMM	yes	—	yes	—	—
Bonding	yes	OS-managed	yes	—	—

On the JavaScript port, Web Bluetooth limits the central role to the browser's device chooser (Chrome-family browsers over HTTPS): `startScan(…)` surfaces the chooser built from the scan filters and delivers the single user-picked device as one `ScanResult`. No further sightings ever arrive, the RSSI is unknown, the MTU is fixed at 512 and peripheral mode, classic Bluetooth and L2CAP are unavailable.

Always branch through the capability queries — `isLeSupported()`, `isPeripheralModeSupported()`, `isL2capSupported()`, `isClassicSupported()` — rather than through platform detection.

75.1. Quick start: Scan and connect

```
Bluetooth bt = Bluetooth.getInstance();
if (!bt.isLeSupported()) {
    // hide the feature on ports without BLE
    return;
}
bt.requestPermissions(BluetoothPermission.SCAN, BluetoothPermission.CONNECT)
```

```
        .onResult((granted, permissionErr) -> {
    if (permissionErr != null || !granted) {
        return;
    }
    ScanSettings settings = new ScanSettings()
            .addFilter(new ScanFilter()
                    .setServiceUuid(BluetoothUuid.fromShort(0x180D))
                    .setNamePrefix("Polar"));
    BleScan[] scan = new BleScan[1];
    scan[0] = bt.getLE().startScan(settings, sighting -> {
        scan[0].stop();
        sighting.getPeripheral().connect()
                .onResult((peripheral, connectErr) -> {
            if (connectErr != null) {
                return;
            }
            peripheral.discoverServices()
                    .onResult((services, discoverErr) -> {
                // the GATT database is ready -- see the
                // following sections
            });
        });
    });
});
```

`ScanFilter` criteria on one filter are AND-combined; multiple filters added to the same `ScanSettings` are OR-combined, and a scan without filters reports every advertising device. Any number of scans may run concurrently — each `BleScan` handle only sees advertisements matching its own filters, and the platform scan stops when the last handle stops. On iOS a service-UUID filter is also what keeps scans alive in the background, so prefer filtered scans.

Peripheral addresses returned by `BluetoothDevice.getAddress()` are stable per app install — the MAC address on Android and desktop, the per-app CoreBluetooth identifier on iOS — and safe to persist for later reconnection through `BluetoothLE.getPeripheral(String)`. They're not portable across devices or platforms, so never treat them as the peripheral's real hardware address.

`getAdapterState()` reports where the local radio stands (`POWERED_ON`, `POWERED_OFF`, `UNAUTHORIZED`, …) and `addAdapterStateListener(…)` fires on the EDT whenever it changes — the natural place to pause scans and gray out UI. `requestEnable()` shows the Android system dialog asking the user to turn the adapter on; on iOS there is no programmatic enable flow, so it resolves `false` and the app should direct the user to the Settings app instead.

Connection lifecycle is equally explicit. `connect(ConnectionOptions)` accepts a timeout (iOS connect requests never time out on their own, so set one) and an `autoConnect` flag that asks the platform to re-establish the link whenever the peripheral comes back into range. `addConnectionListener(…)` reports every transition including link loss, and every failure across the API surfaces as a `BluetoothException` whose `getError()` returns a typed `BluetoothError` constant — no string matching required.

75.2. Reading and writing characteristics

`discoverServices()` caches the peripheral's GATT database; from there `getService(…)`, `getCharacteristic(…)` and the convenience accessors on `GattCharacteristic` cover the day-to-day operations:

```
GattCharacteristic measurement = peripheral.getCharacteristic(
        BluetoothUuid.fromShort(0x180D),
        BluetoothUuid.fromShort(0x2A37));
if (measurement != null && measurement.canRead()) {
    measurement.read().onResult((data, err) -> {
        if (err == null) {
            // raw bytes, delivered on the EDT
            updateHeartRateLabel(data[1] & 0xFF);
        }
    });
}

GattCharacteristic controlPoint = peripheral.getCharacteristic(
        BluetoothUuid.fromShort(0x180D),
        BluetoothUuid.fromShort(0x2A39));
if (controlPoint != null && controlPoint.canWrite()) {
    controlPoint.write(new byte[] {1})
            .onResult((acknowledged, err) -> {
        // resolves once the peripheral acknowledged the write
    });
}
```

All GATT operations return independent `AsyncResource` handles and may be issued concurrently: an internal per-peripheral queue serializes them toward the platform stack (which allows only one in-flight request per connection) and applies a safety timeout, so a lost platform callback can never wedge the queue. Operations on different peripherals run fully concurrently. `writeWithoutResponse(…)` resolves once the value is queued to the controller — there is no remote acknowledgement.

A default BLE connection carries 23 bytes per attribute operation; `requestMtu(…)` negotiates a larger value and resolves with what was granted (on iOS the OS negotiates by itself, so the request resolves immediately with the current value — check `getMtu()` before chunking data). `requestConnectionPriority(…)` trades latency against battery on Android and is a successful no-op on iOS. `createBond()` initiates pairing where the peripheral requires an encrypted link; on iOS bonding is OS-managed and triggered automatically by encrypted characteristics, so the call resolves `true` without user interaction.

75.3. Notifications

```
GattCharacteristic measurement = peripheral.getCharacteristic(
        BluetoothUuid.fromShort(0x180D),
```

```
        BluetoothUuid.fromShort(0x2A37));
GattNotificationListener listener = (characteristic, data) -> {
    // fires on the EDT for every notification while subscribed
    updateHeartRateLabel(data[1] & 0xFF);
};
measurement.subscribe(listener).onResult((armed, err) -> {
    if (err != null) {
        // the CCCD write was rejected or the link dropped
    }
});

// later, e.g. when leaving the form:
measurement.unsubscribe(listener);
```

The Client Characteristic Configuration descriptor (CCCD) is handled automatically: the first listener triggers the descriptor write that arms notifications (indications are used when the characteristic only supports those) and removing the last listener disarms it again. Values stream to the listeners on the EDT until unsubscribed or disconnected.

75.4. Peripheral mode

When `isPeripheralModeSupported()` returns `true` the device can serve data itself — open a local GATT server, add service definitions and advertise them:

```
Bluetooth bt = Bluetooth.getInstance();
if (!bt.isPeripheralModeSupported()) {
    return;
}
GattLocalCharacteristic status = new GattLocalCharacteristic(
        BluetoothUuid.fromShort(0x2A37),
        GattCharacteristic.PROPERTY_READ
                | GattCharacteristic.PROPERTY_NOTIFY,
        GattLocalCharacteristic.PERMISSION_READ)
        .setValue(new byte[] {0, 72});
GattLocalService service = new GattLocalService(
        BluetoothUuid.fromShort(0x180D))
        .addCharacteristic(status);
bt.getLE().openGattServer(new GattServerAdapter() {
    @Override
    public void centralConnected(BleCentral central) {
        // a central connected to this device
    }

    @Override
    public void characteristicWriteRequest(GattWriteRequest request) {
        // handle the written bytes, then acknowledge
        if (request.isResponseRequired()) {
            request.respond();
        }
```

```
    }
}).onResult((server, err) -> {
    if (err != null) {
        return;
    }
    server.addService(service).onResult((added, addErr) -> {
        if (addErr != null) {
            return;
        }
        bt.getLE().startAdvertising(
                new AdvertiseSettings(),
                new AdvertiseData()
                        .addServiceUuid(BluetoothUuid.fromShort(0x180D))
                        .setIncludeDeviceName(true),
                null).onResult((advertisement, advErr) -> {
            // broadcasting; keep the handle and stop() it when done
        });
        // push a new value to every subscribed central
        server.notifyValue(status, new byte[] {0, 80});
    });
});
```

Characteristics with a static value (`setValue(…)`) are served without involving the listener; characteristics without one route every read to `characteristicReadRequest(…)`, which must answer via `respond(…)` or `reject(…)` — centrals time out unanswered requests.

Two iOS platform notes: CoreBluetooth only broadcasts the local name and service UUIDs, dropping manufacturer data, service data and TX power from advertisements (Android broadcasts everything). And iOS serves descriptors from their static values only — descriptor read/write requests never reach the listener there, so always give local descriptors a static value for cross-platform behavior.

75.5. L2CAP channels

L2CAP connection-oriented channels provide a raw bidirectional byte stream — much higher throughput than chunking data through GATT characteristics. The peripheral side opens a listener and publishes its Protocol/Service Multiplexer (PSM), typically through a GATT characteristic; the central side connects to that PSM:

```
if (!Bluetooth.getInstance().isL2capSupported()) {
    return;
}
peripheral.openL2capChannel(psm, true).onResult((channel, err) -> {
    if (err != null) {
        return;
    }
    // the streams block -- always consume them off the EDT
    CN.startThread(() -> {
        try {
```

```
            OutputStream out = channel.getOutputStream();
            out.write(new byte[] {1, 2, 3});
            out.flush();
            InputStream in = channel.getInputStream();
            byte[] buffer = new byte[4096];
            int size = in.read(buffer);
            // process the response...
        } catch (IOException ioErr) {
            // transport failure
        } finally {
            try {
                channel.close();
            } catch (IOException ignored) {
            }
        }
    }, "L2CAP IO").start();
});

// the peripheral side listens and publishes its PSM to centrals
Bluetooth.getInstance().getLE().openL2capServer(true)
        .onResult((server, serverErr) -> {
    if (serverErr == null) {
        int assignedPsm = server.getPsm();
        // advertise assignedPsm through a GATT characteristic,
        // then server.accept() incoming channels
    }
});
```

On Android an L2CAP channel establishes its own link and doesn't require `connect()` first; on iOS the peripheral must be connected. The streams throw plain `java.io.IOException` on transport failure and, like all Bluetooth streams, block — never touch them on the EDT.

75.6. Classic Bluetooth

Classic (BR/EDR) Bluetooth covers inquiry discovery, bonding and RFCOMM stream connections — the Serial Port Profile (SPP) world of printers, scanners and industrial equipment. iOS doesn't expose classic Bluetooth to applications, so this role is Android, desktop and simulator only; `isClassicSupported()` is the gate:

```
Bluetooth bt = Bluetooth.getInstance();
if (!bt.isClassicSupported()) {
    // classic Bluetooth is unavailable -- iOS among others
    return;
}
BluetoothClassic classic = bt.getClassic();
classic.startDiscovery(sighting -> {
    if ("SerialPrinter".equals(sighting.getDevice().getName())) {
        classic.connect(sighting.getDevice(), BluetoothUuid.SPP, true)
                .onResult((connection, err) -> {
```

```
            if (err != null) {
                return;
            }
            // consume the blocking streams off the EDT, exactly
            // like the L2CAP example
        });
    }
});

// accepting incoming SPP clients
classic.listen("Codename One SPP", BluetoothUuid.SPP, true)
        .onResult((server, err) -> {
    if (err == null) {
        server.accept().onResult((connection, acceptErr) -> {
            // one client accepted; call accept() again for the next
        });
    }
});
```

`startDiscovery(…)` runs an inquiry scan (about 12 seconds) and returns a live `ClassicDiscovery` handle that resolves when the inquiry ends. `getBondedDevices()` lists already-paired devices without a discovery, and `connect(String, BluetoothUuid, boolean)` reconnects to a persisted address directly.

75.7. Permissions and build hints

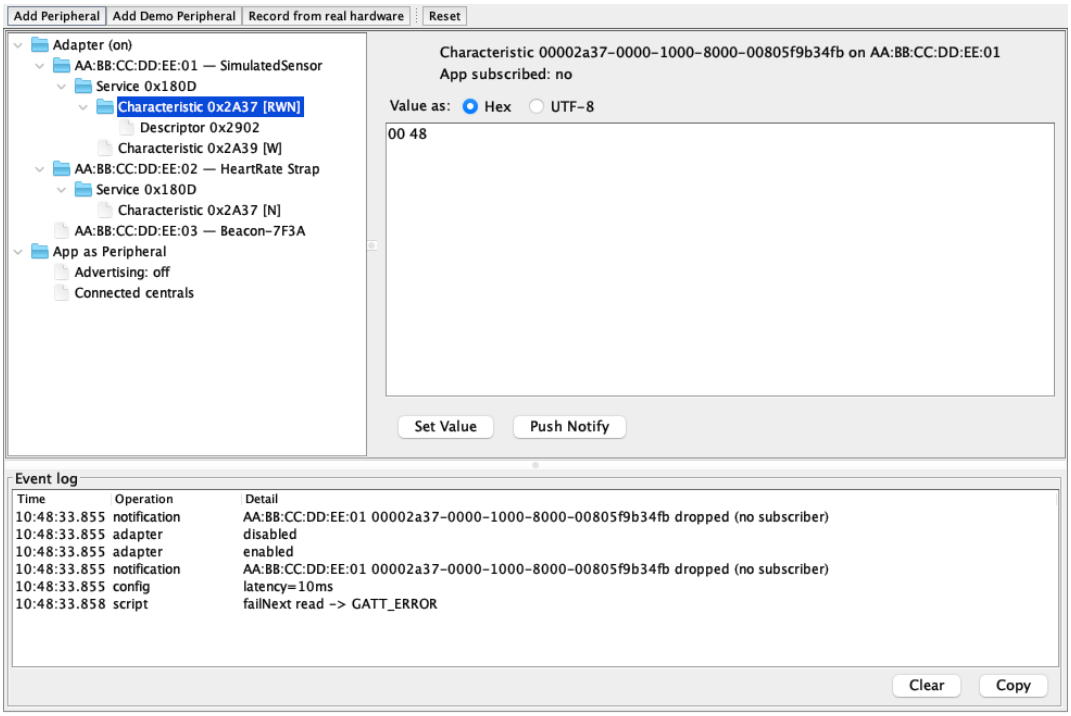
The build pipeline scans the application's bytecode and injects only what the referenced packages need — apps that never touch `com.codename1.bluetooth` see no manifest or plist change, and a central-only app never carries advertise permissions.

Detected usage	Android injected (target SDK 31+)	iOS injected
Any `com.codename1.bluetooth` reference	`BLUETOOTH` (capped at `maxSdkVersion="30"`), `<uses-feature android:name="android.hardware.bluetooth_le">`	`NSBluetoothAlwaysUsageDescription` + `NSBluetoothPeripheralUsageDescription` defaults (only if unset), CoreBluetooth.framework, the CN1 Bluetooth natives
Scanning (`ScanSettings` / `BleScan` / classic discovery)	`BLUETOOTH_ADMIN` (capped at 30), `BLUETOOTH_SCAN` with `usesPermissionFlags="neverForLocation"`, `ACCESS_FINE_LOCATION` (capped at 30)	—
Connections (GATT, `BlePeripheral`, RFCOMM, L2CAP)	`BLUETOOTH_CONNECT`	—

Detected usage	Android injected (target SDK 31+)	iOS injected
Peripheral mode (`com.codename1.bluetooth.le.server`)	`BLUETOOTH_ADMIN` (capped at 30), `BLUETOOTH_ADVERTISE`	—
Classic (`com.codename1.bluetooth.classic`)	`<uses-feature android:name="android.hardware.bluetooth">`	not supported

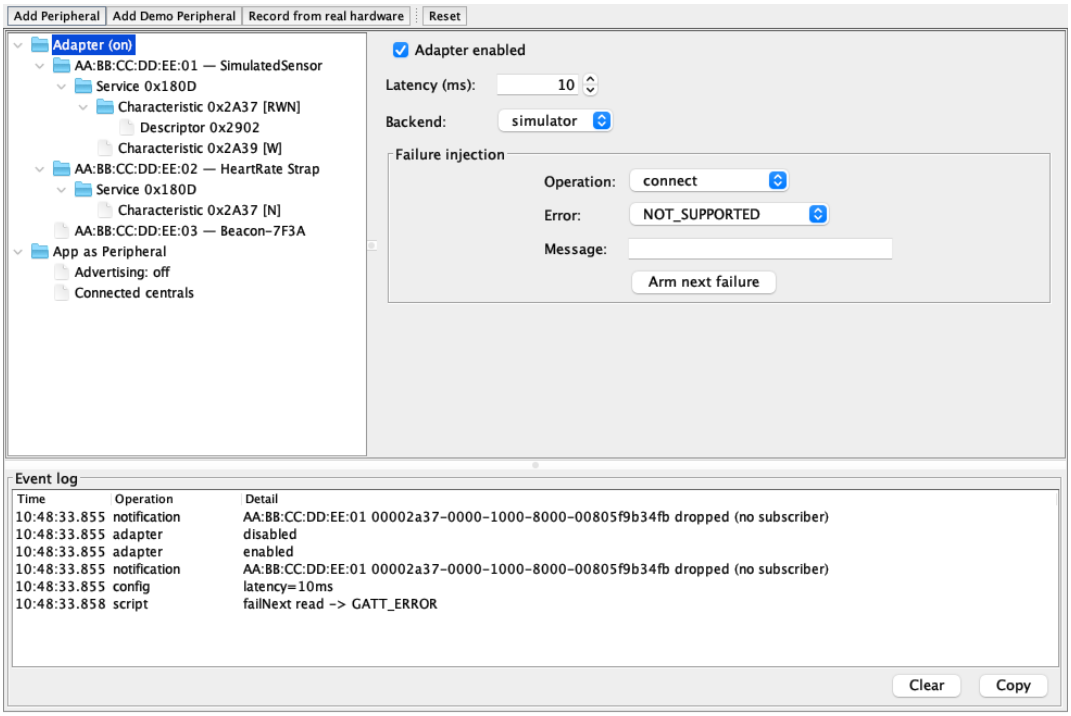
Builds targeting an SDK below 31 receive the legacy permissions uncapped and none of the Android 12 ones. Permissions you declare yourself (via `android.xpermissions`) are never duplicated.

Override the defaults with the matching build hints:



Build hint	Default	Notes
`android.bluetooth.neverForLocation`	`true`	Declares that scan results never derive the user's location, which caps `ACCESS_FINE_LOCATION` at API 30 and flags `BLUETOOTH_SCAN` accordingly
`android.bluetooth.required`	`false`	Marks the BLE hardware feature required so stores hide the app on devices without it
`ios.bluetooth.background`	(none)	`central`, `peripheral` or `central,peripheral` — merged into `UIBackgroundModes` as `bluetooth-central` / `bluetooth-peripheral`
`ios.NSBluetoothAlwaysUsageDescription`	"Communicates with nearby Bluetooth accessories."	Localise this — Apple rejects builds that ship generic privacy copy

Beacon and indoor-positioning apps are the one case where the `neverForLocation` default is wrong: an app that derives location from BLE sightings must set `android.bluetooth.neverForLocation=false`, otherwise Android 12+ filters beacon advertisements out of its scan results. With the hint set to `false` the location permission stays uncapped and the app keeps prompting for it on Android 12+.



75.8. Simulator support

The JavaSE simulator implements the whole API against a scriptable virtual Bluetooth stack. `Simulate → Bluetooth Simulation` opens a window with a tree of the simulated adapter, the virtual peripherals and the app's own peripheral role; selecting a node opens its detail editor (hex value editors on characteristics), a toolbar stages demo devices, failure injection arms the next operation of a chosen kind (`connect`, `read`, `write`, `discover`, `subscribe`, `scan` and the rest) to fail with a chosen

`BluetoothError`, a latency spinner delays every asynchronous completion and a live event log shows what the stack does. All settings persist between simulator runs.

The window's backend selector switches the simulator between the virtual stack and a native backend that drives the host machine's real Bluetooth radio through a bundled btleplug library (`libcn1ble`) loaded in-process (CoreBluetooth on macOS, BlueZ on Linux, WinRT on Windows). The native backend is central-only — real scanning, connections and GATT operations against physical devices, without leaving the simulator. The initial backend comes from the `cn1.bluetooth.backend` system property (default `simulator`); point `cn1.bluetooth.libraryPath` at a locally built `libcn1ble` to override the bundled one.

The `Simulate → Bluetooth` menu exposes the same operations as one-click hooks; every item is also callable from cross-platform code via `CN.execute("bluetooth:itemN")`:

Hook	Menu label	Effect
`bluetooth:item1`	Toggle Adapter	Flips the simulated adapter between `POWERED_ON` and `POWERED_OFF`
`bluetooth:item2`	Add Demo Peripheral	Registers the canonical demo device: `AA:BB:CC:DD:EE:01` "SimulatedSensor" with service `0x180D`, a read/write/notify characteristic `0x2A37` (carrying a CCCD) and a writable `0x2A39`
`bluetooth:item3`	Push Demo Notification	Pushes a rolling one-byte notification from the demo peripheral's `0x2A37` characteristic
`bluetooth:item4`	Disconnect All	Drops every live connection from the remote side
`bluetooth:item5`	Clear Peripherals	Removes every registered virtual peripheral
`bluetooth:item6`	Use Simulator Backend	Switches back to the virtual stack
`bluetooth:item7`	Use Native Backend	Switches to the host machine's real radio
`bluetooth:item8`	(API only)	Arms the next GATT read to fail with `GATT_ERROR`

Everything the window does goes through the scriptable `BluetoothSimulator` API in `com.codename1.impl.javase.bluetooth`, so tests and sample apps can stage the same devices programmatically. This code runs against the JavaSE port only — it isn't part of the cross-platform API and won't compile in a portable code base, so keep it in your test or debug scaffolding:

```
BluetoothSimulator.addPeripheral(
        new VirtualPeripheral("AA:BB:CC:DD:EE:10")
                .setName("Thermometer")
                .addAdvertisedServiceUuid(BluetoothUuid.fromShort(0x1809))
                .withService(new VirtualService(BluetoothUuid.fromShort(0x1809))
                        .withCharacteristic(new VirtualCharacteristic(
                                BluetoothUuid.fromShort(0x2A1C),
                                GattCharacteristic.PROPERTY_READ
                                        | GattCharacteristic.PROPERTY_INDICATE,
                                new byte[] {0, 0, 0, 98})
                                .withDescriptor(new VirtualDescriptor(
                                        BluetoothUuid.CCCD, new byte[] {0, 0})))));
BluetoothSimulator.setLatencyMillis(50);
BluetoothSimulator.failNext("connect",
```

```
        BluetoothError.CONNECTION_FAILED, "Injected for testing");
```

75.8.1. Record and replay

Fixtures bridge the two backends: the window's "Record from real hardware" button (or `scripts/bluetooth/capture-fixture.sh`) scans the host machine's real radio through the native backend for a chosen duration, captures device identities, RSSI timelines, advertisement payloads and GATT databases, scrambles the trace deterministically so committed fixtures never carry real device identities, and writes it as JSON. `BluetoothSimulator.loadFixture(InputStream)` replays the trace into the virtual stack — devices appear at their recorded first-sighting times and their RSSI timelines replay on the stack's scheduler, so a scan against messy real-world radio traffic becomes a reproducible test input.

75.9. Testing

Cross-platform test code drives the simulation through the hooks: `CN.execute("bluetooth:item2")` stages the demo peripheral, the test scans for `SimulatedSensor`, connects and subscribes to `0x2A37`, and `CN.execute("bluetooth:item3")` pushes a notification to assert on — no simulator-only imports needed, so the same test class compiles for device targets and runs unchanged in the simulator's test runner. Failure paths test the same way: `CN.execute("bluetooth:item8")` arms the next GATT read to fail with `GATT_ERROR`, letting a portable test verify the app's error handling.

For fully deterministic unit tests the JavaSE port also allows constructing a private `SimulatedBluetoothStack` on a `ManualScheduler`, where time only advances when the test pumps it — no sleeps, no flakiness from real timers; see the Bluetooth tests under the `javase` Maven module for the pattern.

75.10. Platform behaviour

Platform	Address semantics	MTU	Bonding	Notes
Android	Real MAC address	`requestMtu(…)` negotiates, default 23	`createBond()` prompts the user	Background scanning is throttled by the OS; use filtered scans and expect slower sightings
iOS / macOS	Per-app CoreBluetooth identifier UUID	Negotiated by the OS; `requestMtu(…)` resolves with the current value	OS-managed, triggered by encrypted characteristics; `getBondedPeripherals()` is empty	Background operation needs `ios.bluetooth.background` plus service-UUID scan filters; advertisements carry only name and service UUIDs

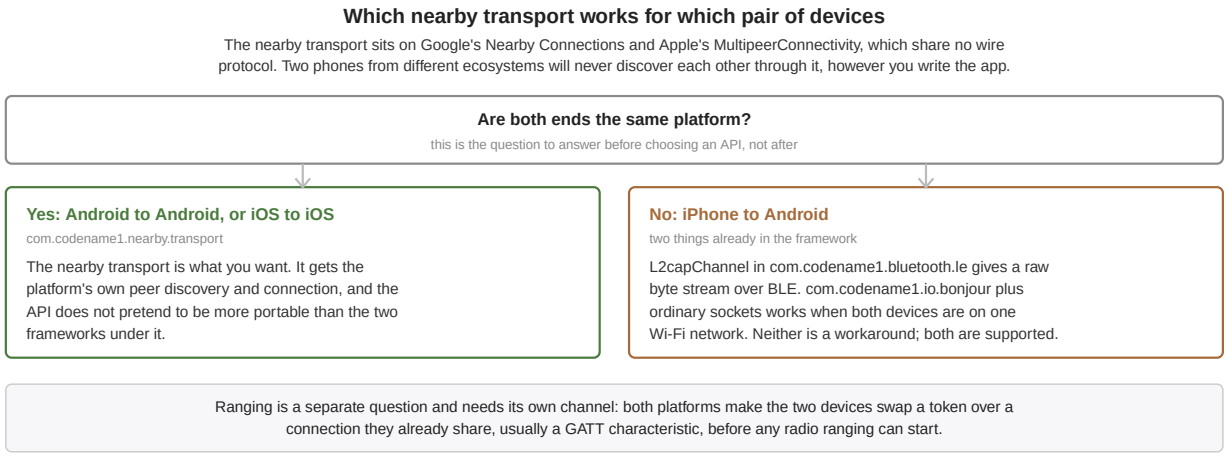
Platform	Address semantics	MTU	Bonding	Notes
Simulator (mock)	Synthetic (`AA:BB:CC:DD:EE:01`)	Simulated negotiation	Simulated	Timestamps come from a monotonic counter — treat them as ordered, not as wall-clock times
Simulator (native backend)	Host-OS device identifier	Real negotiation	Not supported	Central role only; requires the bundled `libcn1ble` library and OS Bluetooth permission for the terminal/IDE
JavaScript	Per-origin Web Bluetooth identifier	Fixed at 512	Browser-managed	One user-picked device per chooser; `startScan` requires a user gesture (call it from a button handler); RSSI unavailable

Persist addresses only for same-install reconnection, branch on the capability queries rather than on `Display.getPlatformName()`, and keep every byte-stream consumer off the EDT — those three rules keep one code base working across every column of the capability matrix.

Chapter 76. Nearby Devices

Codename One answers three questions about the surrounding devices, under `com.codename1.nearby`: how far away one is and in which direction (`com.codename1.nearby.ranging`), which one is yours (`com.codename1.nearby.companion`), and how to send it something (`com.codename1.nearby.transport`).

They're three packages rather than one because referencing a package is the whole opt-in. The build server decides what native machinery an app gets by scanning bytecode for these prefixes, so an app that only wants to know how far away its keyring tag is pays for ranging alone — no Play Services dependency, no local network prompt, no companion permissions. Referencing `com.codename1.nearby` itself costs nothing; it holds only the shared value types.



Capability	iOS	Android	Simulator and desktop	JavaScript
Precision ranging, peer to peer	yes (U1 chip, iPhone 11 and later)	yes (UWB hardware)	simulated	simulated
Ranging an accessory	yes (Nearby Interaction Accessory Protocol)	yes (join the session it names)	simulated	simulated
Direction as well as distance	where the hardware provides it	where the hardware provides it	simulated	simulated
Companion association	yes (iOS 18 and later)	yes (Android 8 and later)	simulated	simulated
Presence notifications	—	yes (Android 12 and later)	simulated	simulated
Device-to-device transport	Apple devices only	Android devices only	simulated loopback	simulated loopback
Connection authentication token	—	yes	—	—

Branch on the capability queries — `Ranging.isSupported()`, `Ranging.getCapabilities()`, `CompanionDevices.isSupported()`, `NearbyTransport.isSupported()` — rather than on platform detection. Ranging in particular is absent on plenty of current phones, so treat it as an enhancement to a feature that also works without it rather than as the feature itself.

Every callback in this family arrives on the EDT.

76.1. Three Things Worth Knowing Before You Design Around This

The transport doesn't cross ecosystems. Underneath are Google's Nearby Connections on Android and Apple's MultipeerConnectivity on iOS, which share no wire protocol. An iPhone and an Android phone will never discover each other here, however the app is written. Nothing in the API hides that, because an API that looked portable and never found the peer would be worse than an honest limitation. When both ends aren't the same platform, two things that do work across the divide are already in the framework: `com.codename1.bluetooth.le.L2capChannel` for a raw byte stream over BLE, and `com.codename1.io.bonjour` plus ordinary sockets when both devices share a Wi-Fi network.

Ranging needs `com.codename1.bluetooth`, or something like it. Both platforms require the two devices to swap a token over a channel they already share before any radio ranging can begin. A GATT characteristic is the usual channel. The two APIs are designed to be used together.

Background ranging is opt-in and needs Apple's permission. On iOS it requires the `com.apple.developer.nearby-interaction` entitlement, which has to be enabled on the App ID before it will sign. Codename One never injects it on its own, because an entitlement the App ID doesn't carry fails codesigning with an error naming the entitlement and not the reason it appeared. Set `ios.nearby.background=true` once the capability is enabled, and note that `RangingCapabilities.isBackgroundRangingSupported()` reports `false` until then.

76.2. Ranging: How Far, And Which Way

Ultra-wideband measures distance by timing a radio round trip, which is worth about ten centimeters. That's a different kind of answer from a Bluetooth signal-strength estimate, which is worth a few meters on a good day and swings when someone puts a hand over the phone.

A session is prepared, then started. There's no honest one-call form, because the token exchange has to happen between the two:

```
if (!Ranging.isSupported()) {
    return;                        // no ultra-wideband radio on this device
}
```

```
Ranging.prepareSession(RangingRole.CONTROLLER).onResult((session, err) -> {
    if (err != null) {
        return;
    }
    // 1. publish our token however the two apps already talk
    characteristic.write(session.getLocalToken().toByteArray());

    // 2. when theirs arrives, start measuring
    session.addRangingListener(new RangingAdapter() {
        public void updated(RangingUpdate u) {
            if (u.hasDistance()) {
                label.setText(Math.round(u.getDistance(RangingUnit.CENTIMETERS)) + " cm");
            }
            if (u.hasDirection()) {
                arrow.setAngle(u.getAzimuth());
            }
        }
    });
    session.start(RangingToken.fromByteArray(theirToken));
});
```

One session ranges one peer. That's a hard limit of Apple's `NINearbyPeerConfiguration` rather than a simplification, so an app tracking several peers prepares several sessions.

Pick a role even though iOS ignores it: Android needs exactly one controller, and choosing costs nothing on the other side.

Every field of a `RangingUpdate` except the timestamp is optional, and they drop out independently. A peer directly behind the phone commonly reports a distance with no direction, and a peer at the edge of range reports neither — so guard each read with its `has` method rather than assuming a sentinel. There's no zero-argument `getDistance()`: meters read as feet is the accident that convention exists to prevent.

Azimuth is degrees in the range -180 to 180, zero straight ahead and positive to the right; elevation is -90 to 90, positive above the device. Android reports both angles natively. iOS reports a unit direction vector instead and the port derives the angles from it, so the same code reads the same on both; `getDirectionVector()` still hands back the untouched vector where there is one.

A peer that walks away produces `peerRemoved` and the session stays alive, ready to resume if it comes back — gray the UI out rather than tearing it down. A session that dies for good produces `invalidated` and can't be restarted.

76.3. Ranging An Accessory

A third-party ultra-wideband tag isn't a phone, and the two platforms disagree about what talking to one means.

On iOS there is a defined handshake. The accessory publishes a blob of configuration data over its own channel, and the session answers with bytes that have to travel back before the accessory begins ranging:

```
Ranging.prepareSession(RangingRole.CONTROLLER).onResult((session, err) -> {
    if (err != null) {
        return;
    }
    session.addRangingListener(listener);
    session.startAccessory(configurationFromTheAccessory)
            .onResult((shareable, failure) -> {
                if (failure == null) {
                    characteristic.write(shareable);   // forward it back
                }
            });
});
```

Android has no equivalent protocol. There, an accessory simply names the channel and session to join, so build a token from what it published and call `start`:

```
RangingToken tag = RangingToken.forUwbAddress(address, channel, preambleIndex,
        sessionId, sessionKey);
session.start(tag);
```

`startAccessory` fails with `NearbyError.NOT_SUPPORTED` on Android, and a token built by `forUwbAddress` is rejected on iOS. A token is opaque and never portable between the two platforms; `RangingToken.fromByteArray` says so rather than handing garbage to a native call.

76.4. Companion Devices: Which One Is Yours

Associating isn't pairing. It's the app telling the operating system that a particular accessory belongs to it, through a chooser the OS draws and the user picks from, and getting privileges back that an ordinary Bluetooth scan doesn't carry: the OS watches for the device instead of the app, scanning stops needing location permission on Android, and the user sees one honest prompt naming one device.

```
AssociationRequest request = new AssociationRequest.Builder()
        .addFilter(DeviceFilter.bleService("180D"))
        .build();
CompanionDevices.associate(request).onResult((device, err) -> {
    if (err == null) {
        Preferences.set("sensor", device.getId());
        CompanionDevices.startObservingPresence(device.getId());
    }
});
```

An association outlives the app: it survives restarts and reboots, and ends only when the app drops it, the user revokes it in system settings, or the app is uninstalled. Persist `CompanionDevice.getId()` and look the device up again on the next launch instead of asking the user to pick it twice. `CompanionDevice.getAddress()` is the same handle `BluetoothLE.getPeripheral(String)` takes, which is

what makes an association useful rather than decorative.

Ask for `CompanionProfile.GENERIC` unless the device is a watch, a head-mounted display or a computer. A profile is a request for elevated privileges as much as a description, and the specific ones cost the user a stronger prompt. The build scanner can't see which profile a request asks for, because it arrives as an enum constant, so name it yourself: set `android.nearby.watchProfile`, `android.nearby.computerProfile` or `android.nearby.glassesProfile` to `true` for whichever of `CompanionProfile.WATCH`, `COMPUTER` and `GLASSES` you use. Each declares that profile's own permission, and without it Android rejects the association before the chooser opens — which looks to the user like nothing happened.

Profiles arrived at different Android versions: `WATCH` at 12, `COMPUTER` at 13, `GLASSES` at 14. Asking for one the running device doesn't have fails with `NearbyError.NOT_SUPPORTED` rather than associating without it. A profile is a request for elevated privileges, and an association that lacks them without saying so is worse than one that didn't happen. Fall back to `CompanionProfile.GENERIC` yourself if that's what you want.

Two platform differences to design around. Presence notifications are Android only: AccessorySetupKit reports an accessory being added to or removed from the app's set, which isn't the same event as it coming into range, so `startObservingPresence` answers `false` on iOS and an app that needs live proximity there should scan with `com.codename1.bluetooth`. And AccessorySetupKit only ever discovers Bluetooth services an app declared up front, so set `ios.nearby.accessoryServices` to a comma-separated list of the service UUIDs your accessories advertise — without it the picker finds nothing on iOS, and the build log says so.

Register the presence listener from your app's `init()` rather than from a form. Android may start the process to deliver a sighting and nothing else, with no form on screen, and a listener that a form registers doesn't exist yet at that point. An event that arrives before any listener is registered is held and replayed to the first one that registers, so a wake-up isn't lost, but only the 64 most recent are kept.

Presence doesn't run your code the moment a device comes into range. Android can start the process for the companion service alone, and Codename One doesn't run an application's `init()` there — a form has nowhere to live in a service. Your listener hears about the sighting, in order, when the app next initializes. Treat presence as a record of what happened while the app was away rather than as a background execution mechanism; for work that must happen without the app, use the background features in the notifications chapter.

76.5. Transport: Sending Something

```
NearbyTransport.addTransportListener(new TransportAdapter() {
    public void endpointFound(Endpoint e) {
        NearbyTransport.requestConnection(e, "Shai's phone");
    }
    public void connectionRequested(IncomingConnection r) {
        // show r.getAuthenticationToken() on both screens first
        r.accept();
    }
```

```
    public void connected(Endpoint e) {
        NearbyTransport.send(e, Payload.fromBytes(data));
    }
    public void payloadReceived(Endpoint e, Payload p) {
        process(p.getBytes());
    }
});
NearbyTransport.startAdvertising("chat", "Shai's phone", TransportStrategy.CLUSTER);
NearbyTransport.startDiscovery("chat", TransportStrategy.CLUSTER);
```

`getAuthenticationToken()` is a short string both devices derive from the connection's own key exchange, so a device relaying between them can't make both ends show the same value. Showing it on both screens and asking whether they match is what makes the pairing trustworthy; skipping that step is a choice to trust whoever answered first.

It's empty on iOS. MultipeerConnectivity exposes nothing to derive one from, and a token computed from the service name and the display names would be one a relay can reproduce at both ends — a check that looks like a defense and isn't. An iOS app that needs to know who it's talking to has to establish that itself, over a channel the relay doesn't control.

Answer every `connectionRequested`. You don't have to answer inside the callback — showing the token and waiting for the user is the whole point, and the request stays live until you call `accept()` or `reject()` — but a request that's never answered at all holds radio resources open on both sides until the far end times out. If nothing is listening when a request arrives, it's rejected for you, so the far end learns immediately instead of waiting.

The strategy you pass to `startAdvertising` and `startDiscovery` is a limit, not a hint. Under `POINT_TO_POINT` a second connection is refused with `NearbyError.BUSY` on either side, and under `STAR` the discovering side holds one connection while the advertising side accepts many. `CLUSTER` is the only one with no limit. Disconnect before connecting elsewhere.

On iOS, list your service ids at build time. The service id becomes a Bonjour service type there, and iOS browses only the types an app declared in its `Info.plist` — a type that isn't declared produces no peers and no error. The build can't see the strings you pass to `startAdvertising`, so name them in `ios.nearby.serviceType` as a comma-separated list. Miss one and the call fails with a message telling you which id to add, which beats an app that finds nothing and says nothing.

The platform restricts the type to fifteen characters of lowercase letters, digits and hyphens, so a reverse-DNS string that's legal on Android is folded to fit: `com.example.chat` becomes something like `com-exampl-jd3q`. The last four characters are derived from the whole id, because the fold alone is lossy — `com.example.chat` and `com.example.charts` both reduce to `com-example-cha`, and without the suffix two unrelated apps would discover each other's peers. Case doesn't split a service: `Chat` and `chat` are the same id and get the same type. The build log names every type it declared.

Byte payloads are capped at `NearbyTransport.getMaxPayloadSize()`, a few kilobytes on both platforms; anything larger goes as a file payload, which streams and reports progress. Call `NearbyTransport.stop()` when the feature's UI closes — both platforms keep the radios busy until something says stop.

A terminal `PayloadStatus.SUCCESS` means the bytes reached the peer, not that they were handed to the radio. Watch for it rather than treating a resolved `send()` as delivery: the resource resolves when the platform accepts the payload, which is earlier. If the peer disappears between the two you get `FAILURE`, so every send reaches one terminal status or the other.

76.6. Developing Without Hardware

The simulator, the desktop ports and the JavaScript port carry a working implementation rather than a stub, and report `NearbyAvailability.LOCAL_ONLY` so an app can tell the developer its peers are not real. Almost none of a ranging feature is about radios — laying out the screen, animating an arrow, deciding what to show while the direction drops out, handling the peer walking away — and a port that answered `NOT_SUPPORTED` would make every line of it testable only on a pair of phones.

Two things it does that a mock wouldn't. It never completes inline, because code written against an implementation that answers instantly races the moment it meets one that doesn't. And its peers move, along a bounded random walk, because a constant 1.5 m would let an app ship with a distance label that flickers unreadably against real hardware.

What it won't do behind your back is drop a peer or suspend a session at random. Those are real events an app must handle, but a simulation that fired them unpredictably would make every test using it flaky, so they're controls the simulator drives instead.

76.7. Build Hints

Hint	Default	What it does
`ios.nearby.serviceType`	derived from the package name	Comma-separated list of the service ids the app passes to `startAdvertising`. Each is folded to a Bonjour service type and declared; the runtime refuses an id that isn't on the list.
`ios.nearby.accessoryServices`	unset	Comma-separated Bluetooth service UUIDs the association picker may discover. Required for the picker to find anything on iOS.
`ios.nearby.background`	`false`	Requests the `com.apple.developer.nearby-interaction` entitlement and the matching background mode. Enable the capability on the App ID first.
`android.nearby.watchProfile`	`false`	Declares the watch companion profile permission, for an app that associates with `CompanionProfile.WATCH`.

Hint	Default	What it does
`android.nearby.computerProfile`	`false`	The same for `CompanionProfile.COMPUTER`, which Android honours from API 33.
`android.nearby.glassesProfile`	`false`	The same for `CompanionProfile.GLASSES`, which Android honours from API 34.

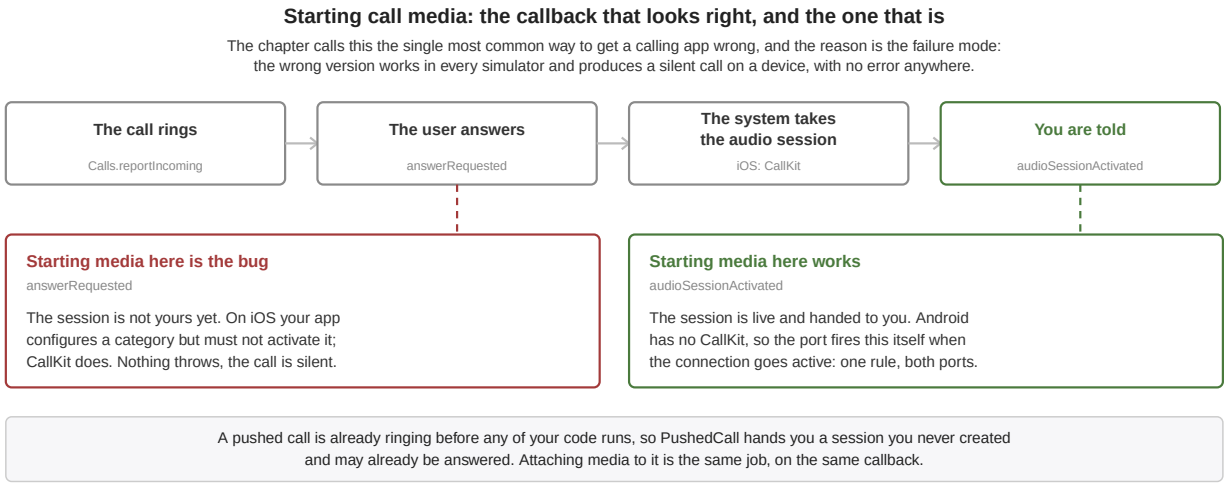
Everything else is automatic. Referencing a package links its frameworks, injects its privacy strings and adds its permissions; referencing none of them changes nothing about the app.

Chapter 77. Call Management

Codename One can make a call your app carries look, to the operating system and to the user, like a call the phone itself placed. That means the lock-screen call UI, the ringtone that plays while your app isn't running, the entry in the system call log, the audio session the OS hands over and takes back, and the caller's name shown for an incoming number the address book has never seen.

The APIs live under `com.codename1.call`, in three sub-packages, and they're separate packages rather than one because referencing a package is the whole opt-in. The build server decides what native machinery an app gets by scanning bytecode for these prefixes, so an app that only labels spam numbers pays for none of the calling machinery — no telephony permissions, no VoIP background mode. Referencing `com.codename1.call` itself costs nothing; it holds only the shared value types.

Capability	iOS	Android	Simulator and desktop	JavaScript
System call UI	yes (CallKit)	yes (Android 8 and later, see below)	simulated	—
Ring while the app isn't running	yes (`com.codename1.call.voip`)	yes, from your own push handler	simulated	—
Answer, hold, mute, keypad from the system	yes	yes	simulated	—
Set the system mute state from your app	yes	—	simulated	—
Audio session handoff	yes	synthesized	simulated	—
Conference grouping	—	—	—	—
Caller identification	yes (Call Directory)	—	simulated	—
Call blocking	yes	yes (Android 10 and later)	simulated	—



Branch on the capability queries — `Calls.isSupported()`, `Calls.getCapabilities()`, `VoipPush.isSupported()`, `CallDirectory.isSupported()` — rather than on platform detection. There is no way to make a desktop show a lock-screen call, so an app that offers calling needs an in-app fallback screen whatever else it does.

Every callback in this family arrives on the EDT.

77.1. Five Things Worth Knowing Before You Design Around This

These APIs don't carry the voice. There is no codec and no signalling here: carrying audio and video is `com.codename1.webrtc` (Real-Time Audio and Video), and the signalling is your app's. What was missing was everything *around* the media, and without it an app couldn't ring at all while backgrounded — which is why a Codename One app couldn't previously be a calling app no matter how good its audio was.

Start media when the audio session activates, not when the user answers. This is the single most common way to get a calling app wrong. On iOS the system owns the audio session: your app configures a category but must not activate it, and CallKit activates it and tells you. Code that starts its audio engine in `answerRequested` works in every simulator and produces a silent call on a device, with no error anywhere. Use `audioSessionActivated`. The Android port synthesizes the same callback when the connection goes active, so the one piece of advice is correct everywhere.

A pushed call is already ringing. When a call arrives as a VoIP push, iOS requires it to be reported to the system *before any of your code runs* and kills the app when it isn't — so native code does the reporting from a fixed payload, and your listener is told afterward. `PushedCall` therefore hands you a `CallSession` you never created, possibly one the user has already answered. Your job is to attach media to a call that exists, not to decide whether to ring.

The two platforms draw the ringing screen differently. On iOS CallKit presents the call and there is nothing to build. On Android a self-managed calling app gets no system call screen at all: Telecom arbitrates with other calls, routes the audio and writes the call log, but presenting the call is the application's job. The port does that for you — a call-category notification carrying a full-screen intent, and the ringing screen that intent launches. On an unlocked device you get the notification as a heads-up banner; on a locked one the platform shows the ringing screen over the keyguard. Answer and Decline appear on both and are wired to the same listeners as everywhere else. The screen is a plain one, because it ships inside the port and has no resources of its own: if you want your own, present it from your `incomingCall` listener and it draws on top. Two consequences are yours: the labels come from the `android.call.incomingTitle`, `android.call.answerLabel` and `android.call.declineLabel` build hints and are English until you set them, and the user can turn the **Incoming calls** notification channel down in Settings. Anything below high importance files the notification in the shade instead of ringing, so the port treats it as it treats a revoked

`POST_NOTIFICATIONS`: `Calls.getAvailability()` answers `NOT_PERMITTED` and `Calls.reportIncoming` is refused, rather than reporting a call that rings nowhere.

Implement `providerReset`. It means every call your app had is gone, because the user switched calling off or the platform recovered from an error. Drop your media and forget your sessions, but don't call `end()` on them — they no longer exist as far as the system is concerned. An app that leaves this method empty leaks its media engine and shows calls that aren't there.

77.2. Owning A Call

Configure once, then listen. `Calls.configure` must run before anything is reported: on Android an unregistered account makes `TelecomManager` ignore every reported call — no exception, no log line, no call.

```
if (!Calls.isSupported()) {
    return;                          // fall back to an in-app call screen
}
Calls.configure(new CallConfiguration().displayName("Acme Talk"));

Calls.addActionListener(new CallActionAdapter() {
    public void answerRequested(String callId, CallAction action) {
        signalling.accept(callId);
    }

    public void endRequested(String callId, CallAction action) {
        signalling.hangUp(callId);
        media.stop();
    }

    public void audioSessionActivated(CallAudioSession session) {
        media.start(session.getCallId());   // here, NOT in answerRequested
    }

    public void audioSessionDeactivated(String callId) {
        media.stop();
    }

    public void providerReset() {
        media.stopEverything();             // every call is gone
    }
});
```

An incoming call your app learned about over its own connection is reported with an identifier you allocate. Both ends must use the same one for the life of the call.

```
String callId = CallId.random();          // the id both ends will use
Calls.reportIncoming(callId, CallHandle.phone(theirNumber), "Ada Lovelace", false)
        .onResult((session, err) -> {
```

```
            if (err != null) {
                // The system refused to ring: an emergency call, another
                // app's call, or Do Not Disturb. Tell the caller.
                return;
            }
            signalling.invite(callId, theirNumber);
        });
```

Note the failure path isn't decoration. The system genuinely refuses to ring a call during an emergency call, when another app holds one, or when the user has switched your app's calling off, and `Calls.getAvailability()` will tell you before you try. An app that assumes reporting always succeeds shows a caller "ringing" over a phone that's silent.

One difference between the platforms is worth designing around rather than discovering. On iOS the provider is configured for a single call, so while your app holds one, CallKit refuses the next report and `getAvailability()` answers `THIS_APP_IN_CALL`. Android Telecom accepts a second self-managed call from the same account, so it keeps answering `AVAILABLE`. If your app offers call waiting, branch on the availability rather than assuming a second call can always ring.

Outgoing calls are the same shape, with two extra reports that drive what the user sees: `reportStartedConnecting` while the far end is being rung, and `reportConnected` when media is actually flowing, which is what starts the call duration.

```
String callId = CallId.random();
Calls.reportOutgoing(callId, CallHandle.phone("+14155551212"), "Ada", false)
        .onResult((session, err) -> {
            if (err != null) {
                return;
            }
            session.reportStartedConnecting();     // we are ringing them
            signalling.place(callId, "+14155551212");
            // ... and once the far end picks up:
            session.reportConnected();             // starts the duration
        });
```

`CallSession` carries the rest: `end`, `setHeld`, `setMuted`, `sendDigits`, `update` and `groupWith`. Three are worth reading twice. `setMuted` tells the operating system what the mute button should look like and does **not** stop your app sending audio — nothing in this package touches media. It's the one `CallSession` method the two platforms don't agree on: check `CallBridge.CAPABILITY_MUTE`, which Android doesn't offer, because a self-managed call there can't tell Telecom its mute state and the call answers `NOT_SUPPORTED`. Hearing what the user does with the system's mute button is a different thing and arrives on both through `muteRequested`. `reportEndedRemotely` rather than `end` is what you call when the hang-up came down your own signalling, so the system call log says the far end hung up instead of blaming the user.

And `groupWith` answers `NOT_SUPPORTED` everywhere, which is why the matrix above shows conference grouping as absent on both platforms. Neither lets an app conference two of its own calls: CallKit's group action travels from the system to your app with no counterpart in the other

direction, and Telecom conferences self-managed calls only through a `ConnectionService` conference Codename One doesn't build. Nothing stops you mixing several streams into one call yourself and reporting that as a single call — that needs no permission from either platform, and it's what apps that offer conferencing actually do.

77.3. The Values These APIs Hand You

Everything above takes or returns a handful of small types from `com.codename1.call`. Six are enumerations — `CallState`, `CallDirection`, `CallEndReason`, `CallAvailability`, `CallHandleType` and `CallError` — so a value that isn't one of their constants won't compile, though a `switch` over one isn't required to cover every constant and an unhandled state falls through rather than failing the build. `CallHandle` and `CallException` are ordinary classes and `CallId` is a holder for static helpers whose identifiers are plain strings, so none of those three offer `values()` or anything else enum-shaped.

`CallState`

`RINGING`, `DIALING`, `ACTIVE`, `HELD`, `ENDED`. Incoming calls start at `RINGING` and outgoing ones at `DIALING`, but `ACTIVE` and `HELD` cycle in both directions — `CallSession.setHeld(false)` and a fulfilled resume both put a held call back to `ACTIVE`, so code that treats `HELD` as one-way rejects a legitimate resume or leaves media paused. `ENDED` is the only terminal state, and it's where you release whatever the call was holding. The session's asynchronous operations — `end`, `setHeld`, `setMuted`, `sendDigits`, `groupWith` — fail with `CallError.INVALID_ID` once a call has ended, which is how a bookkeeping bug in the app surfaces; the reporting methods that return `void`, such as `reportConnected` and `update`, return without a word instead, so don't wait on them for that signal.

`CallDirection`

`INCOMING` or `OUTGOING`, fixed when the session is created and never changing after that. Read it when you hold a session you didn't report yourself — a session passed to a listener, or fetched from `Calls.getSessions()` — rather than keeping your own note of the direction beside the call id.

`CallEndReason`

`REMOTE_ENDED`, `LOCAL_ENDED`, `UNANSWERED`, `BUSY`, `FAILED`, `FILTERED`. `FILTERED` covers more ground than its name suggests. It's documented as the system declining the call rather than the user — Do Not Disturb, or a blocked number — and it differs from `UNANSWERED` in that the call never rang. The Android port also reports it for a fulfilled reject, though, so a Decline from the lock screen arrives as `FILTERED` there while a hang-up after answering arrives as `LOCAL_ENDED`. Read it as "this call ended without being taken, and not because the far end gave up," and don't try to tell an explicit decline from a silent block out of this value alone.

`CallAvailability`

what `Calls.getAvailability()` answers before you report a call, and `AVAILABLE` is the only value that lets one ring. Check it before an incoming report; an outgoing call is a different question. On Android the notification gate that makes this answer `NOT_PERMITTED` applies to incoming calls alone — an outgoing call never rings, so `reportOutgoing` goes through and refusing it would take away a call the user started. The values need three different responses, not two. `EMERGENCY_CALL_IN_PROGRESS` and `OTHER_APP_IN_CALL` pass on their own, so a retry is the right move — `THIS_APP_IN_CALL` is in the same family, though Android's bridge never reports it by

design, because Telecom accepts a second call from the same account. `NOT_CONFIGURED` means `Calls.configure` hasn't completed successfully, which is yours to fix in code and not something a user can clear; prompting for it strands them in front of a dialog that changes nothing. Read it as "not configured," not as "never called," because on Android a `configure` that threw answered `UNAUTHORIZED` and left the port without a registered account, so calling it again without fixing what it reported changes nothing. `NOT_PERMITTED` is Android only — iOS never answers it — and it covers three conditions with three different fixes, none of which is the calling switch. `MANAGE_OWN_CALLS` missing: that one is a normal permission granted at install, so there's no prompt behind it and `Calls.requestPermissions` doesn't ask. The builder declares it for you whenever the app uses the call packages, so its absence means something rewrote the manifest, and the fix is in the build rather than on the device. `POST_NOTIFICATIONS` not yet granted on Android 13 and later: that one is a runtime permission, asking for `PERMISSION_NOTIFICATIONS` is exactly right, and it's the usual answer the first time an app rings. Notifications switched off for the app, or the incoming-call channel dropped below high importance: no permission is missing, so only the system's own notification settings can clear it. Only `UNSUPPORTED` is permanent.

`CallHandle` and `CallHandleType`

who the call is with, and one of `GENERIC`, `PHONE_NUMBER` or `EMAIL_ADDRESS`. Build a handle with `CallHandle.phone(…)`, `CallHandle.email(…)` or `CallHandle.generic(…)` rather than by hand; the type travels with the value and decides how the system displays and dials it.

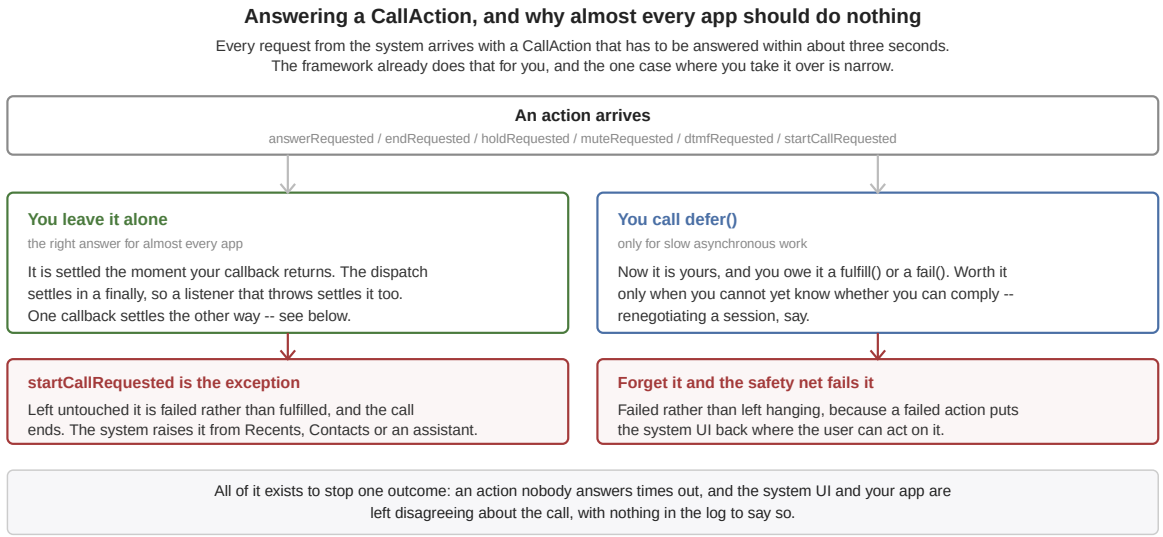
`CallId`

static helpers for the identifier both ends of a call have to agree on, which is a `String` rather than a type of its own. `CallId.random()` mints one, `CallId.isValid(…)` checks one that arrived over your own connection, and `CallId.normalize(…)` puts it in the form the platform expects.

`CallError` and `CallException`

why an action failed, as an enum and the exception that carries it. Don't sort these into "this call" and "this app" — the codes cut across that line, and what to do about one depends on the condition behind it rather than on the code alone.

`CALL_REFUSED` is the system declining to place or ring the call right now, and it spans both kinds of cause: an emergency call or another app's self-managed call passes on its own, while the user having switched your app's calling off, or `Calls.configure` not having run, refuses every report until something changes. Nothing in the code tells you which you got: Android's refusal carries one message naming all three causes. `Calls.getAvailability()` is worth asking first, and won't always separate them either — it never checks whether the registered `PhoneAccount` was disabled, and its foreign-call test needs `READ_PHONE_STATE`, which the port doesn't declare by design and treats as "no" when absent. It can answer `AVAILABLE` and the report still come back `CALL_REFUSED`. Retry on a timer that slows down rather than reading anything into a repeat: the emergency or foreign call that caused the first refusal is often still up for the second, and a persistent refusal looks identical.



`CALL_FILTERED` means the system suppressed the call before it rang — Do Not Disturb on iOS, or a blocked number — so no action will arrive for it. `DUPLICATE_CALL` means that identifier is already live. `Calls.report` checks its own session map first, so a second report of an id your app already has fails here and never reaches a port — retrying it fails identically every time. Fetch the existing session and update that instead. The reconciliation the ports do, folding a repeat into an update, is for reports arriving from the native side, not for this call.

`NOT_SUPPORTED` is either the whole integration or the one operation you asked for. `Calls.isSupported()` covers the first — Android self-managed calls need API 26, CallKit is absent from tvOS and watchOS — so branch on it rather than waiting for the error. It doesn't cover the second: `setMuted` answers `NOT_SUPPORTED` on Android because Telecom won't let a self-managed call set its own mute state, and `groupWith` answers it on every port today. Disable the capability that came back unsupported, not calling as a whole.

`UNAUTHORIZED` comes from two places on Android and nowhere else: a `SecurityException` out of configure or a report, which means `MANAGE_OWN_CALLS` is missing, and an incoming report refused because notifications are off or the incoming-call channel sits below high importance. That second one is two conditions wearing one code, and they part exactly as they do under `NOT_PERMITTED` above: a `POST_NOTIFICATIONS` the user hasn't granted is cleared by asking, while notifications switched off or a lowered channel is a setting no prompt reaches. Ask once, and if the code comes back with the permission already granted, stop asking — the recovery is in settings. A denied microphone grant or a declined call-screening role doesn't arrive here — `Calls.requestPermissions` resolves with the bitmask it got and `CallDirectory.requestScreeningRole` resolves `false`, so read those results rather than waiting for an error.

`BUSY` is about neither a call nor the app: a conflicting operation is already running, which can be another call but can equally be an unrelated request holding a shared channel — `CallDirectory.requestScreeningRole()` answers it when another dialog owns the activity result — so retry the operation rather than blaming a session. And `PROVIDER_RESET` says the call provider was reset while that one operation was in flight, so it could never be answered; the provider works again afterward and the next report may well succeed.

77.4. Actions, And Why They Have To Be Answered

When the user answers on the lock screen, hangs up from the car, or taps the keypad, the request arrives with a `CallAction`. Both platforms require an answer within a few seconds, and an unanswered one times out and leaves the system UI and your app disagreeing about the call, with nothing in the log to say so.

Almost every app should ignore this entirely: an action the listener doesn't touch is fulfilled automatically, which is the correct behaviour. Only an app that must do slow asynchronous work

before it knows whether it can comply — renegotiating a session, say — calls `action.defer()` and then `fulfill()` or `fail()` itself. A deferred action that's forgotten is failed by a safety timer, because a failed action puts the UI back in a state the user can act on and a timed-out one doesn't.

77.5. Ringing When The App isn't Running

A VoIP push is delivered straight to the calling machinery, launching the app if it has to. It's the only way an app that isn't running can make the phone ring.

```
VoipPush.setListener(new VoipPushListener() {
    public void callReceived(PushedCall call) {
        if (call.isStale()) {
            history.addMissed(call.getHandle());   // it is already over
            return;
        }
        // The phone is ALREADY ringing. Attach media and wait for the
        // ordinary answerRequested; do not report the call again.
        signalling.attach(call.getSession().getCallId(), call.getData());
    }

    public void tokenChanged(String token) {
        signalling.registerVoip(token);
    }
});
VoipPush.register();
```

`com.codename1.call.voip` is iOS-only, and that isn't a gap. It exists because iOS reports a pushed call to the system before any of your code runs and kills the app when it doesn't — a constraint Android doesn't have. On Android a high-priority FCM message reaches your ordinary push callback like any other, and you call `Calls.reportIncoming` from there. `VoipPush.isSupported()` answers false on Android so you can branch on it.

Because the call is reported to the system before any Java runs, **the native code parses the push itself** and your server has to honour a fixed shape:

```
{ "cn1call": { "uuid": "6B29FC40-CA47-1067-B31D-00DD010662DA",
               "handle": "+14155551212", "handleType": "phoneNumber",
               "displayName": "Jane Doe", "video": false,
               "ttl": 30, "data": "opaque, handed back untouched" } }
```

`uuid` and `handle` are required; everything else falls back to the build hints. `data` is never parsed by the framework and is how you carry a room id or a session token through to code that runs later. To retract a call that was cancelled before it was answered, send the same `uuid` with `"cancel": true`.

Sending a payload without `cn1call` wakes the app and rings nothing, which on iOS is the case that gets the app killed.

Set the listener before or after registering, as you like — calls that arrived first are held and drained when a listener appears. An app that never sets one will find its calls timed out and ended by the platform.

`UIBackgroundModes: voip` is added only for apps that reference `com.codename1.call.voip`, and Apple rejects an app that carries it without a working call implementation. That's the entire reason this is a separate package from `com.codename1.call.session`.

77.6. Naming And Blocking Other People's Callers

This is caller ID and spam blocking: an ordinary cellular call arrives, and the system asks the installed directories whether any of them recognizes the number. It has nothing to do with calls your app carries, which is why it's a package of its own and carries no telephony permissions.

```
DirectoryEntry[] entries = {
    new DirectoryEntry(14155551212L, "Acme Support"),
    new DirectoryEntry(14155559999L, null, true)      // blocked outright
};
CallDirectory.setEntries(entries).onResult((ok, err) -> {
    if (err == null) {
        CallDirectory.reload();
    }
});
```

Numbers are `long` rather than `String` on purpose. Both platforms require the list in ascending numerical order and reject the whole list — not the offending row — when it isn't, and a string list sorts lexicographically, which puts +1999⋯ before +12⋯. `CallDirectory` sorts and de-duplicates what you give it, so you need not.

Three platform facts to design around. On iOS the numbers are read by a separate app extension the system starts on its own schedule, so installing the data and asking the system to read it are two steps. Caller identification is **off until the user enables your app** in Settings, which nothing you write can do for them — check `DirectoryStatus.isEnabled()` before concluding that a load failed.

And **Android blocks but doesn't label**. A `CallScreeningService` may allow, reject or silence a call; Android gives a third-party app no way to put a name on one. `blocked` entries work there and labels are ignored, which is why `Calls.getCapabilities()` reports `CAPABILITY_SCREENING` and not `CAPABILITY_DIRECTORY` on Android.

77.7. Developing Without Hardware

The simulator and the desktop builds run a real simulated call stack rather than reporting the feature unsupported, so a ringing screen, an in-call screen and a media lifecycle can all be built and tested without a phone.

It's a simulation and not a stub, and the difference is deliberate: nothing completes inside the

calling stack frame, and the audio session arrives well after the answer rather than with it, because that gap is where media bugs live.

The **Simulate → Calls** menu scripts the awkward cases rather than the happy one, which is what makes it worth opening:

- **Ring A Second Call While Busy** — where a single-call state machine breaks.
- **Refuse The Next Call** — the emergency-call refusal an app that assumes reporting always succeeds never handles.
- **Never Activate The Audio Session** — makes the silent-call mistake above reproduce on your desk instead of on a device.
- **Queue A Call That Already Ended** — the cold-start call that must be logged as missed, never answered.

Every item is also callable from a test with `CN.execute("call:itemN")`.

77.8. Build Hints

Hint	Default	What it does
`ios.call.providerName`	the app's display name	The name shown above a call in the system UI.
`ios.call.ringtone`	the system ringtone	A sound file in the bundle to ring with.
`ios.call.icon`	none	A template image shown beside the call.
`ios.call.unknownCaller`	none	The name shown when a push carries no `displayName`.
`ios.call.pushTTL`	`30`	Seconds a pushed call waits for your code before the system ends it as unanswered.
`ios.call.video`	`false`	Whether the provider offers video calls.
`ios.call.recents`	`true`	Whether calls appear in the system call log.
`android.call.incomingTitle`	`Incoming call`	The text on the Android ringing notification.
`android.call.answerLabel`	`Answer`	The Android answer button.
`android.call.declineLabel`	`Decline`	The Android decline button.
`android.call.channelName`	`Incoming calls`	The notification channel the user sees in Settings.

Hint	Default	What it does
`call.video`	`false`	Whether video calls are offered, on both platforms. Overridden per platform by `ios.call.video` and `android.call.video`.
`android.call.video`	`false`	Whether the Android manifest declares `CAMERA`. Required for video calls.

`videoSupported(true)` on `CallConfiguration` isn't enough on its own for a video call. The camera permission has to be in the manifest, and a manifest is written at build time, so the build has to be told: set `call.video` (or `android.call.video`) as well. Without it Android refuses to grant `CAMERA` — a permission the manifest never asked for can't be granted, and the request resolves denied every time. `Calls.getCapabilities()` won't report `CAPABILITY_VIDEO` on such a build, so branch on that rather than assuming the configuration was enough.

The `ios.call.` hints are baked into `Info.plist` rather than set from code because native code needs them during launch, before any of your code has run. The `android.call.` labels are read when the call rings, and exist because a ringing screen is the last place to show an untranslated English string. Setting only `CallConfiguration` and expecting a pushed call to ring with the right name is the mistake to avoid; `CallConfiguration` refines them once the app is up.

Everything else is automatic. Referencing `com.codename1.call.session` links CallKit, registers the Android service, and declares the two Android permissions the ringing notification needs — `POST_NOTIFICATIONS` and `USE_FULL_SCREEN_INTENT`, the second of which Google restricts to calling and alarm apps and which is injected here on the strength of the package you referenced; referencing `com.codename1.call.voip` adds PushKit and the `voip` background mode; referencing `com.codename1.call.directory` generates the iOS Call Directory extension and the Android screening service.

CallKit can't be used in apps distributed in mainland China, and an app that ships it to that storefront is rejected or removed. Codename One can't detect where you intend to publish, so if that applies to you, keep the calling packages out of that build.

Chapter 78. Real-Time Audio and Video

`com.codename1.webrtc` carries live audio and video between two devices: a voice call, a video call, or a camera stream. It's WebRTC, so the media goes directly between the devices when a path exists and is encrypted on the way, with a relay between them when it doesn't.

The package does one thing. It opens the camera and the microphone, sets up the connection and draws the pictures. It doesn't ring, place the call in the system call log or wake a sleeping phone — that's Call Management, which a calling app uses beside this package — and it doesn't signal.

78.1. Signalling is yours

Before two devices can talk they have to exchange a few messages: a description of what each can send and receive, and the network addresses each found for itself. WebRTC defines what those messages say, not how they travel. Codename One creates them and hands them to you, and you carry them to the other side over whatever you already have: your own server, a WebSocket, a push. Nothing in the package sends one for you. That keeps the package free of any particular backend, and means the same call code works whether your server is a Codename One Backend or anything else.

The exchange is the standard one:

1. The caller adds its tracks, creates an offer, sets it as its local description and sends it.
2. The callee sets the offer as its remote description, adds its own tracks, creates an answer, sets it as its local description and sends it back.
3. The caller sets the answer as its remote description.
4. Meanwhile each side sends the other every `IceCandidate` its listener is given, and adds each one it receives.

78.2. A call

`WebRtc.openUserMedia(audio, video, frontCamera)` opens the camera and the microphone, asking for permission where the platform asks, and answers a `LocalMedia` with a `MediaTrack` for each. `WebRtc.createPeerConnection` makes the connection, and a `PeerConnectionConfig` names the STUN and TURN servers it uses to find a path. The listener hears about the candidates to send, the connection's state and the other side's tracks, all on the EDT:

```
if (!WebRtc.isSupported()) {
    return;
}
WebRtc.openUserMedia(true, true, true).ready(media -> {
    PeerConnectionConfig config = new PeerConnectionConfig()
            .addIceServer(IceServer.stun("stun:stun.example.com:3478"))
            .addIceServer(new IceServer(new String[] {"turn:turn.example.com:3478"},
                    "username", "credential"));
```

```
    pc = WebRtc.createPeerConnection(config, new PeerConnection.Listener() {
        public void iceCandidate(PeerConnection connection, IceCandidate candidate) {
            signalling.send(candidate);
        }

        public void stateChanged(PeerConnection connection, String state) {
            if (PeerConnection.FAILED.equals(state)) {
                Log.p("No path to the other side");
            }
        }

        public void remoteTrack(PeerConnection connection, MediaTrack track) {
            if (track.isVideo()) {
                remoteView = new VideoView(track, false);
                form.add(BorderLayout.CENTER, remoteView);
                form.revalidate();
            }
        }
    });
    pc.addTrack(media.getAudio());
    pc.addTrack(media.getVideo());
    form.add(BorderLayout.SOUTH, new VideoView(media.getVideo(), true));

    pc.createOffer().ready(offer -> pc.setLocalDescription(offer)
            .ready(done -> signalling.send(offer)));
});
```

The callee answers with the offer that arrived over your signalling:

```
pc.setRemoteDescription(offer).ready(done -> {
    pc.addTrack(media.getAudio());
    pc.addTrack(media.getVideo());
    pc.createAnswer().ready(answer -> pc.setLocalDescription(answer)
            .ready(sent -> signalling.send(answer)));
});
```

Each candidate that arrives afterward goes into the connection:

```
pc.addIceCandidate(new IceCandidate(sdpMid, sdpMLineIndex, sdp));
```

A candidate can arrive before the description it belongs to, because your channel doesn't promise an order; hold it until the description is set. When the call is over, close the connection and release the media so the camera light goes off:

```
pc.close();
media.release();
if (remoteView != null) {
```

```
    remoteView.release();
}
```

78.3. When the network changes

A phone that moves from Wi-Fi to mobile data loses the path its call was using: the addresses the two sides agreed on no longer reach it. The connection reports `DISCONNECTED`, and the remote video stops on its last frame. Show that state, for example as "Reconnecting…", rather than a frozen picture of a call that still says it's connected. A `DISCONNECTED` connection can recover by itself after a brief loss. If it doesn't recover within a second or two, or it reports `FAILED`, restart ICE:

```
if (PeerConnection.FAILED.equals(state)) {
    pc.restartIce();
    pc.createOffer().ready(offer -> pc.setLocalDescription(offer)
            .ready(done -> signalling.send(offer)));
}
```

`restartIce()` changes nothing by itself. The next offer carries new credentials, the other side answers it as it answered the first, and new candidates flow both ways. Tracks and views stay in place, and the connection reports `CONNECTED` once it finds a new path. Restart from one side only, by convention the caller. If both sides offer at once, neither offer can be answered.

To test it, start a call on Wi-Fi and switch one phone to mobile data, with a running stopwatch in front of the camera so a frozen frame is obvious. In the simulator, `CN.setProperty("platformHint.webrtc.dropNetwork", "true")` drops the path of every connected call until it restarts.

78.4. Tracks and views

A `MediaTrack` is one stream of audio or video, local, or remote. `setEnabled(false)` mutes it: it keeps flowing as silence or black frames, so unmuting is instant and the other side's connection never notices. `switchCamera()` flips a local video track between the front and back cameras. `WebRtc.setSpeakerphone(true)` routes the call's audio to the loudspeaker and `false` returns it to the earpiece or headset.

A `VideoView` draws a video track and is laid out like any other component. Pass `true` as its second argument for your own front camera, which people expect mirrored. Call `release()` when you discard it.

78.5. STUN and TURN

Most connections find a direct path with only a STUN server, which tells a device how the internet sees it. Between two phones on mobile networks that often fails, and the media has to go through a TURN server that relays it. Add both to the configuration with `IceServer.stun(url)` and `new IceServer(urls, username, credential)`. TURN credentials should be short-lived and handed out by your own server per call, rather than built into the app. `setRelayOnly(true)` uses only relayed paths,

so the other side never learns the device's own addresses, at the cost of every call going through the relay.

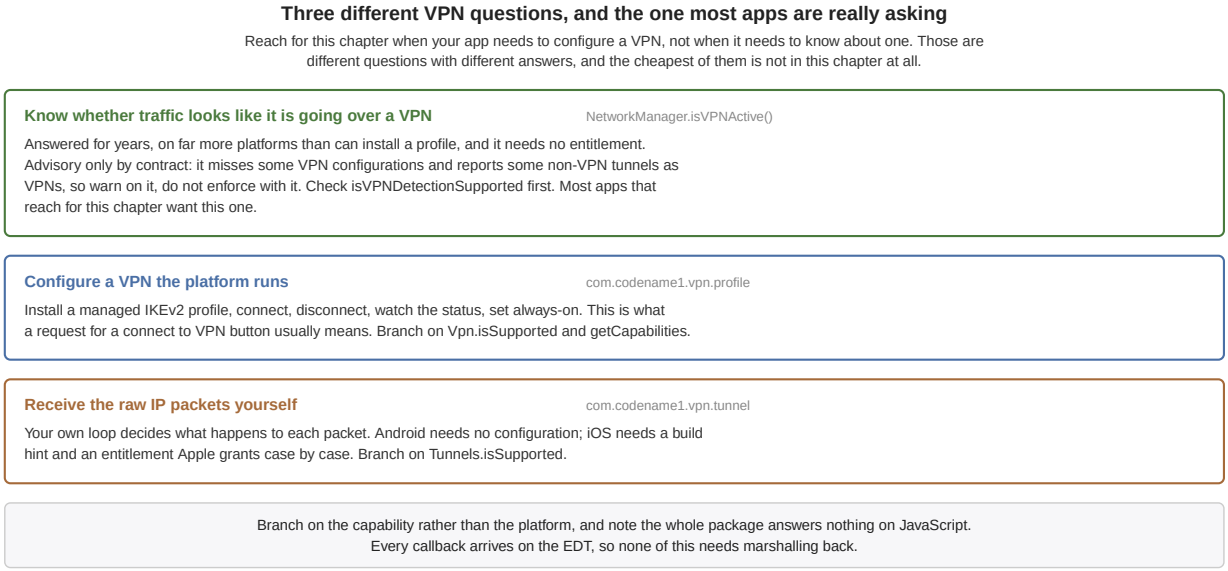
78.6. Platforms

On Android the package is Google's WebRTC library and on iOS the Apple-platform build of the same library. In a browser it's the browser's own WebRTC. Referencing the package is what adds the native library to an Android or iOS build, along with the camera and microphone permissions, so an app that doesn't use it pays for none of that. `WebRtc.isSupported()` says whether the platform can carry media.

The simulator connects calls without carrying any media. Tracks open, descriptions are exchanged and the connection reaches `PeerConnection.CONNECTED`, and each video view shows a test pattern. The whole call flow — signalling, states, screens — can be developed and run on the desktop, but what you hear and see needs two devices.

The Parley sample uses this package, with `com.codename1.call` for the system call screen and a VoIP push, for its voice and video calls: see Section 58.5, "Calls".

Chapter 79. VPN



Two quite separate things are called VPN support, and conflating them wastes a great deal of time.

The first is **asking the operating system to run a standard tunnel** — an IKEv2 configuration the platform implements itself, which your app installs, starts, stops, and watches. That's portable, needs a capability any paid developer account can switch on, and is what almost every app that says "connect to VPN" actually wants. It's `com.codename1.vpn.profile`, and it's what this chapter is mostly about.

The second is **shipping a tunnel of your own** that receives raw IP packets and decides what to do with them. That's `com.codename1.vpn.tunnel`. It runs on Android with no configuration at all, and on iOS behind a build hint and an entitlement Apple grants case by case; the section below covers both, and what to write so the loop you wrote is the loop that runs on either.

Capability	iOS	Android	Simulator and desktop	JavaScript
Install a managed IKEv2 profile	yes	yes (Android 11 and later)	simulated	—
IPsec with a pre-shared key	yes	—	simulated	—
Connect, disconnect, observe status	yes	yes (Android 11 and later)	simulated	—
Always-on / on-demand	yes	yes	simulated	—
A tunnel your app implements	yes (see below)	yes	simulated	—
Detect that some VPN is active	yes	yes	yes	—

Branch on `Vpn.isSupported()` and `Vpn.getCapabilities()` for the managed profile, and on `Tunnels.isSupported()` for a tunnel of your own, rather than on the platform. Every callback arrives on the EDT.

79.1. Detecting A VPN Is A Different Question, And Already Answered

If all you want to know is whether this device's traffic looks like it's going over a VPN, `NetworkManager.isVPNActive()` has answered that for years, works on far more platforms than can install a profile, and needs no entitlement at all. Check `isVPNDetectionSupported()` first, because not every platform implements it.

Its own contract calls the answer advisory: the platform APIs and interface-name heuristics behind it miss some VPN configurations and report some non-VPN tunnels as VPNs. Warn on it, log it, degrade on it — but don't build enforcement on it, because both kinds of mistake are available to it and neither is rare enough to design around.

```
if (NetworkManager.getInstance().isVPNActive()) {
    // traffic is being tunnelled by something
}
```

Reach for this chapter only when your app needs to *configure* a VPN, not when it needs to know about one.

79.2. Installing And Running A Managed Profile

```
if (!Vpn.isSupported()) {
    return;                          // no managed VPN on this platform
}
VpnProfile profile = new VpnProfile("vpn.example.com")
        .protocol(VpnProtocol.IKEV2)
        .remoteIdentifier("vpn.example.com")
        .localIdentifier("alice")
        .usernamePassword("alice", secret)
        .displayName("Acme Corporate");
```

```
Vpn.install(profile).onResult((ok, err) -> {
    if (err instanceof VpnException
            && ((VpnException) err).getError() == VpnError.USER_DECLINED) {
        return;                     // ordinary outcome, not a failure
    }
    if (err == null) {
        Vpn.start();
    }
});
```

Three things about that code are worth spelling out.

The user may be asked, and you can't skip the asking. The platform shows a system prompt when it wants consent, and neither lets an app avoid it. A declined prompt fails with `VpnError.USER_DECLINED`, which is an ordinary outcome and not something to report as an error — the snippet treats it as a normal return.

It isn't a prompt on every install, though. Android asks once and remembers, so replacing a profile in an app the user has already approved goes through with nothing shown. Be ready for the prompt; don't build a flow that depends on it appearing, and don't tell the user a dialog is coming.

One configuration per app. Both platforms give an app a single managed configuration, so `install` replaces whatever was there rather than adding to it.

The platform keeps the secret. A profile read back with `Vpn.load()` describes the configuration but its `getPassword()` is always null, because the password lives in the platform keychain and is never handed back. Use `isPasswordKnown()` to tell a profile built without a password from one that was loaded, where the platform kept it".

Watching the tunnel is a listener, and worth having: it can go down without your app asking.

```
Vpn.addStatusListener(status -> {
    switch (status) {
        case CONNECTING:
            ui.showConnecting();
            break;
        case CONNECTED:
            ui.showConnected();
            break;
        default:
            ui.showOffline();       // it can drop without being asked
            break;
    }
});
```

Note the states aren't decoration either. `CONNECTING` can last as long as a real negotiation takes, and an app that only watches for `CONNECTED` looks frozen for the duration.

79.3. Where The Platforms Disagree

Android needs version 11. `VpnManager` and `Ikev2VpnProfile` arrive in API 30. Codename One doesn't raise your app's `minSdkVersion` for this — a feature that can report itself absent isn't worth cutting off older devices for — so `Vpn.isSupported()` answers false below that and your app needs a path for it.

Android offers IKEv2 only. There is no pre-shared-key IPsec equivalent in the managed profile API. A profile asking for `VpnProtocol.IPSEC` is refused with `INVALID_CONFIGURATION` rather than installed as something else without comment.

Starting isn't the same as connected. On Android the platform accepts the start request and reports nothing further, so a successful `start()` means the request was accepted, not that the tunnel is up. Watch the status.

79.4. A Tunnel Your App Implements

If your VPN speaks a protocol the platforms don't implement — anything that isn't IKEv2 or IPsec — you write the packet loop yourself, in Java, once. Extend `VpnTunnel` and hand it to `Tunnels.start`.

`Tunnels.isSupported()` answers true on Android, true on an iOS build that generated the extension, and false everywhere else — including an iOS build that didn't ask for one, which is every iOS build by default. Ask it, and keep a path for the answer being no: `Tunnels.start` refuses with `NOT_SUPPORTED` rather than pretending.

The addresses in a `TunnelSetup` are read before the platform is asked. An address, a route or a DNS server that isn't an IP literal fails the start with `INVALID_CONFIGURATION`, and the message names the field. A setup with no `address` at all fails the same way, because a link with no address isn't one a platform can establish. That check runs in `Tunnels.start` on every platform, so a setup the simulator accepts is a setup a device accepts.

On Android the tunnel runs inside a `VpnService` in your app's own process. The instance you passed to `Tunnels.start` is the instance that runs, and everything it closed over is still there.

On iOS it runs inside a **Network Extension**: a separate process with its own bundle identifier, its own provisioning profile and a hard memory limit. The build generates that extension for you — a target of its own, carrying a virtual machine, running the class you name in `ios.vpn.tunnel.class`.

The extension is **its own translation**, rooted at your tunnel rather than at your app. That's what makes it possible at all: an app extension compiles with `APPLICATION_EXTENSION_API_ONLY`, and the iOS port's own natives call `UIApplicationMain` and `[UIApplication sharedApplication]`, which an extension may not touch — so a target carrying the application's translation couldn't be built. Rooted at the tunnel it carries what the tunnel reaches, and the application shell is simply not in it.

The extension has no networking stack. It carries the translated program and the virtual machine, and nothing else — so `com.codename1.io.Socket`, `ConnectionRequest` and everything else that reaches `Util.getImplementation()` finds nothing there. ParparVM's `java.net` is URI and URL; there are no sockets in it

> either.
>
> What an iOS tunnel can do, then, is everything that happens **on the device**: see every packet, inspect it, rewrite it, drop it, answer it with `forward`. That covers filtering, local DNS, per-destination decisions and anything else your own code can decide from the packet and from `TunnelSetup.data`.
>
> What it can't do is **relay** to a remote VPN server, because it has no way to open the connection. On Android it can — the tunnel runs in your app's own process, where the implementation is installed — so the same tunnel class is not equally useful on both. Write the relay behind an interface if you need one platform to do it and the other to fall back.
>
> A Mac Catalyst slice reports the tunnel unsupported, and that's deliberate: the extension target is built for the iOS destination only, so the Mac app has no provider to start. `Tunnels.isSupported()` answers false there, and the managed profile in `com.codename1.vpn.profile` still works.

Which turns the advice below into a build error rather than a disappointment. Write the tunnel as though it ran in a process of its own, because it does: no statics you set, no `Display`, no open connections, and the tunnel constructed fresh with none of them — iOS constructs it, so it needs an accessible no-argument constructor. A tunnel that reaches for your app's other classes drags them into this translation, and the ones backed by native code fail the extension's **link**, naming the symbol they wanted. That includes a `NativeInterface` from a cn1lib: the extension carries the translated program and the virtual machine, and nothing the port or a library hand-wrote.

Two things are yours to arrange, and neither is something a build can do for you. Apple grants `com.apple.developer.networking.networkextension` case by case rather than from the developer portal, so setting `ios.vpn.tunnel=true` is you saying you hold it — an App ID without it fails codesigning with an error naming the entitlement and not the reason it appeared.

Both App IDs need it, which surprises people. The extension carries the entitlement because it **is** the provider; the app carries it because `NETunnelProviderManager` — what `Tunnels.start` uses to save the configuration and start the tunnel — is Network Extension API too. Signing only the `.appex` leaves the app unable to start its own tunnel: every attempt fails with a permission error. The build writes the entitlement into both, and refuses before the archive if either profile doesn't grant it.

And the extension signs under its own App ID, `<packageName>.vpntunnel`, so a device archive needs a provisioning profile for that identifier passed as `ios.appext.CN1VpnTunnel.provisioningData` or `.provisioningURL`, exactly as the Call Directory extension does. Override the identifier with `ios.vpn.tunnel.buildSettings.PRODUCT_BUNDLE_IDENTIFIER` if you must; it has to stay inside the app's own namespace, because Apple rejects an embedded extension that isn't.

`TunnelSetup.data` exists for that reason, and the rule worth taking away follows from it:

- Everything the tunnel needs arrives through `VpnTunnel.onStart`.
- Anything it reaches for outside that becomes a static, which works while the tunnel shares the app's process and goes missing the moment it doesn't.

When the iOS half lands it will also need the `com.apple.developer.networking.networkextension` entitlement, which Apple grants case by case rather than self-serve.

79.5. Developing Without Hardware

The simulator and the desktop builds run a simulated configuration store that tunnels nothing, so an install flow, a status screen and a reconnect button can all be built without a device or a server.

A packet tunnel runs there too, over a loopback: `Tunnels.start` calls your `onStart`, packets you feed in reach `onPacket`, and what you `forward` comes back out where a test can read it. The transport is fake and the packet loop is the real one, which is what makes a tunnel testable at all — neither platform lets you run one on a desktop.

Like the call simulation it keeps the awkward orderings: connecting passes through `CONNECTING`, and a profile read back has no password, because a simulation that handed the secret back would let code depend on something no device does.

The **Simulate → VPN** menu scripts the failures:

- **Decline The Next Install Prompt** — the outcome apps routinely treat as impossible.
- **Refuse The Credentials On Connect** — the install and the connection fail in different places for different reasons, and apps commonly handle only the first.
- **Drop The Tunnel** — a tunnel going down without being asked.

Every item is also callable from a test with `CN.execute("vpn:itemN")`.

79.6. Build Hints

Hint	Default	What it does
`ios.entitlements.com.apple.developer.networking.vpn.api`	injected as `allow-vpn`	The Personal VPN capability. Enable it on the App ID or the app won't sign.
`ios.vpn.tunnel`	`false`	Generates the packet tunnel extension. Also your assertion that the App ID holds the Network Extension grant; see above.
`ios.vpn.tunnel.class`	none	Which `VpnTunnel` subclass the extension runs, fully qualified. Required when the hint above is true, and checked against the compiled classes.

Hint	Default	What it does
`ios.appext.CN1VpnTunnel.provisioningData`	none	The extension's own provisioning profile, base64, for a device archive. `.provisioningURL` is the hosted alternative.
`ios.vpn.tunnel.buildSettings.<KEY>`	none	Overrides a build setting on the generated target, as the other extensions' equivalents do.

Referencing `com.codename1.vpn.profile` links `NetworkExtension.framework` and injects the Personal VPN entitlement with no hint at all.

Codename One never injects `com.apple.developer.networking.networkextension` from a class reference. Apple grants it case by case rather than self-serve, and an entitlement an App ID doesn't carry fails codesigning with an error naming the entitlement and not the reason it appeared. That's why the hint exists at all rather than the package alone turning the extension on: the hint is the assertion that both App IDs hold the grant, and it's on that assertion — and only then — that the build writes the entitlement into the app and into the extension.

Android needs no hints. Referencing the package adds the `VpnService`, its `BIND_VPN_SERVICE` declaration and the foreground-service permissions the platform requires to keep a tunnel running.

Chapter 80. Health

Codename One ships a cross-platform health API under `com.codename1.health` that reads and writes the platform health store — HealthKit on iOS and watchOS, Health Connect on Android — summarizes data over time, watches it for changes, records workouts, and streams live measurements from standard Bluetooth health sensors.

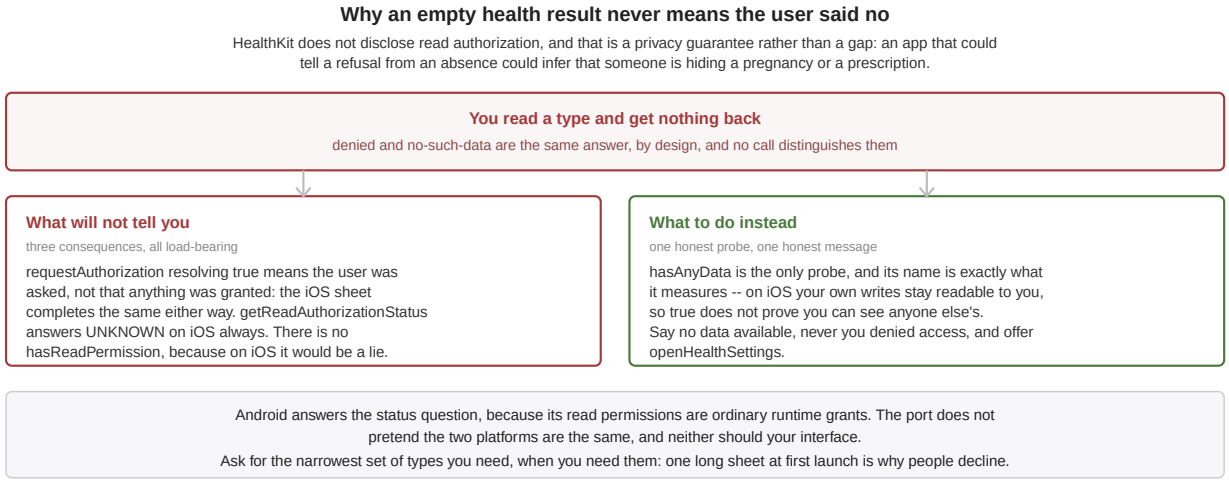
`Health.getInstance()` is the single entry point and never returns `null`: ports without health support return a fallback whose operations fail fast with `HealthError.NOT_SUPPORTED`, so calling code needs no platform-specific `if`.

Every callback — `AsyncResource` results, sensor samples, workout events, change batches — is delivered on the EDT, on every platform. That includes the local-backed ports: the simulator, desktop and JavaScript stores hand results back on the EDT rather than on whichever thread called, so a read started from a worker thread can update the UI from its callback directly, with no `callSerially` of your own. A background change delivery may arrive with no visible UI, after the OS relaunched your app, but it's still on the EDT.

Capability	**iOS 26+**	**iOS < 26**	**watchOS**	**Android**	**Simulator**	**Desktop / JavaScript**
Read samples and aggregates	yes	yes	yes	yes	yes (scripted)	local only
Write samples	yes	yes	yes	yes	yes	local only
Read-authorization introspection	no	no	no	yes	yes	n/a
Background push delivery	**no**	**no**	**no**	**no**	**no**	no
Change delivery while running	yes	yes	yes	yes	**no**	**no**
Live workout session	**recorded**	recorded	**recorded**	recorded	recorded	recorded
Automatic sensor collection in a workout	**no**	no	**no**	no	no	no

Capability	iOS 26+	iOS < 26	watchOS	Android	Simulator	Desktop / JavaScript
Bluetooth health sensors	yes	yes	limited	yes	yes	yes

Subscriptions are the one place the local-backed ports aren't a substitute for a device. `subscribe()` registers, persists its cursor and restores across launches everywhere, but nothing on the local store records a mutation as a change, so `drainChanges()` there resolves with zero and no listener ever fires. Subscription code can be written and its registration exercised on the desktop; whether it actually delivers has to be tested on a phone.



Branch through the capability queries — `Health.getAvailability()`, `HealthStore.isTypeSupported(…)`, `WorkoutManager.isLiveSessionSupported()`, `HealthSubscription.isPushDelivery()` — rather than through platform detection.

80.1. Quick start

```
Health health = Health.getInstance();
HealthAvailability availability = health.getAvailability();
if (availability == HealthAvailability.PROVIDER_NOT_INSTALLED
        || availability == HealthAvailability.PROVIDER_UPDATE_REQUIRED) {
    health.openProviderSetup();
    return;
}
if (availability == HealthAvailability.NOT_SUPPORTED) {
    return;
}
HealthStore store = health.getStore();
store.requestAuthorization(
        HealthAccess.read(HealthDataType.STEPS),
        HealthAccess.read(HealthDataType.HEART_RATE))
     .onResult((asked, err) -> {
         if (err != null) {
             Log.e(err);
             return;
         }
         // asked == true means the user has now been ASKED, not that
         // anything was granted. On iOS the sheet completes identically
         // whether they enabled every switch or none.
     });
```

Check `getAvailability()` before anything else. On Android it distinguishes a working provider from one that's missing or out of date, and both of those are recoverable by the user through `openProviderSetup()`. On the desktop and JavaScript ports it returns `LOCAL_ONLY`, meaning reads and writes work and are durable but the data is only ever your own app's.

80.2. Permissions, and the one thing that will surprise you

You can’t ask whether you are allowed to read.

HealthKit doesn’t disclose read authorization. A read the user denied returns an empty result, indistinguishable from having no data at all, because an app that could tell the two apart could infer that a user is hiding a pregnancy or a prescription. That’s a privacy guarantee, not a gap in this API.

Three consequences follow, and all three are load-bearing:

1. `requestAuthorization(…)` resolving `true` means the user **has been asked**, not that anything was granted. On iOS the sheet completes identically whether they enabled every switch or none of them.
2. `getReadAuthorizationStatus(…)` returns `UNKNOWN` on iOS in every case. Android answers, because its read permissions are ordinary runtime grants; the Android port doesn’t pretend otherwise, and neither should your UI.
3. There is no `hasReadPermission()` anywhere in this API, because on iOS it would be a lie.

```
HealthStore store = Health.getInstance().getStore();

// Write authorization is answerable on both platforms.
HealthAuthorizationStatus write =
        store.getWriteAuthorizationStatus(HealthDataType.BODY_MASS);

// Read authorization is NOT. On iOS this is always UNKNOWN, by design.
HealthAuthorizationStatus read =
        store.getReadAuthorizationStatus(HealthDataType.STEPS);
if (read == HealthAuthorizationStatus.UNKNOWN) {
    // The only honest probe: ask whether any data actually came back.
    store.hasAnyData(HealthDataType.STEPS, HealthTimeRange.lastDays(7))
         .onResult((hasData, err) -> {
             if (err == null && !hasData.booleanValue()) {
```

```
                // Denied OR genuinely empty -- indistinguishable.
                // Say "no data available", never "you denied access".
                Health.getInstance().openHealthSettings();
            }
        });
}
```

`hasAnyData(…)` is the only honest probe, and its name says exactly what it measures. Note also that on iOS your own writes stay readable to you even when read access was denied, so a `true` here doesn't prove you can see other apps' data.

Never tell a user "you denied access" on the strength of an empty result. Say "no data available," and offer `openHealthSettings()`. Getting this wrong produces an app that accuses users of something they didn't do.

Request the narrowest set of types you actually need, at the moment you need them. Both stores present every requested type on one sheet, and a long list at first launch is the most common reason people decline.

80.3. Reading samples

```
SampleQuery query = new SampleQuery()
        .addType(HealthDataType.HEART_RATE)
        .setTimeRange(HealthTimeRange.lastHours(24))
        .setSortDescending(true)
        .setLimit(500);

Health.getInstance().getStore().readSamples(query)
        .onResult((samples, err) -> {
            if (err != null) {
                Log.e(err);
                return;
            }
            for (HealthSample s : samples) {
                QuantitySample hr = (QuantitySample) s;
                // Reading a value forces you to name the unit, which is
                // what removes the whole wrong-unit class of bug.
                double bpm = hr.getValue(HealthUnit.COUNT_PER_MINUTE);
                Log.p(hr.getStartMillis() + ": " + bpm + " bpm");
            }
        });
```

Values always come back in the type's canonical unit unless the query asks for another, so the two ports return identical objects. Reading a number out of a `HealthQuantity` requires naming the unit at the call site — there is no zero-argument `getValue()` — which removes the entire class of bug where pounds are read as kilograms and every downstream chart is wrong by a factor of 2.2.

On Android a limit applies per data type when a query names several: Health Connect pages per

record type, so a limit of ten over two types can return twenty. Query one type per call when the cap has to be exact, which is what iOS does anyway — `HKSampleQuery` reads one type per query.

Always set a limit for high-frequency types. A year of continuous heart rate is on the order of half a million samples; the default cap of 10,000 exists so a naive query can't exhaust the heap, and `readSamplePage(…)` is there for walking more than that.

Health Connect stores a heart-rate series as one record containing many samples, while HealthKit returns many independent samples. `SampleQuery.setFlattenSeries(boolean)` defaults to `true` so both platforms hand back plain `QuantitySample` objects. Turn it off to keep a Health Connect record whole, which is what you want when you intend to delete it: you get one `SeriesSample` carrying the record identifier and every measurement in it. HealthKit has no series records at all, so iOS answers with plain samples whichever way the flag is set. Every flattened measurement still carries its record identifier, so record-level deletion works either way — and `isDeletable(…)` is a separate question from `isWritable(…)`, so the series-shaped types Health Connect won't let you write can still be deleted.

Writing a `SeriesSample` to a phone stores its measurements individually — neither platform accepts a series through this API — so the write result carries one identifier per measurement rather than one for the record. A series is unit-checked and converted exactly like a scalar write, and one longer than the platform's batch limit is split across several calls. Sleep and workout samples can't be written to HealthKit or Health Connect at all; writing one is refused with `TYPE_NOT_SUPPORTED` rather than reported as a success that stored nothing.

Sleep isn't readable on either phone in this release. The iOS type map carries quantity types only, so `HealthDataType.SLEEP` is refused before a query runs, and `SampleQuery.setSleepSessionGapMillis(long)` — which configures the session reassembly that port will eventually need — changes nothing today. Android refuses it too: sleep is absent from the readable type set and the bridge has no record class for it, so a query fails with `TYPE_NOT_SUPPORTED` rather than returning nothing. Sleep works fully against the local and simulator stores, which is where to develop against it for now.

Heart-rate variability is two different statistics with one name. HealthKit stores SDNN, and stored only SDNN until iOS 27 added RMSSD; Health Connect has only ever stored RMSSD. `HealthDataType.HEART_RATE_VARIABILITY_RMSSD` is therefore the cross-platform one and the one to reach for, and it's the first HRV type Android can answer at all — `HEART_RATE_VARIABILITY_SDNN` has no Health Connect record behind it and is refused there with `TYPE_NOT_SUPPORTED`. RMSSD on iOS needs both an iOS 27 device and an application built with the iOS 27 SDK, because the identifier doesn't exist in older SDKs; anything else reports `TYPE_NOT_SUPPORTED` rather than substituting SDNN.

80.4. Aggregates and time buckets

```
AggregateQuery query = new AggregateQuery()
        .addType(HealthDataType.STEPS)
        .addMetric(AggregateMetric.TOTAL)
        .setTimeRange(HealthTimeRange.calendarDays(7, ZoneId.systemDefault()))
        // Calendar days, not a fixed 24 hours: a day is 23 or 25 hours
        // across a daylight-saving transition.
```

```
        .setBucket(HealthInterval.calendarDays(1, ZoneId.systemDefault()));

Health.getInstance().getStore().aggregate(query)
        .onResult((buckets, err) -> {
            if (err != null) {
                Log.e(err);
                return;
            }
            for (AggregateResult bucket : buckets) {
                HealthQuantity total = bucket.get(HealthDataType.STEPS,
                        AggregateMetric.TOTAL);
                if (total == null) {
                    // No data for that day. NOT the same as zero steps --
                    // render a gap rather than a bar at zero.
                    continue;
                }
                Log.p(bucket.getBucketStartMillis() + ": "
                        + (long) total.getValue(HealthUnit.COUNT));
            }
        });
```

Two rules here are easy to get wrong and hard to notice.

A bucket with no data returns `null`, never zero. A day on which no data was recorded and a day on which the user genuinely took no steps are different facts. Substituting zero turns an absence of data into a claim that nothing happened and draws a flat line through every day the phone stayed in a drawer.

Use calendar buckets when your UI labels them with dates. `HealthInterval.calendarDays(1, tz)` follows the calendar; a fixed `86_400_000` doesn't, and drifts against the dates the user sees twice a year at each daylight-saving transition. Calendar intervals require an explicit `TimeZone` — nothing in this API reads the JVM default, because a server-side default of UTC would file a user's evening walk under the wrong day.

Overlapping sources are counted twice, on every platform including iOS. When a phone and a watch both record steps for one walk, a total over them counts the walk twice. HealthKit's statistics engine does de-duplicate overlapping sources, but no port uses it in this release — every metric is computed by shared code from raw samples, so the bucket arithmetic has one implementation rather than one per platform that can drift, and iOS double-counts exactly as Android does. This API leaves that visible rather than papering over it with a heuristic, because guessing which of two overlapping sources is authoritative is exactly the kind of quiet wrongness health data can't afford. Use `addSource(…)` to pin a query to the source you trust, and tell the user which device a figure came from.

80.5. Writing samples

```
QuantitySample weight = QuantitySample.create(
```

```
        HealthDataType.BODY_MASS,
        new HealthQuantity(178.4, HealthUnit.POUND),
        System.currentTimeMillis());
weight.setRecordingMethod(RecordingMethod.MANUAL_ENTRY);

Health.getInstance().getStore().write(weight)
        .onResult((result, err) -> {
            if (err instanceof HealthException
                    && ((HealthException) err).getError()
                            == HealthError.UNAUTHORIZED) {
                Health.getInstance().openHealthSettings();
                return;
            }
            if (result != null && result.hasRejections()) {
                // A batch can partially succeed; surface what was dropped
                // rather than discarding it silently.
                for (String reason : result.getRejections()) {
                    Log.p("rejected: " + reason);
                }
            }
        });
```

Writes are validated before the platform is touched: a type this app can't write, an instantaneous sample of a cumulative type such as `STEPS`, or a quantity whose unit measures the wrong dimension all fail immediately with a message naming the offending sample, rather than as an opaque platform error later. Large batches are chunked automatically to the platform's limit.

Set `RecordingMethod` on what you write. Other apps use it to decide how much to trust a value, and a manually typed weight is a different kind of evidence from one a scale reported.

`HealthSample.getId()` is assigned by the platform, is scoped to this install, and won't survive a reinstall, so don't use it as a primary key on your server. Keep your own identifier in your own storage and correlate on that. `getMetadata()` looks like the natural home for it and isn't: metadata round-trips through the local and simulator stores but isn't written to HealthKit or Health Connect in this release, so on a phone the identifier is gone the moment you read the sample back.

80.6. Background delivery

```
SubscriptionRequest request = new SubscriptionRequest("steps-v1")
        .addType(HealthDataType.STEPS)
        .setIncludeDeletions(true);

HealthSubscription sub = Health.getInstance().getStore()
        .subscribe(request, StepWatcher.class);

if (!sub.isPushDelivery()) {
    // Android: Health Connect never wakes the app. Drain from your
    // background-fetch handler instead of assuming push.
    Display.getInstance().setPreferredBackgroundFetchInterval(900);
```

```
}
```

The subscription id keys the persisted cursor that records how far you have read. Reuse it across launches and app updates and you resume exactly where you left off; change it and the framework treats it as new and resynchronizes from scratch. Hard-code it, and version it explicitly (`"steps-v1"`) if you ever want a clean start.

No platform wakes your app for health data today. `isPushDelivery()` answers `false` everywhere, and that's the honest answer rather than a placeholder: nothing arrives while your app is closed, so your app has to ask.

On Android this is permanent. Health Connect has no push mechanism at all and Google's own guidance is to poll. On iOS, HealthKit does offer `HKObserverQuery` with background relaunch, but this release doesn't register one, so iOS behaves the same way as Android for now. `isPushDelivery()` is the query to branch on; it will start answering `true` on iOS when observers land, and code that already polls will simply poll less often.

Draining is what delivers changes, and your app has to ask for it. Nothing here hooks the application lifecycle: call `drainChanges()` when you come to the foreground, and from your background-fetch handler. Omit it and a subscription delivers nothing at all, however much data arrives. This is the one place where forgetting a call looks exactly like having no new data.

The two backends drain differently, and the difference is visible to you. Android uses Health Connect change tokens, so a drain reports deletions as well as additions and never re-reports a sample you have already seen. iOS re-reads each subscribed type over the window since the last drain: additions arrive, deletions don't, and a sample edited in place looks like a new one. Both advance their cursor only after your listener returns, so a crash re-reads rather than skips.

On iOS a subscription can miss backdated data, and there is no way around it in this release. The cursor is a timestamp, so it finds samples by when they were **measured**, not by when they arrived in the store. A watch that syncs an hour late, or a reading the user types in for yesterday, lands entirely behind the cursor and no later drain will ever see it. HealthKit's own `HKAnchoredObjectQuery` is what solves this — it's ordered by insertion and would fix deletions and edit-detection at the same time — and this release doesn't use it. If your app has to be complete rather than merely current on iOS, do a full `readSamples` over the range you care about on a schedule of your own, and treat the subscription as a prompt to refresh rather than as the source of truth. Android is unaffected: change tokens are insertion-ordered already.

A busy window on iOS can hold more samples than one HealthKit query returns, and HealthKit offers no continuation token. When that happens the cursor advances only as far as the samples actually delivered and the batch reports `hasMore()`, so the next drain picks up the remainder rather than skipping it. Draining more often keeps each window small; a subscription left undrained for weeks will take several drains to catch up.

Handle `isResyncRequired()`. A Health Connect change token expires after 30 days and an iOS anchor can be rejected after a restore from backup; when that happens the batch carries no data and you must do a full time-range read to catch up.

A `HealthBackgroundListener` must be a public top-level class with a public no-argument constructor.

Unlike some older callback APIs in this framework there is **no** need to do anything to keep it from being stripped: the build server scans for implementations and generates a factory that constructs each one with a direct `new`, so shrinking and obfuscation both follow the reference correctly.

80.7. Workouts

```
WorkoutManager workouts = Health.getInstance().getWorkouts();
workouts.startSession(new WorkoutConfiguration()
        .setActivityType(WorkoutActivityType.RUNNING)
        .setLocationType(WorkoutLocationType.OUTDOOR))
    .onResult((session, err) -> {
        if (err != null) {
            Log.e(err);
            return;
        }
        if (!session.isLive()) {
            // Android phones and iOS before 26: the clock and the saved
            // record are real, but nothing is collected unless you feed
            // it -- from a sensor, from location, or by hand.
            Log.p("Recording; connect a strap for heart rate");
        }
        session.start();
    });
```

Two capabilities that are easy to conflate and that this API keeps separate:

- `isLiveSessionSupported()` — the OS runs a real session and keeps the app alive. **False everywhere in this release.** `HKWorkoutSession` exists on watchOS and on iOS 26 and later, and `androidx.health.services` exists on Wear OS, but neither is wired up yet, so every platform currently uses the recorded session described below. Branch on this query rather than on the OS version and your code will pick up native sessions when they land.
- `isSensorCollectionSupported()` — the OS also gathers heart rate and energy into that session by itself. **False everywhere in this release**, for the same reason: the live session is what collects, and there isn't one yet.

The second being false everywhere today, **a workout records only what you feed it**. On an Android phone that isn't a degraded fallback: Health Connect has no live-session concept, and inserting a session, batching your own data and updating it at the end is precisely the flow Google documents. Feed it with `addSamples(…)`, or by attaching a Bluetooth sensor.

`getStatistic(…)` returns `null` rather than a fabricated zero when nothing has been collected. Sessions aren't restored after the process dies — a killed workout is over, `end()` was never called, and nothing is written.

Ending a workout tells you what the platform would not keep. `WorkoutSample.WORKOUT_NOT_PERSISTED` is set when the session record itself has no write form — neither mobile platform accepts one through this API — and `WorkoutSample.SAMPLES_NOT_PERSISTED` names the data types whose samples were refused, comma separated. Power, speed and both cadences are the ones that bite: they're

exactly what a bike or foot pod feeds in, and Health Connect has no single-value write form for any of them. Check both and upload what matters to you; the workout object itself is complete either way.

80.8. Bluetooth health sensors

```
HealthSensors sensors = Health.getInstance().getSensors();
if (!sensors.isSupported()) {
    return;
}
SensorScanSettings settings = new SensorScanSettings()
        .addProfile(HealthSensorProfile.HEART_RATE)
        .setTimeoutMillis(15000);

sensors.startScan(settings, new SensorDiscoveryListener() {
    public void sensorDiscovered(HealthSensor sensor) {
        sensors.connect(sensor, HealthSensorProfile.HEART_RATE,
                new SensorSessionOptions().setAutoReconnect(true))
            .onResult((session, err) -> {
                if (err != null) {
                    return;
                }
                session.addListener(new SensorSampleListener() {
                    public void sensorSample(SensorSession s,
                            HealthSample sample) {
                        Log.p("bpm: " + ((QuantitySample) sample)
                                .getValue(HealthUnit.COUNT_PER_MINUTE));
                    }
                    public void sensorStateChanged(SensorSession s,
                            SensorSessionState state) { }
                    public void sensorError(SensorSession s,
                            HealthException e) { }
                });
            });
    }
    public void scanFailed(HealthException e) {
        Log.e(e);
    }
});
```

`com.codename1.health.sensors` covers the adopted Bluetooth SIG profiles — Heart Rate, Cycling Power, Cycling and Running Speed & Cadence, Health Thermometer, Weight Scale, Blood Pressure and Glucose — so any conforming device works without per-vendor code.

This layer is built entirely on `com.codename1.bluetooth.le` and needs no platform health store, so it works identically everywhere Bluetooth LE does, including the desktop and JavaScript ports where no health store exists at all. It needs **Bluetooth** permissions, not health ones, and the build server makes the same distinction: an app that uses only this package isn't treated as a health-data app and gets neither a HealthKit entitlement nor a Google Play health-permissions review.

Speed and cadence sensors transmit cumulative counters rather than rates, with counters and event timers that wrap every 32 or 64 seconds. The framework differences them for you; hand-rolling that arithmetic is the most commonly botched part of these profiles.

`SensorSessionOptions.setWriteToStore(…)` defaults to `false` on purpose. When the OS is recording heart rate into HealthKit during a workout, a strap that also writes its own samples double-counts in every downstream average. Attach the session to the workout with `setWorkoutSession(…)` instead; turn write-through on for standalone measurements the OS knows nothing about, such as a weight from a scale.

A heart-rate session reports the rate. RR intervals are decoded by `HeartRateMeasurement` but aren't delivered as samples — they're the input to an HRV calculation, not a measurement of it, and no platform has a data type that would store them. If you need HRV, subscribe to characteristic `0x2A37` through `com.codename1.bluetooth.le` and call `HeartRateMeasurement.parse(…)` on the raw value yourself; both are public API.

Blood pressure is the exception: it's two values in one reading, which HealthKit models as a correlation and Health Connect as its own record type, and neither is implemented in this release. A cuff reading routed to the store fails with `TYPE_NOT_SUPPORTED` on both phones rather than being dropped without a word; the local and simulator stores keep it fine. Read it off the session and persist it yourself for now.

80.9. Nutrition

`com.codename1.health.nutrition` logs food and drink as a sparse set of nutrient amounts. A logged apple sets four fields and a scanned packaged food might set thirty; both platforms model this as a record with several dozen optional fields, and `NutritionSample` keeps that sparseness explicit rather than exposing forty nullable getters. A nutrient that was never measured reads back as `null`, not zero — the same distinction aggregate buckets make, and one that matters to someone managing their sodium.

`HealthDataType.NUTRITION` is local and simulator only in this release. Neither the wire format nor either port's type map knows the multi-nutrient record shape, so a read or write of it on a phone is refused with `TYPE_NOT_SUPPORTED` before it reaches the platform rather than being dropped without a word. Individual dietary quantities do reach the phones as ordinary quantity samples — `HYDRATION` on both, `DIETARY_ENERGY` on iOS — so use those when the number has to land in the user's real health store.

80.10. Build configuration

Health data is the most regulated data these APIs touch, and the build is strict about it.

Table 14. iOS build hints

Hint	Effect
`ios.NSHealthShareUsageDescription`	Why your app reads health data. **Required** if you touch the store; the build fails without it.

Hint	Effect
`ios.NSHealthUpdateUsageDescription`	Why your app writes health data. Required if you write.
`ios.health.backgroundDelivery`	Adds the background-delivery entitlement. Inferred from observer usage.
`ios.health.recalibrateEstimates`	Adds the estimate-recalibration entitlement.
`ios.health.required`	Adds `healthkit` to `UIRequiredDeviceCapabilities`.

Table 15. Android build hints

Hint	Effect
`android.health.read`	Comma-separated data types to read. **Required.**
`android.health.write`	Comma-separated data types to write.
`android.health.background`	Adds `READ_HEALTH_DATA_IN_BACKGROUND`.
`android.health.history`	Adds `READ_HEALTH_DATA_HISTORY`.
`android.health.privacyPolicyUrl`	Your privacy policy. **Required.**
`android.health.connectVersion`	Overrides the Health Connect client version.

Codename One **doesn't** inject a placeholder privacy string for health, unlike camera or Bluetooth. Apple reviews health purpose strings against what the app actually does, so a generic placeholder is precisely what gets an app rejected — it would not even achieve the "keeps the build working" goal. The build fails with a message naming the hint instead.

The Android data types can't be inferred. A data type is referenced as a constant, which compiles to a field read, and the build server's class scanner records only type and method references — so the permission set genuinely can't be derived from your bytecode. Declaring it explicitly also matches Google Play policy, which requires you to request exactly what you use. Health Connect additionally raises `minSdkVersion` to 26 and requires `targetSdkVersion` 30 or higher.

HealthKit is entitlement-gated, unlike CoreBluetooth. The `com.apple.developer.healthkit` capability must be enabled for your App ID and present in the provisioning profile you build with, or the build fails at code-signing.

An app that only uses `Health.getSensors()` needs none of this. The sensor layer is built on `com.codename1.bluetooth.le` and touches no HealthKit, so the build injects neither the framework nor the entitlement nor the usage strings, and none of the hints above apply — it needs `ios.NSBluetoothAlwaysUsageDescription` instead. Reaching for the store is what pulls HealthKit in, and it's `getStore()` rather than `Health.getInstance()` that reports a missing usage string, so the sensor-only path stays clear of the whole apparatus.

80.11. Privacy and store policy

Read this section before shipping. Both stores enforce policies that go well beyond the technical

permissions.

Apple. HealthKit data may not be used for advertising or use-based data mining beyond health, fitness and medical research, and may not be shared with third parties without explicit consent for that specific sharing. A privacy policy URL in App Store Connect is mandatory — HealthKit apps are rejected without one. HealthKit data may not be stored in iCloud. Purpose strings must be specific: "Reads your step count to show weekly activity trends," not "Needs health access."

Google. Health Connect access is gated by the Play Console health apps declaration form, and each permission is approved individually. Your app must implement a privacy-policy activity that's shown **before** the permission dialog — Codename One declares it for you, and this isn't optional: Health Connect declines to show its consent dialog to an app that lacks one. Play's Health Apps policy prohibits using the data for ads, for credit, insurance or employment decisions, or transferring it to a data broker.

What Codename One itself does. The framework never uploads health data anywhere. The simulator's event log records data types and counts but never sample values. And the build fails rather than inventing a purpose string on your behalf.

Practical rules. Request the narrowest type set, at the moment of use rather than at launch. Never persist samples to unencrypted `Storage`. Treat the on-device store as the source of truth and avoid server round-trips. Delete health data on account deletion.

Finally, the read-authorization asymmetry is a privacy **feature**, not an obstacle. iOS hides read denial so that an app can't infer what a user is concealing. Design your UI to respect that.

80.12. Simulating health

The simulator ships a scriptable health store under Simulate → Health, and every action is also callable from a test with `CN.execute("health:itemN")`.

Action	Effect
Grant / Deny All Permissions	The permissive and fully denied cases
Grant Write, Deny Read Without Error	Reproduces the iOS trap exactly
Load Demo Dataset (7 days)	Synthetic steps, heart rate, sleep and weight
Emulate HealthKit / Health Connect Permissions	Switches read-denial behaviour
Make Health Unavailable	Emulates a missing provider
`health:item10` / `health:item11`	Arm a one-shot query or save failure

Click "Grant Write, Deny Read Without Error" before you ship. It's the default-adjacent case real users will produce and the one a permissive store never shows you: authorization appears to succeed, the status reads `UNKNOWN`, and every query comes back empty with no error. If your UI shows an error or accuses the user of denying access, it's wrong.

The simulator's data is synthetic and seeded, not recorded from anyone. That's intentional: unlike Bluetooth traces, where the sensitive parts are identifiers that can be scrubbed, the sensitive part of a health sample **is** the value being asserted on, and a resting heart rate together with sleep timing

and step cadence is quasi-identifying.

80.13. Troubleshooting

A query returns empty even though permission was granted. On iOS you can't distinguish a denied read from an empty store — this is by design. Use `hasAnyData(⋯)`, show "no data available," rather than an error, and offer `openHealthSettings()`. Reproduce it in the simulator with "Grant Write, Deny Read Without Error."

The chart shows zero for days the user was active. You are substituting zero for a `null` aggregate. An empty bucket means no data, not no steps.

Totals are double. A phone and a watch are both writing the same type, on iOS as much as on Android — aggregation runs on raw samples in shared code, so HealthKit's de-duplicating statistics engine never sees the query. Pin it with `addSource(⋯)`.

Background delivery never fires. No platform pushes health data to a closed app in this release — see the subscriptions section. Call `drainChanges()` from your background-fetch handler and branch on `isPushDelivery()` rather than assuming.

Replaying stored glucose records isn't implemented. `SensorSession.requestStoredRecords(⋯)` always fails with `NOT_SUPPORTED` in this release. Replay runs over the Record Access Control Point — a stateful protocol on a second characteristic — and shipping it untested against real meters would be worse than saying so. Live glucose notifications work normally.

Sample metadata doesn't reach the phone's health store. `HealthSample.getMetadata()` round-trips locally — the simulator, desktop and JavaScript store — but isn't persisted to HealthKit or Health Connect in this release, so a sample written and read back on a device returns without it. Health Connect has no arbitrary metadata at all, only a single client record id. Keep your correlation identifier in your own storage.

Recorded workouts aren't kept alive on Android. The manifest declares no foreground service, so a recorded workout lives exactly as long as your process does. If you need one to survive backgrounding, keep the app alive yourself.

`BODY_MASS_INDEX` is rejected on Android. Health Connect has no BMI permission or record — BMI is derived, not stored — so the build fails rather than requesting an unrelated body-composition permission on your behalf. Read `BODY_MASS` and `HEIGHT` and compute it. HealthKit does store BMI, so iOS is unaffected.

Deleting a sample by id does nothing. Health Connect deletes by record class plus id, so `HealthDeleteRequest.byId(⋯)` takes the data type alongside the identifier. Naming the wrong type deletes nothing and still reports success.

The weekly chart is off by a day twice a year. You are bucketing by a fixed 24 hours across a daylight-saving transition. Use `HealthInterval.calendarDays(1, tz)`.

The iOS build fails complaining about a usage description. That's intentional — add `ios.NSHealthShareUsageDescription` with text describing what your app actually does with the data.

The Health Connect permission dialog never appears. Health Connect requires the permissions-rationale activity, which Codename One declares only when it detects health usage. Check that the build log mentions the health manifest fragments.

Chapter 81. Smart Home

Codename One ships a cross-platform smart-home API under `com.codename1.home` that reads the accessories in a user's home, reads and writes what they can do, watches them for change, runs scenes, and adds new Matter accessories.

`SmartHome.getInstance()` is the single entry point and never returns `null`: ports without smart-home support return a fallback whose operations fail fast with `HomeError.NOT_SUPPORTED` and whose graph accessors return empty lists, so calling code needs no platform-specific `if`.

Every callback — `AsyncResource` results, change batches, structure events — is delivered on the EDT, on every platform. That includes the desktop, the simulator and the JavaScript port, which marshal rather than answering on whichever thread called, so a read started from a worker thread can update the UI from its callback directly.

81.1. The model

A `HomeStructure` holds rooms (`HomeRoom`) and accessories (`Accessory`). An accessory has one or more services (`AccessoryService`) — a two-gang wall switch is one accessory with two services — and a service exposes traits (`Trait`).

A trait is a canonical capability, not a platform identifier. `Trait.BRIGHTNESS` is the same constant whether the accessory is behind HomeKit or Matter, and the port maps it to `HMCharacteristicTypeBrightness` or to Level Control's `CurrentLevel` for you. No HomeKit characteristic string and no Matter cluster id ever reaches your code.

Graph objects are immutable snapshots. Nothing on an `Accessory` calls into the platform when you read a getter; when the topology moves, a `HomeStructureListener` tells you to call `refresh()` and read the graph again once it completes.

Capability	**iOS / iPadOS**	**watchOS / tvOS**	**Android (default)**	**Android (Home APIs)**	**Simulator / desktop**
Read the accessory graph	yes	yes	**no**	yes	yes (synthetic)
Read and write traits	yes	yes	**no**	yes	yes
Run scenes	yes	yes	**no**	yes	yes
Create scenes	yes	yes	**no**	varies	yes
Live change delivery	yes (foreground)	yes (foreground)	**no**	**no**	**no**
Add a Matter accessory	yes	**no**	yes	yes	yes (synthetic)
Zones	yes	yes	**no**	**no**	**no**

Capability	iOS / iPadOS	watchOS / tvOS	Android (default)	Android (Home APIs)	Simulator / desktop
Automations and triggers	**no**	**no**	**no**	**no**	**no**

Branch through the capability queries — `SmartHome.getAvailability()`, `AccessoryService.supports(…)`, `TraitSubscription.isPushDelivery()`, `Commissioner.isSupported()` — rather than through platform detection.

81.2. Quick start

```
SmartHome home = SmartHome.getInstance();
HomeAvailability availability = home.getAvailability();
if (availability == HomeAvailability.PROVIDER_NOT_INSTALLED
        || availability == HomeAvailability.PROVIDER_UPDATE_REQUIRED) {
    home.openProviderSetup();
    return;
}
if (availability == HomeAvailability.NOT_CONFIGURED) {
    // Authorized, and the user has never set up a home. Sending them
    // to the ecosystem app is the only way forward.
    home.openEcosystemApp();
    return;
}
if (availability == HomeAvailability.COMMISSIONING_ONLY) {
    // The ordinary Android answer: accessories can be ADDED and not
    // read. Say so rather than rendering an empty house.
    Log.p("smart home is add-only on this build");
}
home.refresh().onResult((structures, err) -> {
    if (err != null) {
        Log.e(err);
        return;
    }
    HomeStructure h = home.getPrimaryStructure();
    if (h == null) {
        return;
    }
    for (Accessory a : h.getAccessoriesSupporting(Trait.ON_OFF)) {
        cnt.add(new Label(a.getName()));
    }
});
```

Check `getAvailability()` before anything else. Several of its states are recoverable by the user, and the recovery differs: sending someone to Google Play for a provider update when what they need is to open the Home app helps nobody.

81.3. Android's default answer isn't "available"

This is the one thing worth understanding before you design a screen.

With no extra setup, an Android app can commission a Matter accessory into the user's Google Home and can do nothing else. The graph is empty and no trait can be read or written. `getAvailability()` reports `COMMISSIONING_ONLY`, and that state exists so the word `AVAILABLE` doesn't mean something different on Android than it does on iOS.

Reading and controlling accessories on Android needs the Google Home APIs, which need a Google Cloud project and a Google Home Developer Console registration carrying the SHA-1 of your own signing key. Codename One can't create those on your behalf. That integration isn't in this release; commissioning is.

`SmartHome.getConfigurationProblems()` explains the gap in text aimed at you rather than at your user — log it or show it in a debug screen, and don't put it in front of somebody holding a phone.

81.4. Reading and writing

A read returns one `TraitReading` per requested trait, and **a partial success is the normal case**: three values and one unreachable accessory is a successful read with one failed row, not a failed operation.

```
TraitReadRequest request = new TraitReadRequest()
        .add(thermostat, thermostatService, Trait.CURRENT_TEMPERATURE)
        .add(thermostat, thermostatService, Trait.CURRENT_HUMIDITY);

SmartHome.getInstance().read(request).onResult((readings, err) -> {
    if (err != null) {
        Log.e(err);
        return;
    }
    for (TraitReading reading : readings) {
        if (reading.isFailed()) {
            label.setText("unavailable");
        } else if (!reading.hasValue()) {
            // Not an error, and not zero: the accessory has nothing to
            // report yet. Rendering this as 0 degrees is the bug this
            // check exists to prevent.
            label.setText("no reading yet");
        } else if (reading.getTrait() == Trait.CURRENT_TEMPERATURE) {
            label.setText(reading.getValue()
                    .getDouble(TraitUnit.CELSIUS) + " C");
        }
    }
});
```

Note the three-way branch. A reading can carry a value, carry an error, or carry neither — and the

third is the one that catches people. An accessory can legitimately have nothing to report: a sensor that hasn't measured yet, a light in white mode that has no meaningful hue. Nothing in this API substitutes a zero for a measurement that was never taken, so `hasValue()` has to be asked.

Writing is the mirror image, and a batch write partly succeeding is equally normal — "turn off every light" against a home with one dead bulb mostly worked.

```
AccessoryService svc = lamp.getPrimaryService();
TraitConstraint dimming = svc.getConstraint(Trait.BRIGHTNESS);

// The accessory's own range, not the trait's nominal 0..100. A slider
// built from the wrong one offers values the lamp refuses -- and a
// refused write is an error rather than a silent clamp.
Slider slider = new Slider();
slider.setMinValue((int) dimming.getMinimum());
slider.setMaxValue((int) dimming.getMaximum());

SmartHome.getInstance()
        .write(new TraitWrite(lamp, svc, Trait.BRIGHTNESS,
                TraitValue.of(slider.getProgress(), TraitUnit.PERCENT)))
        .onResult((result, err) -> {
            if (err != null) {
                Log.e(err);
            } else if (!result.isApplied()) {
                Log.p("the lamp refused: " + result.getError());
            }
        });
```

Build controls from the accessory's own `TraitConstraint` rather than from the trait's nominal range. A dimmer whose floor is 10 percent says so there, and writing below the floor is **refused rather than clamped**: an app that asked for 5 percent and got 10 percent without being told never learns it was wrong.

81.5. Values and units

`TraitValue` is one type with kind-checked getters rather than a class per trait. There's no zero-argument `getDouble()` on purpose: `getDouble(TraitUnit)` makes you name the unit you expect and refuses a cross-dimension request, which is what stops a Celsius setpoint being rendered as Fahrenheit.

Everything proportional is normalized to a percentage, so Matter's 0-254 level control and 0-10000 covering position never reach your code. Color temperature is in mireds, because that's what both platforms use natively — and remember that **a higher mired value is a warmer light**. `TraitValue.getColorTemperatureKelvin()` converts if you would rather think in Kelvin.

Where a mapping is lossy, `TraitValue.getRawPlatformValue()` carries the platform's own ordinal alongside the canonical one. Air quality has six levels on HomeKit and seven on Matter; the canonical enum follows Matter and the raw value is there for an app that needs to be exact.

81.6. Watching for change

Nothing wakes your app for an accessory change. HomeKit delivers changes only while your app is running in the foreground, and the Google Home APIs need a live signed-in client — the home hub, not your app, is what reacts to a sensor while the phone is asleep.

```
TraitReadRequest resync = new TraitReadRequest()
        .add(lamp, lamp.getPrimaryService(), Trait.ON_OFF)
        .add(lamp, lamp.getPrimaryService(), Trait.BRIGHTNESS);
SubscriptionRequest request = new SubscriptionRequest()
        .add(lamp, lamp.getPrimaryService(), Trait.ON_OFF)
        .add(lamp, lamp.getPrimaryService(), Trait.BRIGHTNESS)
        .setDeliverInitialValues(true);

TraitSubscription subscription = SmartHome.getInstance()
        .subscribe(request, batch -> {
            if (batch.isResyncRequired()) {
                // Changes were missed, so everything not in this batch
                // is stale. Ignoring this leaves a screen showing
                // values from before the gap, indefinitely.
                SmartHome.getInstance().read(resync);
            }
            for (TraitReading reading : batch.getReadings()) {
                label.setText(String.valueOf(reading.getValue()));
            }
        });

if (!subscription.isPushDelivery()) {
    // Everywhere except HomeKit in the foreground. Without a drain the
    // listener never fires, which looks exactly like a sensor that
    // never triggers.
    SmartHome.getInstance().drainChanges();
}
```

Ask `isPushDelivery()` rather than assuming. Where it answers `false`, which is everywhere except HomeKit in the foreground, the listener fires only when you call `drainChanges()`. Wire that into the point where your app comes to the foreground.

Within a subscription's window, changes are coalesced per accessory, service and trait, keeping only the newest value — so dragging a dimmer produces one reading showing where it ended up rather than forty showing the journey. A batch is a state update, not an event log.

Hold on to the `TraitSubscription` and stop it. A dropped one keeps its listener reachable and keeps the platform delivering.

81.7. Scenes

A scene is a named set of accessory states that can be applied in one go: HomeKit's action set, a

Google Home scene. `TraitWrite.toSceneAction()` turns the changes a user just made into one.

Automations — a scene plus a trigger — **aren't supported**. HomeKit, Google Home and Matter model triggers in three incompatible ways and Matter has none, so there's no honest common shape. `SmartHome.isAutomationSupported()` answers `false` everywhere, so an app can say why the feature it wanted isn't offered.

81.8. Adding an accessory

```
Commissioner commissioner = SmartHome.getInstance().getCommissioner();
if (!commissioner.isSupported()) {
    commissioner.openEcosystemApp();
    return;
}

// Validated here, in your own words, rather than failing inside the
// operating system's sheet with wording about the app.
SetupPayload payload;
try {
    payload = SetupPayload.parse(scannedCode);
} catch (IllegalArgumentException badCode) {
    label.setText(badCode.getMessage());
    return;
}

commissioner.commission(new CommissioningRequest()
                .setSetupPayload(payload)
                .setSuggestedName("Kettle"))
        .onResult((result, err) -> {
            if (err != null) {
                Log.e(err);
                return;
            }
            if (result.wasCommissionedToThisApp()) {
                SmartHome.getInstance().refresh();
            } else {
                // Added to the user's home, and this app cannot
                // address it. Say that, rather than showing an empty
                // device screen.
                label.setText("Added " + result.getAccessoryName()
                        + " to your home");
            }
        });
```

Two things about this flow.

The interaction isn't yours. Both mobile backends hand it to an operating-system sheet, and the user may be several minutes — they have to power the accessory on, hold a button, sometimes join it to Wi-Fi. There's no progress reporting. Don't put a short timeout or a determinate progress bar

behind it.

Success doesn't always mean you got a device. `wasCommissionedToThisApp()` is the difference between "the accessory was added to the user's home" and "your app can address it." On Android with Play services alone the answer is the former: you're told the name and nothing more. On iOS it's the former too — Apple's sheet reports that the flow finished without saying what was added or which home it went to — so refresh the graph and look at what's new. An app that assumes otherwise shows a "your new device" screen with nothing on it.

`SetupPayload.parse()` validates a scanned QR or typed manual code in pure Java before any of that starts, so a mis-scanned sticker gets a message in your wording rather than an opaque failure inside the OS sheet.

81.9. Build hints

```
# iOS: required as soon as your app touches accessories. The build FAILS
# without it, deliberately -- iOS terminates an app that reaches HomeKit with
# no usage description, and Codename One will not invent privacy copy in your
# name.
codename1.arg.ios.NSHomeKitUsageDescription=Controls the lights and locks in your home

# Optional. Opt out of the generated Matter add-device extension target.
codename1.arg.ios.home.commissioning=false

# Optional. The app group the extension and the app share; defaults to
# group.<your.package.name>.
codename1.arg.ios.home.appGroup=group.com.example.myapp

# Optional. Refuse to install on a device without HomeKit.
codename1.arg.ios.home.required=true
```

Everything else is automatic, and automatic in both directions: an app that never references `com.codename1.home` gets no HomeKit framework, no entitlement, no Play services dependency and no extra Xcode target. The build server decides by scanning your bytecode.

Two consequences worth knowing:

- The `com.apple.developer.homekit` entitlement is added only when your app actually touches accessories. An app that only calls `getAvailability()` links HomeKit and gets no entitlement — which matters, because that entitlement has to be enabled on your App ID and signing without it fails. If your app does touch accessories, enable HomeKit for your App ID in the Apple developer console and regenerate your provisioning profile; the build checks and tells you if you haven't.
- Commissioning is separated because on iOS it costs an entire generated app-extension target. That's why `com.codename1.home.commissioning` is its own package: referencing the package is what asks for the extension.

81.10. Previewing in the simulator

The simulator, the desktop ports and the JavaScript port run a local simulated house rather than reporting themselves unsupported. It's awkward rather than tidy on purpose — a two-gang switch, a bridged pair of lights behind a hub, an unreachable socket, a thermostat in auto mode where `TARGET_TEMPERATURE` genuinely has no value, and a dimmer with a real floor — because those are the shapes that break naive code.

It also doesn't push changes and never completes an operation inline, matching what a real backend does. Code written against a store that answers instantly races the moment it meets one that doesn't.

81.11. Not claimed in this release

Stated plainly, because each of these has a query that answers rather than a silence:

- **Automations, triggers and conditions.** Scenes only.
- **Background accessory events.** Nothing wakes your app; see `isPushDelivery()`.
- **Topology writes.** Creating homes, renaming rooms, moving accessories between rooms, inviting users. The graph is read-only.
- **Cameras and video.** A camera is visible in the graph and there's no stream, snapshot or recording API.
- **Security systems and alarm panels.** Matter has none in shipping releases, and a half-working alarm API is a safety problem rather than a feature gap.
- **Matter events.** Only attributes, which is why `LockState.JAMMED` is unreachable outside HomeKit — a jam is an event on Matter and an attribute on HomeKit.
- **Energy, appliance and diagnostic clusters.**
- **The Google Home APIs accessory graph on Android.** See above.

And one structural point: by default Codename One isn't a Matter controller. There's no fabric of its own, no direct on-network commissioning and no Thread border-router interaction. Everything Matter goes through the operating system's ecosystem, so the Apple Home or Google Home app has to be installed and set up.

81.12. Commissioning onto your own fabric

`CommissioningRequest.setCommissionToThisApp(true)` asks for one thing more: that the accessory also join a Matter fabric your app owns, as a second administrator beside the user's home. On iOS the generated commissioning extension then carries Apple's own Matter stack, a fabric key it keeps in the keychain and the controller storage that fabric persists through — so the build sees the call and switches that machinery on. Set `codename1.arg.ios.home.commissioning.fabric=true` if your call is somewhere the class scanner can't see, such as behind reflection, and `codename1.arg.ios.home.commissioning.vendorId` to your own Matter vendor id — the default is the test vendor `0xFFF1`, which some accessories refuse.

Apple's Matter framework starts at iOS 16.4, so an own-fabric extension is built for 16.4 while your app keeps the 16.1 floor MatterSupport asks for. On 16.1 through 16.3 the extension can't load, and `Commissioner.getStyle()` answers `ECOSYSTEM_APP_HANDOFF` there rather than `OS_OWNED_UI` — the accessory is added in the Home app, exactly as in a build with no extension. Ask for the style before you offer the button and that difference is invisible to your user.

Read the generated `CN1MatterSetup/RequestHandler.swift` before you turn it on. The implementation ships in every commissioning build, commented out, precisely so that what you enable is code you have read.

What it doesn't buy you is a way to talk to the accessory over that fabric: Codename One has no API for that yet, and reads and writes still go through the ecosystem. What it buys is that the accessory is already commissioned when such an API arrives, and that `CommissioningResult.wasCommissionedToThisApp()` can be true. Android's Play Services commissioning can't do it at all, and ignores the request.

Chapter 82. Printing

Codename One can hand a document to the platform printing system through the `com.codename1.printing` package. The API shows the native print dialog where the user picks a printer, adjusts options and confirms the job. It works on iOS (AirPrint), Android, desktop builds, the simulator, Windows and the JavaScript port.

The document is a file in `FileSystemStorage` identified by its path and mime type. Every printing platform accepts PDF (`application/pdf`) and common image types (`image/png`, `image/jpeg`).

82.1. Quick start: Print a PDF

`Printer.printPDF(path, listener)` is shorthand for `Printer.print(path, "application/pdf", listener)`. Use the general `print` variant for other document types, for example `Printer.print(photoPath, "image/jpeg", listener)`.

Gate the call on `isPrintingSupported()`. When it returns `false` the listener receives a `FAILED` result without any UI appearing, so an unguarded call does no harm, but a well-behaved app hides or disables its print button instead.

82.2. Printing images

`Printer.printImage(image, listener)` prints a `com.codename1.ui.Image` directly. The image is encoded to a temporary PNG file behind the scenes and the file is deleted once the print flow finishes:

```
Image chart = renderChart();   // your own drawing code
Printer.printImage(chart, result -> {
    if (result.isFailed()) {
        ToastBar.showErrorMessage("Print failed: " + result.getError());
    }
});
```

This pairs well with drawing on a mutable image, so you can compose a printable page (a receipt, a ticket, a chart) with the standard `Graphics` API and send it to paper without generating a PDF.

82.3. Handling the result

The listener receives a `PrintResult` on the EDT, exactly once per request. The listener may be `null` for fire-and-forget printing. There are three statuses:

- `COMPLETED` – the job was handed to the platform printing system. Most platforms can't observe the physical printer, so this means "queued/sent," not "paper came out."
- `CANCELLED` – the user dismissed the print dialog without printing, on platforms that can observe the dialog outcome.
- `FAILED` – the job couldn't start or the printing system reported an error. `getError()` may carry a short platform message.

Cancel detection is best-effort. iOS, Windows, PDF printing on Android and image printing in the simulator report `CANCELLED` reliably. Image printing on Android, PDF hand-off on the desktop and the browsers report `COMPLETED` once the job is posed, since their printing pipelines don't expose the user's choice.

82.4. Permissions and the user gate

Printing requires no permission, entitlement, manifest entry or build hint on any platform. This is safe because printing is always user-confirmed: the API can only pose the native print dialog, and nothing reaches a printer until the user approves the job there. In that sense it follows the same trust model as the share API.

Silent printing - sending a job to a preselected printer without showing a dialog - isn't supported by design.

Device policy can disable printing entirely, for example a managed Android work profile with the printing restriction or an iOS MDM profile that blocks AirPrint. Those cases surface as `isPrintingSupported()` returning `false` or as a `FAILED` result, so the result-handling code above covers them.

82.5. Platform notes

- iOS – `UIPrintInteractionController` presents the AirPrint sheet; on the iPad it appears as a popover. The completion handler reports completed, cancelled or failed.
- Android – the `android.print` framework. PDFs stream through a `PrintDocumentAdapter`; images go through the support library `PrintHelper`, which reports completion but can't observe cancellation. Printing requires a foreground activity, so calls from background mode fail.
- Desktop / simulator – images print through `java.awt.print.PrinterJob` with the native dialog; PDFs are handed to the operating system's default PDF print flow.
- Windows (native port) – the Win32 print dialog with GDI rendering; PDF pages render through the `Windows.Data.Pdf` API at the printer's resolution.
- JavaScript – the document loads into a hidden frame and prints through the browser's print dialog. Browsers don't report whether the user printed or cancelled, and PDF behavior varies with the browser's built-in viewer.

82.6. Trying it in the simulator

The `PrinterSample` in the samples project demonstrates both flows: it prints a generated image and downloads a small PDF to print. On the desktop the native print dialog of your operating system appears, which makes it a convenient way to test result handling - print to a file or preview instead of paper.

Chapter 83. Deep-Link Routing

Codename One can dispatch a deep link — an iOS Universal Link, an Android App Link, a custom-scheme URL, a push-notification payload, or anything else the platform delivers as a URL — to a specific `Form` by class or by static factory method. The same route table powers in-app navigation through `Navigation.navigate("/path")`, so the application chooses declarative or imperative per call site without maintaining two parallel maps.

The application surface is two annotations plus a tiny `Navigation` class — five static methods and one value type.

83.1. Declare a route

Annotate the target `Form` class:

```
@Route("/users/:id")
public class ProfileForm extends Form {
    public ProfileForm(@RouteParam("id") String id) {
        setTitle("Profile " + id);
        // null
    }
}
```

Or annotate a static factory method:

```
public class Routes {
    @Route("/home")
    public static Form home() {
        return new HomeForm();
    }

    @Route("/users/:id")
    public static Form profile(@RouteParam("id") String id) {
        return new ProfileForm(id);
    }
}
```

Both forms are supported and a project can mix them. Path variables in the pattern (`:id`, `*`) are matched by name against parameters annotated with `@RouteParam`. Missing `@RouteParam` on a path-variable parameter fails the build.

83.2. Path syntax

Pattern	Matches	Bound
`/about`	`/about`	—

Pattern	Matches	Bound
`/users/:id`	`/users/42`	`id = "42"`
`/files/*`	`/files/photo.png` (one segment)	`* = "photo.png"`
`/files/**`	`/files/a/b/c` (catch-all)	`* = "a/b/c"`

Query string parameters are bound the same way as path variables. The build prefers a path-variable match for a given name and falls back to the query string when the pattern doesn't include that name.

83.3. Navigate from app code

The `Navigation` class is the imperative counterpart to `@Route`. Calling `Navigation.navigate("/users/42")` from anywhere in the app resolves the URL through the same generated route table that handles incoming deep links, builds the matching `Form`, pushes it onto the navigation stack, and shows it.

The five-method surface (`navigate`, `back`, `getCurrent`, `getStack`, `popTo`) is everything the application sees — the rest of the URL-to- form machinery is generated. Applications that prefer raw `new MyForm().show()` keep working unchanged; only URL-driven calls update the `Navigation` stack.

83.4. How it works

Codename One scans the project's compiled bytecode at build time and generates an internal dispatcher class from every `@Route` declaration. The dispatcher is bound into the per-platform application stub before `Display.init(…)`, so deep links delivered during launch see the route table immediately. The validation gate catches every problem in a single build run:

- `@Route` declared on a class that doesn't extend `Form`
- Pattern with no leading `/` or empty value
- Path variable with no matching `@RouteParam` on the constructor / factory
- Duplicate pattern declared on two different targets
- `@Route` on an abstract class or non-`public static` method

83.5. iOS Universal Links

Host an `apple-app-site-association` JSON file at `https://your.domain/.well-known/apple-app-site-association` over HTTPS without redirects. The plugin's `AasaBuilder` produces the payload:

```
{
  "applinks": {
    "details": [
      {
        "appIDs": ["ABCDE12345.com.example.app"],
        "components": [
          { "/": "/users/*" },
```

```
          { "/": "/promo/*" }
        ]
      }
    ]
  }
}
```

Tell iOS which domains your app claims by setting the `ios.associatedDomains` build hint — a comma-separated list of `applinks:` entries. The iOS builder writes the Associated Domains entitlement so the resulting `.ipa` is signed for those domains automatically.

```
codename1.arg.ios.associatedDomains=applinks:example.com,applinks:www.example.com
```

83.6. Android App Links

Host an `assetlinks.json` file at `https://your.domain/.well-known/assetlinks.json`. The plugin's `AssetLinksBuilder` produces the payload:

```
[
  {
    "relation": ["delegate_permission/common.handle_all_urls"],
    "target": {
      "namespace": "android_app",
      "package_name": "com.example.app",
      "sha256_cert_fingerprints":
["14:6D:E9:83:C5:73:06:50:D8:EE:B9:95:2F:34:FC:64:16:A0:83:42:E6:1D:BE:A8:8A:04:96:B2:3F:CF:44:E5",
"7B:5A:1F:C9:0E:52:44:7C:82:19:6E:38:0A:B7:D4:11:5C:63:9F:28:E1:47:8B:30:A6:C2:5D:94:F0:6B:38:19"]
    }
  }
]
```

Tell Android which URLs to intercept by setting the `android.xintent_filter` build hint. The Android builder injects the value into the manifest verbatim, so it's the whole `<intent-filter>` element, with `\n` for the line breaks:

```
codename1.arg.android.xintent_filter=<intent-filter android:autoVerify="true">\n  <action
android:name="android.intent.action.VIEW"/>\n  <category android:name="android.intent.category.DEFAULT"/>\n  <category
android:name="android.intent.category.BROWSABLE"/>\n  <data android:scheme="https" android:host="your.domain"
android:pathPrefix="/users"/>\n</intent-filter>
```

Three parts of that carry weight. `android:autoVerify="true"` is what makes Android fetch the `assetlinks.json` above at install time and route the link straight into your app. Leaving it out doesn't fall back to an app chooser: from Android 12 onward an unverified web link goes to the default browser, and your filter never sees it until the user turns the association on by hand under **Settings** > **Apps** > **Open by default**. The `<data>` element needs `android:scheme="https"` and the host, and narrowing it with `android:pathPrefix` keeps the app from claiming every URL on the domain. And the hint holds one value, so an app that also registers a custom scheme puts both `<intent-filter>` elements in the same string rather than setting the hint twice.

The SHA-256 fingerprint comes from `keytool -list -v -keystore …`, or from the Play Console under **Setup** > **App integrity** when using Play App Signing.

83.7. Testing

83.7.1. iOS Simulator

```
xcrun simctl openurl booted "https://example.com/users/42"
```

83.7.2. Android Emulator

```
adb shell am start -a android.intent.action.VIEW \
    -d "https://example.com/users/42" com.example.app
```

83.7.3. Desktop Simulator

Pass `--cn1-arg=https://example.com/users/42` on the run command, or use the simulator's URL-injection helper.

83.8. Back-press guard

Independent of deep linking, individual forms can intercept back / pop attempts so they can confirm before discarding unsaved work:

```
editForm.setPopGuard(new PopGuard() {
    public boolean canPop(Form form, PopReason reason) {
        if (!isDirty()) {
            return true;
        }
        // Discard is the ok command, so it returns true and the pop
        // proceeds. The back key fires the cancel command, which means
        // dismissing this dialog keeps the user on the form.
        return Dialog.show("Discard changes?", "You have unsaved edits.",
                           "Discard", "Stay");
    }
});
```

The guard fires for the toolbar back button, the Android hardware back key, the iOS edge-swipe gesture, and any programmatic back navigation. `PopReason` distinguishes the trigger so a guard can be selective.

Chapter 84. State Restoration and Continuity

An app that's put in the background isn't paused. Android reclaims the process routinely, iOS terminates a suspended app whenever it needs the memory, and in both cases what comes back isn't the app the user left — it's a fresh launch that happens to be wearing the same icon. The user sees their work replaced by the home screen and has no idea why.

`com.codename1.continuity` saves what the user was doing and brings it back. On Apple platforms it does one thing more: it offers that same work to the other devices the person is signed in to, so a draft begun on the phone can be finished on the iPad they pick up.

The two halves cost different things, so they're two packages. `com.codename1.continuity` holds the framework and everything that carries work to a device the user is holding. `com.codename1.continuity.sync` holds a small key/value store the platform keeps in step across their devices, and referencing it earns an iOS build an entitlement. An app that wants the first shouldn't have to arrange the second.

Capability	iOS and macOS	Android	Simulator and desktop	JavaScript
Restore after the process is killed	yes	yes	yes	yes
Restore the `@Route` screen stack	yes	yes	yes	yes
Carry on where they left off, on a device they're holding	yes	—	simulated	—
A key/value store synced across devices	yes (`com.codename1.continuity.sync`)	—	simulated	—
Carry state to any other device	your `StateRelay`	your `StateRelay`	your `StateRelay`	your `StateRelay`

Branch on the capability queries — `Continuity.isSupported()`, `Continuity.isContinuationSupported()`, `SyncedStore.isSupported()` — rather than on platform detection. The first row is the one that matters most and it's supported everywhere, because it's pure storage with no platform behind it.

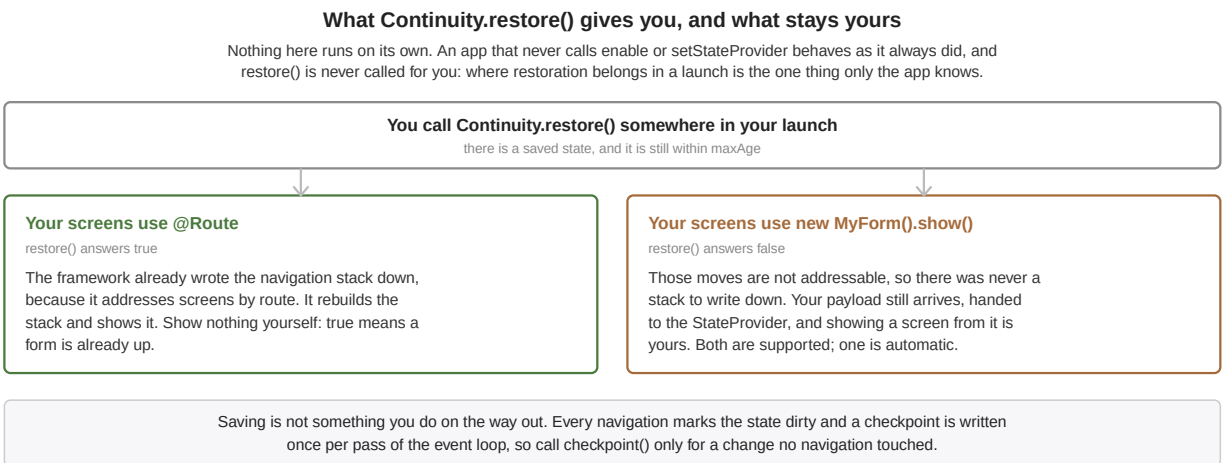
Every callback in this family arrives on the EDT.

84.1. Six Things Worth Knowing Before You Design Around This

Nothing happens until you ask for it. An app that never references this package behaves exactly as it always did, and so does one that references it and never calls `Continuity.setStateProvider` or

`Continuity.enable`. `Continuity.restore()` is never called for you either. Where restoration belongs in a launch is a decision only the app can make, and a framework that guessed would be wrong for the apps that care most.

The route stack is free; everything else is yours. If your screens are declared with `@Route`, the framework already knows the navigation stack and restores it with no code from you. If your app navigates with `new MyForm().show()`, those moves aren't addressable and there's nothing to write down — so `restore()` hands your payload to the `StateProvider` and answers `false`, leaving you to show a screen. Both are supported; only the first is automatic.



Saving happens continuously, not at shutdown. Every navigation marks the state dirty and a checkpoint is written once per pass of the event loop, so by the time the operating system suspends the app the work is already done. Don't look for a place to save on exit; there isn't one worth using. Android blocks its own main thread until your `stop()` returns, so an app that did its saving there would pay for it on every suspend. Call `Continuity.checkpoint()` after changing something your provider reports that no navigation touched.

A payload has to survive leaving the device. It's written to disk, handed to an operating system, and possibly delivered to a different device running a different build of your app — so it admits only `String`, `Integer`, `Long`, `Double`, `Boolean`, and `List` and `Map` of those. Anything else is refused where you produced it, with a message naming the key, rather than becoming a value that stops arriving on the other end with nothing to say so.

Codename One runs no relay server. Continuation between Apple devices is the platform's; anything else — iPhone to Android, two devices that are never in the same room — goes through a `StateRelay`, which is your endpoint. That isn't a gap to be filled later. Deciding which saved states belong to the same **person** is your account system's question, and a framework that answered it would be guessing about your users.

A continuation isn't secure storage. What you put in the payload crosses to another device and is held by the operating system on the way. Tokens, keys and anything you would not want restored on a device that merely shares an account belong in `com.codename1.security.SecureStorage`, with the payload carrying at most an identifier that means nothing on its own.

84.2. Saving and restoring

Two pieces. A `StateProvider` supplies the half the framework can't work out — the scroll position, the half-typed message, the record being edited — and installing one turns the framework on:

```
public void init(Object context) {
    Continuity.setStateProvider(new StateProvider() {
        public Map<String, Object> saveState() {
            Map<String, Object> state = new HashMap<String, Object>();
            state.put("draft", draftField.getText());
            return state;
        }

        public void restoreState(Map<String, Object> state) {
            draftField.setText((String) state.get("draft"));
        }
    });
}
```

Then `start()` reads as "restore, or else begin":

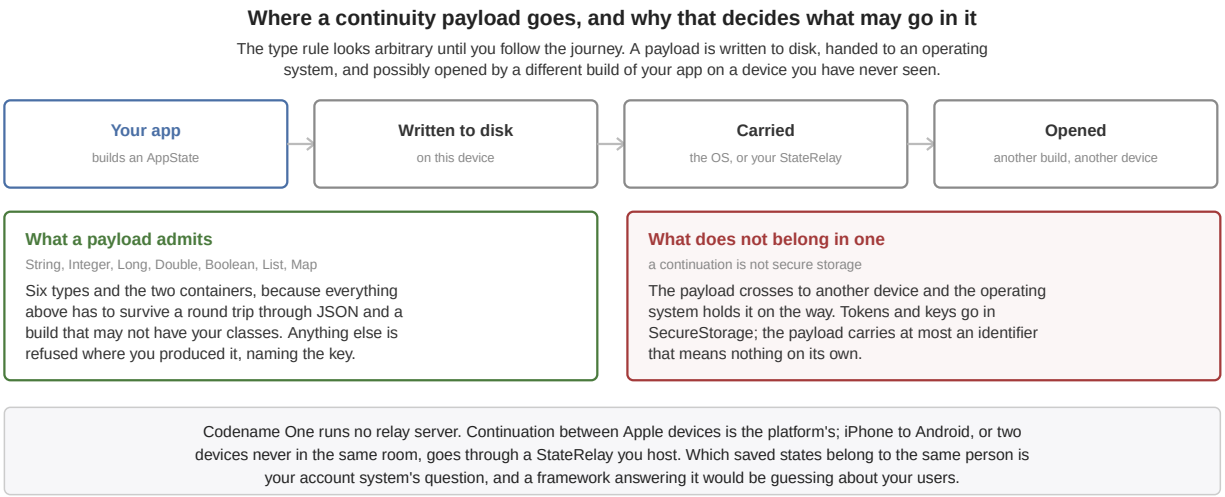
```
public void start() {
    if (!Continuity.restore()) {
        Navigation.navigate("/home");
    }
}
```

`restore()` returns `true` when it put a screen up, so the caller knows not to show its own. It returns `false` when there was nothing to restore **and** when the state carried no routes — the payload-only case above — which is why the fallback branch belongs there rather than behind a null check.

`restoreState` runs before the restored screens are built, so a form the route table is about to construct can read what the provider stashed while that form is being built.

Take a checkpoint by hand after a change no navigation followed:

```
public void onDraftSaved() {
    Continuity.setTitle("Draft to Dana");
    Continuity.checkpoint();
}
```



The title is what a receiving device may show the user before they accept, so it should name the work rather than the screen — `Draft to Dana`, not `Compose`.

By default a saved state never expires, because an app the user opens after a month should still come back where they left it. Where coming back is only meaningful for a while — a checkout, a booking hold, a queue position — say so:

```
public void expireACheckout() {
```

```
    Continuity.setMaxAge(15 * 60 * 1000);
}
```

84.3. Continuing on another device

Nothing extra is required for the Apple case. Every checkpoint advertises the current state, and a device the user is holding is offered it by the system. What you may want is to say so in the interface, which is what the capability query is for:

```
public void describeWhatThisDeviceCanDo() {
    if (Continuity.isContinuationSupported()) {
        showBanner("Open this app on your other device to carry on there.");
    }
}
```

An arriving state is restored automatically. When moving the user is a decision your app should make — they're midway through a payment, or the state belongs to a different account than the one signed in here — take it yourself. A listener that returns `false` has consumed the state: nothing is restored and no other listener is asked, which is what makes holding it and asking work:

```
public void askBeforeMovingTheUser() {
    Continuity.setAutoRestore(false);
    Continuity.addContinuationListener(new ContinuityListener() {
        public boolean stateReceived(AppState state) {
            held = state;
            if (Dialog.show("Continue?", "Pick up \"" + state.getTitle()
                    + "\" from your other device?", "Continue", "Stay here")) {
                Continuity.restore(held);
            } else {
                // Declining is a decision, and it has to be recorded. Returning false alone
                // only suppresses the state for THIS run -- false also means "keep it, I will
                // prompt again later" -- so without this the relay's unchanged document asks
                // the same question after every relaunch.
                Continuity.acknowledge(state);
```

```
            }
            // Consumed either way: the decision has been made here, and recorded either way.
            return false;
        }
    });
}
```

A state this device published is never offered back to its own listener, and a state already acted on is never acted on twice — a continuation and a relay routinely carry the same one.

84.4. Reaching every other device

A `StateRelay` is your endpoint, and `RestStateRelay` covers the common case:

```
public void useMyOwnEndpoint() {
    Continuity.setRelay(new RestStateRelay("https://api.example.com/continuity") {
        @Override
        protected String getToken() {
            return session.getAccessToken();
        }
    });
}
```

Two requests against the one URL. A `POST` carries the state as a JSON body, which you store against the signed-in user, replacing whatever you held for them. A `GET` answers with the newest state you hold for that user, or an empty body when you hold none. The JSON is a closed shape: your endpoint stores and returns the document and never needs to look inside it.

The token comes from `getToken()` rather than from the constructor because it's read at every request, so a session that refreshes its token is followed with no further code.

A relay is written to when the app checkpoints and read only when something asks, so ask when the app comes back to the foreground:

```
public void onAppResumed() {
    Continuity.pollRelay();
}
```

On Android that call is already made for you when the activity resumes. Making it yourself as well is harmless — a state already seen is ignored.

Put `Continuity.clear()` **and** `Continuity.disable()` on your logout path, and `Continuity.enable()` on your login path. The advertised activity outlives your app's own screen, so an account's work would otherwise stay on offer to the devices around it after the user signed out — and anything still queued for the relay would have gone out later under the next account's credentials, because a relay reads its token when the request runs:

```
public void onLogout() {
    // Both, and in this order. clear() forgets the account's data; disable() closes the
    // door behind it. clear() on its own leaves continuity ON, so a continuation that
    // arrives while your login screen is up is a valid arrival to a framework that is
    // still listening -- and the signed-out account's routes and payload get restored
    // over it.
    Continuity.clear();
    Continuity.disable();
}

public void onLogin() {
    // And open it again. Continuity stays off until you say otherwise, which is what
    // makes the gap above safe.
    Continuity.enable();
}
```

`clear()` alone isn't a logout. It forgets the account's data — the stored checkpoint, the advertised activity, anything queued for the relay — and it leaves continuity switched on by design, because forgetting state and turning the feature off are two different things and an app is entitled to do the first without the second. That means a continuation arriving while your login screen is up reaches a framework that's still listening, and the signed-out account's routes and payload are restored over it. `disable()` is what closes that gap, and `enable()` at login is what reopens it.

84.5. The synced store

`com.codename1.continuity.sync.SyncedStore` is the slow, patient half: a handful of durable choices — which theme, which sort order, which tutorial they already dismissed — kept in step across the devices one person is signed in to, without those devices ever being near each other.

```
public String readSortOrder() {
    return SyncedStore.get("sortOrder", "byName");
}

public void writeSortOrder(String order) {
    if (!SyncedStore.put("sortOrder", order)) {
        // No synced store here, or it is full. The value still has to live somewhere, so
        // fall back to this device's own preferences rather than losing the choice.
        com.codename1.io.Preferences.set("sortOrder", order);
    }
}
```

Note the shape: a read always has a default, and a write reports whether the store actually took the value — checked by reading it back, not assumed. That isn't defensive style, it's the API being honest. The store is empty on a device that has never synced, the user can switch the whole mechanism off, and it exists on Apple platforms only — so a synced value with a local default behind it makes the design work on every platform.

Changes made elsewhere arrive without values, on every platform that has such a store at all, so re-read what your screen shows rather than assuming you know which key moved:

```
public void followTheStore() {
    SyncedStore.addChangeListener(new SyncedStoreListener() {
        public void storeChanged() {
            // No values are carried, on any platform. Re-read what this screen shows.
            applySortOrder(SyncedStore.get("sortOrder", "byName"));
        }
    });
}
```

This isn't storage. It's small, the platform decides when to sync it, and nothing in it should be anything your app can't do without.

84.6. Developing Without Hardware

The simulator carries a simulated continuity platform, so all this works on the desktop — and the `Simulate → Continuity` menu scripts the cases that are otherwise reachable only with two devices in your hands. Every item is also callable from a test with `CN.execute("continuity:itemN")`.

Continue Here (As Another Device) hands whatever the app is currently advertising straight back to it. That's the whole feature in one click. If it does nothing, the app hasn't taken a checkpoint yet — which is itself the answer to the question of why nothing is being offered.

The rest reproduce traps rather than the happy path:

- **Continue A Route This Build Dropped.** A screen goes away in a rebuild and the states already sitting on the user's other devices still name it. The restore survives on the frames it can still build.
- **Continue With No Routes (Payload Only).** What an app that doesn't use `@Route` produces. An app that assumed `restore()` always shows something finds out here.
- **Continue Something From Yesterday.** Exercises `setMaxAge`, and the listener that has to decide whether moving the user somewhere they were yesterday is a courtesy or an ambush.
- **Change The Synced Store Elsewhere.** The notification carries no values, so an app that re-reads only the key it assumed changed reads a stale one.
- **Make The Synced Store Unsupported** and **Make Continuation Unsupported.** What every non-Apple platform reports. An app that put a required setting in the synced store and never checked `isSupported()` loses it here, with no error, exactly as it would on Android.

84.7. Build Hints

Hint	Default	What it does
`ios.continuity.sync`	unset	Whether this project wants the iCloud key-value store. Left unset the build decides from the bytecode. Set `false` to drop the entitlement; set `true` to declare it, which is what lets the signing preflight check your profile before the build is sent.

Everything is automatic by default. Referencing `com.codename1.continuity` compiles the `NSUserActivity` handling into the iOS build and declares this app's activity type in `NSUserActivityTypes`, which is what lets another device be offered the work — iOS continues an activity only when the app declared its type, so an app that skipped this would publish states nobody is ever shown. Referencing `com.codename1.continuity.sync` additionally asks for the `com.apple.developer.ubiquity-kvstore-identifier` entitlement. Apps that touch neither package get none of it, on any platform. Android needs nothing injected at all: no permission, no manifest entry, no dependency.

The activity type is your package name followed by `.continuity`, derived the same way in the build and at runtime, so there's nothing to configure and nothing to get out of step. `Continuity.getActivityType()` returns it, which is the first thing to check when a continuation never arrives.

That entitlement is the one part of this that can stop a build. Apple grants it only through an App ID with the iCloud capability enabled, so a profile issued before that was switched on matches your bundle id and authorizes none of it — and the build fails at codesigning, talking about an entitlement rather than about the capability. Codename One checks the profile before sending the build and warns, naming both ways out: enable iCloud on the App ID and regenerate the profile, or drop the entitlement.

```
codename1.arg.ios.continuity.sync=false
```

With that set, `SyncedStore.isSupported()` reports `false` at runtime and the rest of the app is unaffected. Handing work to a nearby device needs no entitlement and keeps working either way.

A restored state is restored on a device that has the app, not necessarily on the device that saved it and not necessarily by the person who did. Treat the payload as a description of **what screen to show**, never as proof of who is looking at it: re-check the signed-in account after restoring, and put nothing in a payload that would be a disclosure if it appeared on a family member's iPad. This is also what makes `Continuity.clear()` on logout more than housekeeping.

Chapter 85. App Intents: Siri, Spotlight and Shortcuts

Siri, Spotlight, the Shortcuts app, an Android launcher shortcut, a button on a home-screen widget and a large language model are all asking your application the same question: what can you do, and will you do it now? Codename One models them as one concept — an app intent — under the `com.codename1.intents` package. You declare a capability once and the framework projects it to each of them.

85.1. Three nouns

An **intent** is a named, titled, invokable capability. It takes **parameters**, which are either primitives or **entities** — your application's own nouns, which the platform can list, search and ask the user to choose between before your code runs. It produces an `IntentResult`: a value, a line to speak, a snippet to show, a route to open, or any combination of those.

85.2. Declaring an intent

A handler is a `public static` method carrying `@AppIntent`:

```
@AppIntent(value = "log_workout", title = "Log a workout",
        description = "Records a completed workout",
        phrases = {"Log a workout in ${applicationName}"},
        headless = true, timeoutSeconds = 5)
public static IntentResult logWorkout(
        @IntentParam(value = "kind", title = "What kind of workout?",
                     options = {"run", "ride", "swim"}) String kind,
        @IntentParam(value = "minutes", title = "How many minutes?") int minutes) {
    WorkoutStore.append(kind, minutes);
    return IntentResult.spoken("Logged a " + minutes + " minute " + kind + ".");
}
```

The method is `static` for a reason that matters on a device rather than as a style preference: the build generates a direct static call to it, and a direct call is the only form that survives the iOS translator's dead-code elimination and Android's obfuscation. It also makes the contract visible — a handler can be asked to run in a process that exists only to answer it, where no instance of your class has been constructed and there is no user interface.

At build time the Codename One Maven plugin scans your compiled bytecode, validates every declaration, and generates both the reflection-free dispatch table and the native declarations each platform compiles into the app. A malformed declaration fails the build rather than going quiet on a device.

Spoken phrases carry three rules, which Apple treats as halting errors that produce no App Intents metadata at all. The build checks them for you, so the message names your declaration instead of arriving as an opaque failure from the metadata processor:

- Every phrase must contain `${applicationName}`.
- A phrase may reference **at most one** parameter. Write one phrase per parameter rather than combining them.
- A phrase parameter must be an entity. A primitive can't appear in a phrase — which costs little, because leaving it out still has the platform ask for it, using the title you gave its `@IntentParam`.

85.3. Intents and routes are different questions

A `@Route` answers "given this URL, which screen?" and hands back a `Form`. An intent answers "given this verb and these arguments, what happens and what comes back?" and hands back a value. They can't be merged: a deep link has no return channel, always foregrounds, is stringly typed, and has no way to express "ask the user which playlist first."

They meet at exactly one point — an intent that opens the app **is** a deep link — so that's the one place they're joined. Declare `opensRoute` and the framework builds the URL from the bound parameters and navigates through your existing route table:

```
@AppIntent(value = "show_order", title = "Show order", opensRoute = "/orders/{orderId}")
public static IntentResult showOrder(@IntentParam("orderId") String orderId) {
    return IntentResult.opens("/orders/" + orderId);
}
```

One screen, one route pattern, two ways in. The build checks that `opensRoute` matches a `@Route` you actually declared.

85.4. Entities: The part that makes intents feel intelligent

An entity-typed parameter is what lets the platform run its **own** picker before your code is ever called. "Play a playlist" with nothing specified makes the system ask "Which one?" then fill the list from your suggested query, and hand your handler the chosen object. A plain `String` parameter can never do that — it can only be typed or spoken verbatim.

```
@IntentEntity(value = "playlist", title = "Playlist")
public static class Playlist {
    private String id;
    private String name;

    @EntityId
    public String getId() {
        return id;
    }

    @EntityTitle
    public String getName() {
        return name;
```

```
    }

    @EntityQuery(EntityQuery.Kind.BY_ID)
    public static Playlist byId(String id) {
        return Library.playlist(id);
    }

    @EntityQuery(EntityQuery.Kind.SUGGESTED)
    public static java.util.List<Playlist> recent() {
        return Library.recentPlaylists();
    }

    @EntityQuery(EntityQuery.Kind.SEARCH)
    public static java.util.List<Playlist> matching(String query) {
        return Library.search(query);
    }
}
```

Your class stays your class: there is no interface to implement and no base class to extend, because a domain model outlives the framework it's used with. The build reads the annotated members and generates the adapter.

A `BY_ID` query is mandatory. An entity crosses the platform boundary as its id and nothing else, so resolving that id back to an object is the one lookup the framework can't do without.

Write a query the way you'd write a headless handler: static, reading persisted state, depending on nothing your `init()` set up. The system can ask for a picker while it's still launching your application, and it blocks on the answer, so a query is called at a moment when your own startup may not have run yet — and a query that returns nothing then produces a picker with nothing in it. The framework and its storage are fully up by that point; your application's own singletons aren't.

Entity ids outlive your process and often your release. The device search index and the system's donated shortcuts both persist your id and hand it back later, so an id derived from a list position or a content hash starts resolving to the wrong object after your data changes, with no error reported anywhere.

85.5. Publishing content to device search

Indexing is the half of this feature most applications will get the most from, and it costs the least:

```
// After a sync, off the EDT
Intents.index(recentOrders);

// In init(), so a tap that cold-started the app is delivered as soon as possible
Intents.setSelectionHandler(entity -> Navigation.navigate("/orders/" + entity.getId()));
```

Remove entries when the content behind them goes away. An index entry outlives the data it describes, so deleted content keeps appearing in device search and taps resolve to nothing until the

application removes it:

```
Intents.removeFromIndex("order", orderId);
```

85.6. The headless contract

A `headless` intent can run in a process the system started only to answer it, with nothing on screen. That's what lets an assistant answer without your app appearing, and it's a real constraint rather than a flag.

The default is `false`, and that costs something worth knowing: an intent that doesn't declare `headless` brings the app to the foreground when it runs, so there's a window for it to act on. That isn't permission to touch one directly. No handler runs on the event dispatch thread, foreground or not — see below — so a foreground handler reaches the user interface the way every other background thread in Codename One does, through `Display.callSerially`. What foregrounding buys is that there's something on screen for that call to land on, and somewhere for a route to open. Declaring `headless = true` is what buys the answer-in-place behaviour — and what obliges you to earn it.

A headless handler **may** use `Storage`, `Preferences`, `Database`, `NetworkManager`, `Log`, surfaces publishing and `Intents.index`. It **must not** touch `Form`, `Dialog`, `Component`, `Display.getCurrent()`, the camera, capture, or anything else that needs a window: there is no window. It must also not call `Display.callSeriallyAndWait`, which can deadlock against a foregrounded event dispatch thread.

A platform-dispatched invocation never runs its handler on the event dispatch thread, whatever the platform and whatever the source. One can arrive while your app is visible — a widget button, a search result tapped on a running app — and a handler blocking the event thread there is a visible freeze.

`Intents.invoke` is the exception, by construction: it's synchronous, so it runs the handler on whatever thread called it and hands the result back to that caller. Call it from the event dispatch thread and you block the UI for as long as the handler runs, exactly as any other synchronous call from there would — pass it to `Display.startThread` if the work isn't instant.

Every invocation carries a deadline, and `IntentContext.isCancelled()` flips when it passes. Cancellation is cooperative: nothing interrupts a running handler, and anything a platform invocation returns afterward is discarded, so commit durable work to storage as you go rather than only at the end. `Intents.invoke` is the one exception, by design: you are blocked in that call waiting for the result and nothing else will report it, so a late one is still returned to you rather than thrown away.

The platform will usually allow around twenty seconds. Don't use them. A spoken interaction that takes ten seconds has already failed as an interaction. Aim under two, and for anything genuinely slower return `IntentResult.opens(…)` and do the work in the app where there's a UI to show progress in.

85.7. What each platform actually does

Capability	iOS	Android	Simulator
Declared intent	App Intent and App Shortcut	launcher shortcut	Intents window row
Voice invocation	Siri, from your phrases	**none**	typed into the window
Headless execution	background launch of the app	service, no Activity	in process
Open a route	native, then your route table	trampoline, then your route table	shows the form
Entity parameters	system picker and search	passed by id	picker from your real queries
System disambiguation	yes	**no** — the app foregrounds its own picker	in-app picker
Content indexing	Core Spotlight	long-lived launcher shortcuts	searchable list
Donation	learned suggestions	dynamic shortcuts	logged
Spoken result	spoken aloud	toast, headless runs only	shown as text
Snippet	rendered natively	**not shown**	rasterized preview
Returned value	piped to the next action	**caller only, not the launcher**	shown

The last three rows are where Android differs most, so they're worth stating outright. A launcher shortcut is a launch: it starts something, and nothing waits for an answer, so there is no channel to hand a result back through. A spoken line is shown as a toast, and only when the run was headless — that being the one case with no UI of its own to say it in. A snippet isn't rendered at all; no Android surface displays one for a shortcut, so a handler that returns one isn't failing, its snippet simply has no consumer there. A returned value goes to whoever called `Intents.invoke`, which is how an app uses its own intents as a command layer and works on every port, but it doesn't travel back to the launcher, because nothing there asked a question.

A handler whose entire result is a snippet therefore does nothing observable when it's started from an Android launcher shortcut. Write handlers that also change state, or that name a route with `opensRoute`, and the outcome is visible everywhere.

An intent marked `destructive` is absent from parts of that table by design: it's not published as a launcher shortcut and not donated, because both run on a single tap with nothing between the tap and the action, and confirmation is the whole point of the flag. It stays available through the assistant and the Shortcuts app, which confirm first.

Android isn't Siri parity, and this framework doesn't pretend otherwise. Android has no contract by which an assistant invokes an application capability and receives a typed result back, so

phrases and system disambiguation are iOS-only. Branch on `Intents.isVoiceInvocationSupported()`, not on `areIntentsSupported()`, when deciding whether to tell a user they can talk to your app.

What Android does deliver is real: launcher shortcuts, dynamic shortcuts the system learns to suggest from donation, and genuinely headless execution — the last of which is actually easier there than on iOS, because the Android port already boots without an Activity for background fetch.

85.8. The floor everything else sits on

An intent is guaranteed only to be invokable with its parameters supplied, and to produce a value. Everything else — phrases, pickers, speech, snippets, indexing, donation — is an enhancement some platform may not offer. Write each handler so it's still correct when nothing arrives but its parameters and nothing is consumed but its return value, and it will behave the same everywhere.

Because dispatch is generated code rather than a platform service, `Intents.invoke(…)` works on **every** port, including those with no intent support at all. An application can use its own intents as an internal command layer and get the platform integration as a bonus where it exists.

85.9. Testing without a device

The simulator's `Simulate → App Intents` window lists every intent your application declares, generates a parameter form from the declaration, fills entity pickers from your real query methods, and runs the intent through the same entry point the iOS and Android ports call. Nothing in it shortcuts the framework, so a bug in marshalling, coercion or the deadline shows up on your desktop rather than on a device.

85.10. What this costs your iOS deployment target

Nothing, unless you declare an intent — and possibly nothing even then.

Indexing and donation run on Core Spotlight and `NSUserActivity`, which are Objective-C and have been available since long before the framework's current minimum, so an application that only publishes content to device search never changes its deployment target.

Declaring an `@AppIntent` brings in Apple's App Intents framework, which needs a newer minimum. Every generated type is availability-guarded, so the intended outcome is that your target is untouched and the intents simply don't appear on older devices. Where a toolchain refuses that, the build raises the floor **only for applications that declare an intent**. Two build hints keep the decision yours:

Hint	Effect
`ios.intents.minDeploymentTarget`	A floor a declared intent contributes. Empty by default, so declaring an intent raises nothing: Xcode emits App Intents metadata below the deployment target, and the generated declarations are availability-fenced, so they're simply not offered on devices too old to run them. Set it to `16.0` if you would rather not ship a build whose intents are inert for part of your audience.
`ios.intents.appIntents`	`false` keeps Spotlight indexing and shortcut donation while suppressing App Intents generation entirely.

If you've pinned a deployment target below what a declared intent needs, the build says so and stops rather than moving your pin or dropping your intents behind your back.

85.11. Zero cost when unused

Referencing this package is what makes the build inject the native plumbing. An application that never touches `com.codename1.intents` gets none of it — no frameworks, no shortcut resources, no manifest entries, no deployment-target change — and builds exactly as it did before.

Chapter 86. Document Provider

An app's documents normally live inside it. The user opens your app to reach them, and no other app can. A document provider changes that: the content you publish appears as a location in the system file browser - the Files app on iOS, the storage picker on Android. It can be browsed, previewed and opened by other apps without your app being launched at all.

Codename One generates the platform plumbing for you from build hints. There is no native code in your project on any platform.

86.1. When you need this

If all you want is for the files your app already writes to be visible in the Files app under the device's own heading, you need no extension and none of this chapter. Two plist keys do it:

```
codename1.arg.ios.plistInject=<key>UIFileSharingEnabled</key><true/>\
<key>LSSupportsOpeningDocumentsInPlace</key><true/>
```

That exposes your app's own documents directory as-is. Use the document provider when you want something the directory listing can't give you: a tree that doesn't match your storage layout, content fetched from a server on demand, names and types that differ from the file names, or a location that appears even when the device holds none of the content yet.

86.2. How it works

On iOS the file browser doesn't talk to your app. It talks to an **app extension** - a separate process the system starts on demand, which runs while your app is dead and can't call your Java code. That single fact shapes the whole API.

You don't answer questions from the browser; you **publish**: a tree of `DocumentNode` objects is serialized into a container both processes can read, and the generated extension serves the browser from it. Publish whenever your data changes - after a sync, after a login - not in response to being browsed, because you won't be asked.

Android has no such split; the provider runs inside your app. The API is the same there anyway, so one publishing discipline works everywhere.

86.3. Publishing a tree

Build a tree and publish it. Each file node names its content in one of two ways.

From the shared directory. Write the bytes under `getSharedDirectory()` and give the node a relative `path`. Nothing else is involved - no server, no network code - and the content opens instantly because it's already on the device.

```
String shared = DocumentProvider.getSharedDirectory();
```

```
DocumentNode root = DocumentNode.folder("root", "My Invoices");
for (Invoice invoice : invoices) {
    String name = invoice.title + ".pdf";
    writeInto(shared + "/" + name, invoice.pdf);
    root.add(DocumentNode.file(invoice.id, name)
            .setContentType("application/pdf")
            .setPath(name)
            .setSize(invoice.pdf.length)
            .setLastModified(invoice.modified));
}
DocumentProvider.publish(root);
```

On iOS the shared directory is inside the App Group container, not your app's own sandbox. A file written to `FileSystemStorage`'s home directory is **not** visible to the extension. Always resolve paths against `getSharedDirectory()`.

Update published content by writing a new file and republishing the tree against it, never by rewriting a file already in the published tree. Another app can be reading a published file at any moment, and rewriting one in place refills the same file underneath that reader, which sees the two versions spliced together. Publish the replacement under a new name and call `publish` again: the readers already open finish the old file, and the ones that come after open the new one.

From your server. Give the node a `remoteId` and tell the extension where to fetch it. The index can then list far more than the device holds, which is what a cloud drive wants.

```
DocumentProvider.setRemoteEndpoint("https://api.example.com/drive", sessionToken());
DocumentNode root = DocumentNode.folder("root", "Example Drive");
for (Invoice invoice : invoices) {
    root.add(DocumentNode.file(invoice.id, invoice.title + ".pdf")
            .setContentType("application/pdf")
            .setRemoteId(invoice.serverKey)
            .setSize(invoice.pdf.length)
            // The date, not the size, is what tells the browser the content changed: a
            // correction that keeps the length would move nothing otherwise.
            .setLastModified(invoice.modified));
}
DocumentProvider.publish(root);
```

A node may carry both. The local copy always wins, which is how a cached document opens without a round trip.

The location is read-only. Your app is the only writer, so the browser offers no editing, renaming or deleting and never presents a save that would fail. To change what people see, publish again.

Folders nest as you would expect:

```
DocumentNode root = DocumentNode.folder("root", "My Invoices");
DocumentNode year = DocumentNode.folder("y2031", "2031");
year.add(DocumentNode.file("inv-1", "January.pdf")
        .setContentType("application/pdf")
        .setPath("2031/january.pdf"));
root.add(year);
DocumentProvider.publish(root);
```

Node ids must be stable for the lifetime of the item. The platform remembers them (a favourite in the Files app, a recent document, a running download), so reusing an id for different content, or renumbering ids on every publish, makes the browser point at the wrong thing. Derive the id from your own record key, never from list order.

Call `clear()` on logout. The published content outlives your process, so documents left behind stay browsable by whoever holds the device:

```
DocumentProvider.clear();
```

`isSupported()` tells you whether this platform can show the location, which is worth checking before offering a setting for it. Everything else is a safe no-op where the feature is unavailable, so no other platform guards are needed:

```
if (DocumentProvider.isSupported()) {
    showSetting("Show my documents in Files");
}
```

86.4. Build hints

Referencing `com.codename1.documents` is enough to generate the extension. These hints configure it:

```
codename1.arg.ios.documentProvider.enabled=true
codename1.arg.ios.documentProvider.appGroup=group.com.example.myapp
```

`ios.documentProvider.enabled` is redundant for the build itself - the build detects the reference - but the Certificate Wizard and the signing preflight can't read your bytecode, so setting the hint tells them to create and check the extension's signing assets. The wizard sets it for you.

The App Group defaults to `group.<your package>`. It must start with `group.`, which Apple requires, and it's the entire transport between your app and the extension: without it the location appears empty.

Optional:

```
codename1.arg.ios.documentProvider.displayName=Example Drive
codename1.arg.ios.documentProvider.deploymentTarget=16.0
```

`displayName` names the location in the browser and defaults to your app's display name. `deploymentTarget` defaults to 16.0. Below 16.0 Codename One generates the older `NSFileProviderExtension` instead, which Apple has deprecated; the two claim the same extension point, so a build gets one or the other and never both. Your app's own deployment target is unaffected either way - the extension simply never runs on older systems.

Set `ios.documentProvider.extension=false` to skip the whole iOS lowering and leave the API an inert no-op. Xcode build settings for the extension target can be overridden with `ios.documentProvider.buildSettings.SETTING=value`.

Android needs no configuration. The provider is declared in the manifest with the authority `<your package>.documents` when the app references the API.

86.5. The remote endpoint

When a node with a `remoteId` is opened and no local copy exists, the reader issues:

```
GET <endpoint>/fetch?id=<remoteId>
Authorization: Bearer <token>
```

The reader expects the file's bytes with status 200. Anything else is reported to the user as a failure to open the document. The token is the one you passed to `setRemoteEndpoint`.

The request is made by the extension, not by your app, so it must succeed without any state your app holds in memory - the token is all it carries. Publish a fresh token whenever you renew one; the reader picks up the latest value each time it runs.

This is what the published index looks like on disk, which is worth knowing when you are working out why a location looks wrong:

```
{
  "id": "root",
  "name": "Example Drive",
  "folder": true,
  "children": [
    {
      "id": "inv-2031-01",
      "name": "January.pdf",
      "folder": false,
      "contentType": "application/pdf",
      "remoteId": "invoices/2031/01",
      "size": 48213,
      "lastModified": 1735689600000
    }
```

```
  ]
}
```

86.6. Signing

Apple signs an app extension against its **own** App ID. Your app's profile covers your app's bundle id and nothing beneath it, so the generated `CN1Documents` target needs an App ID of its own - `<your package>.CN1Documents` - with the same App Group, and its own provisioning profile.

The Certificate Wizard does every step: it creates the App Group, enables it on both App IDs, creates the extension's App ID, generates an App Store profile and a development profile for it, downloads them and writes them into your project settings. That's the recommended route.

To do it by hand, create the App ID and profiles in the Apple Developer portal and name them:

```
codename1.ios.appext.CN1Documents.provision=${user.home}/certs/CN1Documents_dist.mobileprovision
codename1.ios.debug.appext.CN1Documents.provision=${user.home}/certs/CN1Documents_dev.mobileprovision
```

The unqualified `codename1.ios.appext.CN1Documents.provision` is the fallback for both build types. You can also host the profile and name the URL in `ios.appext.CN1Documents.provisioningURL`.

Supply nothing and Xcode fails minutes into a cloud build with:

```
Provisioning profile "MyApp_Distribution" has app ID "com.example.myapp", which doesn't
match the bundle ID "com.example.myapp.CN1Documents"
```

Codename One refuses that build before sending it, naming the extension and the bundle id its App ID has to match.

A wildcard App ID (`com.example.*`) isn't a way around this, unlike for other extensions. It covers the bundle id, and it still can't sign this extension: the extension declares the App Group it shares with the app, and Apple doesn't offer the App Groups capability on a wildcard App ID at all. Signing fails on the entitlement rather than on the name, so the build is refused here too. The app's own profile has the same problem, because it carries the same group. Both need explicit App IDs - which is what the Certificate Wizard creates.

A Mac build embeds no extension and needs no signing assets for one: Apple's FileProvider framework is unavailable to Mac Catalyst apps, so the Mac slice of an iOS project can't host a provider however it's entitled. `isSupported()` answers `false` there and every publish call is a no-op, so the same code runs unchanged.

A local "ios-source" build needs none of this either: you sign the generated Xcode project in Xcode as usual.

86.7. Testing

`isSupported()` answers `false` in the simulator, and every publish call is a safe no-op there, so your code needs no guards beyond the one shown above. The simulator still writes everything a device would, under `cn1documents` in the app's home directory, so you can read back exactly what a device would have been handed.

On a device, publish a tree and open the Files app: the location appears under "Browse" alongside iCloud Drive. On Android it appears in the storage picker. A local "ios-source" build produces the `CN1Documents` target in the generated Xcode project, so you can confirm the extension compiles and is embedded before signing anything.

Chapter 87. Apple Wallet Extension

Card issuers (banks, fintechs) can let users add a payment card to Apple Wallet from inside the Wallet app itself. The user opens Wallet, taps the add button and sees the issuer's cards listed under "From apps on your iPhone" - without ever launching the issuer's app. Apple implements this through a pair of app extensions called issuer provisioning extensions, and Codename One can generate them for you from build hints with no native code in your project.

This is distinct from the in-app flow where your app shows an "Add to Apple Wallet" button. The extension flow starts inside the Wallet app, runs in a separate process and usually runs while your app isn't running at all.

87.1. How the extension works

Apple defines two extension points:

- A **non-UI extension** that Wallet queries for status and the list of available cards, and that produces the encrypted provisioning payload when the user adds a card. Wallet gives it 100ms to answer the status query, so it can't perform network calls or heavy work there.
- An optional **authorization UI extension** that presents a login screen inside Wallet when the non-UI extension reports that authentication is required.

Because the extensions run in a separate process, they can't call into your Java code. The Codename One integration bridges this in two ways:

1. Your app pre-publishes the card list, card art and an auth token through `com.codename1.payment.WalletExtension`. The data lands in a shared App Group container where the generated extension reads it instantly.
2. The one step that genuinely needs the issuer's backend - producing `encryptedPassData` from the certificates and nonce that Apple hands the extension - is performed by an HTTPS endpoint you host. The generated extension POSTs the request there and relays the response to Wallet.

87.2. Prerequisites from Apple

Before any of this works you need approvals that only Apple and your card network can grant:

- The `com.apple.developer.payment-pass-provisioning` entitlement is restricted. Apple grants it per app on request (see the In-App Provisioning documentation on the Apple developer site). After approval, enable it under the App ID's **Additional Capabilities** tab for the app **and for each extension App ID**.
- Each extension needs its own App ID (for example `com.mybank.app.WalletNonUIExtension`) and its own provisioning profile carrying the entitlement.
- The card network/PNO pass metadata must list the extension App IDs in `associatedApplicationIdentifiers`, otherwise Wallet never invokes the extensions.
- The extensions require iOS 14. The generated extension targets set their own deployment target, so your app can still target an older iOS version.

87.3. Mode 1: Generate the extensions from build hints

Add these build hints to the iOS build:

```
codename1.arg.ios.wallet.extension=true
codename1.arg.ios.wallet.appGroup=group.com.mybank.app
codename1.arg.ios.wallet.issuerEndpoint=https://api.mybank.com/wallet/provision
```

That generates the non-UI extension, wires it into the Xcode project as an embedded extension target and injects the App Group into the app and extension entitlements. To also generate the login UI extension add:

```
codename1.arg.ios.wallet.includeUI=true
codename1.arg.ios.wallet.authEndpoint=https://api.mybank.com/wallet/login
```

In Java, publish the user's cards whenever they change (typically after login) and keep a fresh token published so Wallet can skip the login screen:

```
if (WalletExtension.isSupported()) {
    WalletExtension.setPassEntries(new WalletPassEntry[] {
        new WalletPassEntry()
            .identifier(card.getPrimaryAccountIdentifier())
            .title("My Bank Debit Card")
            .cardholderName(user.getFullName())
            .primaryAccountSuffix(card.getLast4())
            .paymentNetwork("Visa")
            .localizedDescription("My Bank Debit Card")
            .artPng(cardArt.getImageData())
    });
    WalletExtension.setRemotePassEntries(sameEntries); // Apple Watch list
    WalletExtension.setAuthToken(session.getToken());
    WalletExtension.setRequiresAuthentication(false);
}
```

Call `WalletExtension.clear()` on logout. The card art must be a PNG without personally identifiable information (Apple requires square corners and no full card number). The extension automatically filters out cards that are already provisioned on the device or the paired watch.

87.3.1. The issuer endpoint

When the user adds a card, the generated extension POSTs JSON to the `ios.wallet.issuerEndpoint` URL:

```
{
  "certificates": ["base64...", "base64..."],
  "nonce": "base64...",
```

```
  "nonceSignature": "base64...",
  "cardIdentifier": "the WalletPassEntry identifier",
  "authToken": "the token published via setAuthToken"
}
```

The token is also sent as an `Authorization: Bearer` header. Your backend performs the network-specific encryption (this always happens server side - the keys never live on the device) and responds with:

```
{
  "activationData": "base64...",
  "encryptedPassData": "base64...",
  "ephemeralPublicKey": "base64..."
}
```

For the RSA_V2 scheme return `wrappedKey` instead of `ephemeralPublicKey`.

87.3.2. The login UI extension

When you can't guarantee a fresh token, report `setRequiresAuthentication(true)` and enable the UI extension. It shows a minimal username/password form inside Wallet, POSTs `{"username", "password"}` to the `ios.wallet.authEndpoint` URL, expects `{"token"}` back and stores it where the non-UI extension picks it up. If the generated form doesn't fit your brand or login model, use the injection hints below or bring your own extension (Mode 2).

87.3.3. Customizing the generated code

The generated Objective-C contains marker comments at every interesting point, and each marker has a matching build hint that injects your snippet there: `ios.wallet.nonuiImportsInject`, `ios.wallet.statusInject`, `ios.wallet.passEntriesInject`, `ios.wallet.remotePassEntriesInject`, `ios.wallet.generateRequestInject` (runs before the POST - the mutable `payload` dictionary is in scope, so you can add fields your backend expects), `ios.wallet.generateResponseInject`, `ios.wallet.uiImportsInject`, `ios.wallet.uiViewDidLoadInject`, `ios.wallet.uiAuthRequestInject` and `ios.wallet.uiAuthResponseInject`.

Xcode build settings of the extension targets can be overridden with `ios.wallet.nonui.buildSettings.SETTING=value` and `ios.wallet.ui.buildSettings.SETTING=value` - useful in local builds for `DEVELOPMENT_TEAM` or `CODE_SIGN_STYLE`.

87.3.4. Provisioning profiles for cloud builds

Cloud device builds sign each extension with its own profile. Either place the `.mobileprovision` files under `common/src/main/resources` and name them in build hints:

```
codename1.arg.ios.wallet.nonuiProvisioningProfile=WalletNonUI.mobileprovision
codename1.arg.ios.wallet.uiProvisioningProfile=WalletUI.mobileprovision
```

Alternatively, host them at URLs the build server can reach and supply `ios.wallet.nonuiProvisioningURL` / `ios.wallet.uiProvisioningURL` instead. Profiles contain no private keys, so bundling them in resources is safe; the build keeps them out of the final app bundle. The build validates that each profile matches your distribution certificate and actually carries the payment-pass-provisioning entitlement, and fails with an actionable message when it doesn't.

In local builds ("ios-source" target) no profile hints are needed - you sign the generated Xcode project in Xcode as usual.

87.4. Mode 2: Bring your own extension

If you already have Xcode extension targets - from an issuer SDK vendor or an existing native app - skip the `ios.wallet.*` hints and drop each extension into the generic app extension mechanism instead. Create `ios/app_extensions/MyWalletExtension/` in your project containing:

- The extension's source files (`.m`, `.h`, `.swift`)
- `Info.plist` with the `NSExtension` dictionary
- `MyWalletExtension.entitlements`
- Optional `buildSettings.properties` with Xcode build settings, one per line (set `IPHONEOS_DEPLOYMENT_TARGET=14.0` for Wallet extensions)
- The extension's own `.mobileprovision` for cloud device builds - see below

Each folder becomes an embedded extension target with bundle id `<your package>.<folder name>`. This mechanism isn't Wallet-specific - it embeds any iOS app extension type.

87.4.1. Signing a brought-in extension

Apple signs an app extension against its own App ID. The app's provisioning profile covers the app's bundle id and nothing beneath it, so every extension needs its own App ID and its own profile - two extra of each for a Wallet pair. Supply none and the extension target inherits the app's profile, and Xcode fails the build with:

```
Provisioning profile "MyApp_Distribution" has app ID "com.mybank.app", which does not
match the bundle ID "com.mybank.app.WalletNonUIExtension"
```

Codename One refuses that build before it's sent, naming the extension and the bundle id its App ID has to match. To fix it, create an App ID for `<your package>.<folder name>` in the Apple Developer portal - for a Wallet extension with the `com.apple.developer.payment-pass-provisioning` entitlement Apple grants on request, and with the same App Group as the app - generate a provisioning profile for it against the same certificate as the app, and supply it in one of three ways:

1. Place the `.mobileprovision` file inside `ios/app_extensions/MyWalletExtension/`. It's picked up automatically and kept out of the app bundle. Profiles carry no private keys, so committing one is safe.
2. Point at it from `codenameone_settings.properties`, which suits a profile that lives outside the repository:

```
codename1.ios.debug.appext.MyWalletExtension.provision=${user.home}/certs/MyWalletExtension_dev.mobileprovision
codename1.ios.release.appext.MyWalletExtension.provision=${user.home}/certs/MyWalletExtension_dist.mobileprovision
```

The unqualified `codename1.ios.appext.MyWalletExtension.provision` is the fallback for both build types.

3. Host it and name the URL in `ios.appext.MyWalletExtension.provisioningURL` (or the `ios.debug.appext…` / `ios.release.appext…` variants).

The build validates the profile it's given: it must match the app's signing certificate, cover the extension's bundle id, be current, and grant the App Groups and the payment-pass-provisioning entitlement the extension's `.entitlements` asks for. Each of those fails with a message naming the extension, rather than as an Xcode code signing error minutes into the build.

A wildcard App ID (`com.mybank.*`) is the one case that needs no extra profile - it's already covering the extension bundle ids, and the build lets it through. Wallet extensions can't use one: the payment-pass-provisioning entitlement is granted per explicit App ID.

Local "ios-source" builds need none of this - you sign the generated Xcode project in Xcode as usual.

87.5. Testing

Wallet extensions can't be exercised in the iOS simulator's Wallet app; testing the full flow requires a device, a provisioning profile with the entitlement and a card network sandbox. What you can verify earlier:

- A local "ios-source" build with the hints produces the `WalletNonUIExtension`/`WalletUIExtension` targets - open the generated Xcode project and build.
- `WalletExtension.isSupported()` returns `false` in the simulator and on other platforms, and all publish calls are safe no-ops there, so the Java code needs no platform guards beyond the one shown above.

Chapter 88. Miscellaneous features

88.1. Phone functions

Most of the low-level phone functionality is accessible in the Display [https://www.codenameone.com/javadoc/com/codename1/ui/Display.html] class. Think of it as a global class that covers access to the "system."

88.1.1. SMS

Codename One supports sending SMS messages but not receiving them as this functionality isn't portable. You can send an SMS using either the `Display` singleton or the static helper methods on `CN`. Both APIs throw `IOException`, which you should handle in case the native layer reports a failure:

```
try {
    // true opens the platform composer, which is what both Android and
    // iOS offer. iOS opens it either way, but Android takes the flag
    // literally and its background path is not implemented
    Display.getInstance().sendSMS("+999999999", "My SMS Message", true);
    // Or: CN.sendSMS("+999999999", "My SMS Message", true);
} catch(IOException err) {
    Log.e(err);
    Dialog.show("SMS Failed", "Unable to send the SMS", "OK", null);
}
```

Both Android and iOS launch the native SMS application with your message composed, for the user to send. Neither sends in the background, so check `getSMSSupport` rather than assuming — the constant is the contract, and the base implementation defaults to `SMS_SEAMLESS`.

That's why the samples pass `true` for the interactive argument. On Android the two-argument overload does nothing at all — it asks for the seamless send, and that branch isn't implemented. The iOS port ignores the flag and opens the composer either way, so passing `true` is what works on both.

The `getSMSSupport` API returns one of the following options:

- SMS_NOT_SUPPORTED - for desktop, tablet etc.
- SMS_SEAMLESS - `sendSMS` won't show a UI and will send in the background
- SMS_INTERACTIVE - `sendSMS` will show an SMS sending UI
- SMS_BOTH - `sendSMS` can support both seamless and interactive mode

The `sendSMS` can accept an interactive argument: `sendSMS(String phoneNumber, String message, boolean interactive)`

Pass `true` for it whenever `getSMSSupport` reports `SMS_INTERACTIVE`. The two-argument overload asks for a seamless send, and a port that only offers the system composer does nothing with that request — on Android nothing happens at all, because the background-send path isn't implemented there. Both the Android and the iOS port report `SMS_INTERACTIVE`. A platform reporting `SMS_SEAMLESS`

sends without a composer, and one reporting `SMS_BOTH` does whichever the `interactive` argument asks for, which is why the switch above branches on the constant instead of hard coding one call.

A typical use of this API would be something like this:

```
try {
    switch(Display.getInstance().getSMSSupport()) {
        case Display.SMS_NOT_SUPPORTED:
            return;
        case Display.SMS_SEAMLESS:
            showUIDialogToEditMessageData();
            Display.getInstance().sendSMS(phone, data);
            return;
        default:
            // interactive ports hand off to the platform composer. On
            // Android the two-argument overload asks for a seamless
            // send it does not implement, and nothing happens at all
            Display.getInstance().sendSMS(phone, data, true);
            return;
    }
} catch(IOException err) {
    Log.e(err);
    Dialog.show("SMS Failed", "Unable to send the SMS", "OK", null);
}
```

88.1.2. Dialing

Dialing the phone is pretty trivial. This should open the dialer UI without physically dialing the phone, as that's discouraged by device vendors.

You can dial the phone by using:

```
Display.getInstance().dial("+999999999");
```

88.1.3. Call detection

Codename One includes a generic call detection API through `Display.isCallDetectionSupported()` and `Display.isInCall()`.

This API is intentionally **best effort** and should be used as a UX hint (for example, to defer a non-critical animation while the app is interrupted).

On iOS, `isInCall()` is inferred from app interruption lifecycle events, which means it can report `true` for non-call interruptions (for example: Control Center, app switching, permission sheets), and some call flows may still be missed.

Because iOS toggles this flag during app lifecycle transitions, polling it with a `UITimer` can miss the interruption window entirely (timers are paused while the app is inactive, and the flag is reset

when the app becomes active again). If you need to react, check it from lifecycle callbacks such as your app's `stop()`/`start()` flow instead of periodic polling.

On Android, call detection is unsupported because robust detection would require invasive telephony permissions that are intentionally avoided:

```
Display display = Display.getInstance();
if (display.isCallDetectionSupported() && display.isInCall()) {
    Log.p("Call interruption is currently active (heuristic)");
}
```

88.1.4. E-Mail

You can send an email through the platforms native email client with code such as this:

```
Message m = new Message("Body of message");
Display.getInstance().sendMessage(new String[] {"someone@gmail.com"}, "Subject of message", m);
```

You can add one attachment by using `setAttachment` and `setAttachmentMimeType`.

You need to use files from `FileSystemStorage` and **NOT** `Storage` files!

You can add more than one attachment by putting them directly into the attachment map for example:

```
Message m = new Message("Body of message");
m.getAttachments().put(textAttachmentUri, "text/plain");
m.getAttachments().put(imageAttachmentUri, "image/png");
Display.getInstance().sendMessage(new String[] {"someone@gmail.com"}, "Subject of message", m);
```

Some features such as attachments etc. Don't work in the simulator but should work on iOS/Android

88.2. Larger text accessibility

Codename One can adapt to the operating system's larger text accessibility setting. The Display [https://www.codenameone.com/javadoc/com/codename1/ui/Display.html] APIs expose two signals: `isLargerTextEnabled()` indicates whether the user has enabled larger text, and `getLargerTextScale()` returns the scale factor that should be applied to fonts.

If you want the theme system to automatically scale its fonts when larger text is enabled, enable the UIManager [https://www.codenameone.com/javadoc/com/codename1/ui/plaf/UIManager.html] setting:

```
UIManager.getInstance().setUseLargerTextScale(true);
```

You can also enable this behavior in the theme by setting the `useLargerTextScaleBool` theme constant to `true`.

Component fonts are the theme's job — don't scale them by hand. For anything the theme can't reach, a custom-painted row or an icon measured in code, read the values directly:

```
void snippet() throws Exception {
    Display display = Display.getInstance();
    // 1.0 when the user has not asked for larger text, so the same
    // arithmetic works either way
    float scale = display.isLargerTextEnabled() ? display.getLargerTextScale() : 1f;

    // a custom-painted row has no Style for the theme to scale, so give it
    // the same preference the theme fonts get
    int rowHeight = Math.round(baseRowHeight * scale);
    int iconSize = Math.round(baseIconSize * scale);
    drawingArea.setPreferredH(rowHeight);
    g.drawRect(0, 0, iconSize, iconSize);
}
```

88.2.1. How the scale is computed per platform

- **iOS:** the scale is the ratio between the body text size at the user's current Dynamic Type setting and the iOS standard 17pt body size, that is, `[UIFont preferredFontForTextStyle:UIFontTextStyleBody].pointSize / [UIFont systemFontSize]`. Scales for the standard slider stops range from `0.82x` (Extra Small) through `1.00x` (Large, default) up to `1.35x` (Extra Extra Large). When the user enables *Larger Accessibility Sizes* in Settings → Accessibility → Display & Text Size → Larger Text, the slider extends with five more stops whose scales reach as high as `3.12x`. These values match what every native iOS app sees from `UIFontMetrics`.
- **Android:** the scale is `Configuration.fontScale`, which is bucketed by Android (typically `0.85`, `1.0`, `1.15`, `1.30`).

Because the scale is multiplicative, a base font size that's already larger than the platform default will compound. For example, a `defaultFontSizeInt: 18` in your CSS is 6% larger than iOS's 17pt body, so at iOS Dynamic Type *Extra Extra Large* (`1.35x`) your text will render at `24.3pt` versus a native iOS app's `23pt`. If you intentionally use a base size larger than the platform default and you also enable `useLargerTextScaleBool`, expect the absolute size at high accessibility settings to be visibly larger than typical native apps. Many native iOS apps cap Dynamic Type via `UIFontMetrics maximumPointSize:` for non-text-heavy UIs to avoid layout breakage.

88.2.2. Previewing in the simulator

The JavaSE simulator includes a **Simulate → Larger Text** menu that lets you preview every iOS Dynamic Type stop (Extra Small through Accessibility 5) without leaving your desktop. The

simulator returns the same scale factor that the corresponding iOS device would report, so this is the recommended way to verify how your UI behaves at each setting before testing on hardware. The selected stop is persisted across simulator restarts.

If your app looks correct in the simulator at *Large (default)* but fonts appear oversized on your iPhone with the Display & Brightness slider near the middle, check whether *Settings → Accessibility → Display & Text Size → Larger Text → Larger Accessibility Sizes* is enabled on the device. When that toggle is on, the system reports the larger *Accessibility* size categories whose scales begin at `1.65×` and exceed what the standard slider can reach.

88.3. Contacts API

The contacts API provides you with the means to query the phone's address book, delete elements from it and create new entries into it. To get the platform specific list of contacts you can use `String[] contacts = ContactsManager.getAllContacts();`

Notice that on some platforms this will prompt the user for permissions and the user might choose not to grant that permission. To detect whether this is the case you can invoke `isContactsPermissionGranted()` after invoking `getAllContacts()`. This can help you adapt your error message to the user.

Once you have a Contact [https://www.codenameone.com/javadoc/com/codename1/contacts/Contact.html] you can use the `getContactById` method, but the default method is a bit slow if you want to pull a large batch of contacts. The solution for this is to extract the data that you need through

Here you can specify true for the attributes that actually matter to you.

Another capability of the contacts API is the ability to extract all the contacts. This isn't supported on all platforms but platforms such as Android can get a boost from this API as extracting the contacts one by one is slow on Android.

You can check if a platform supports the extraction of all the contacts through `ContactsManager.isAllContactsFast()`.

When retrieving all the contacts, notice that you should probably not retrieve all the data and should set some fields to false to perform a more efficient query

You can then extract all the contacts using code that looks a bit like this, notice that you use a thread so the UI won't be blocked!

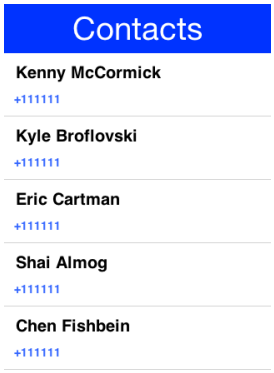


Figure 361. List of contacts

Notice that you didn't fetch the image of the contact as the performance of loading these images might be prohibitive. You can enhance the code above to include images by using slightly more complex code such as this:

The `scheduleBackgroundTask` method is like `new Thread()` in some regards. It places elements in a queue instead of opening too many threads so it can be good for non-urgent tasks

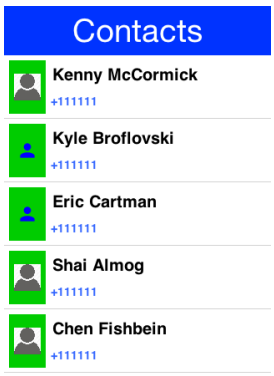

Figure 362. Contacts with the default photos on the simulator, on device these will use actual user photos when available

Notice that the code above uses `callSerially` & `scheduleBackgroundTask` in a liberal nested way. This is important to avoid an EDT violation

You can use `createContact(String firstName, String familyName, String officePhone, String homePhone, String cellPhone, String email)` to add a new contact and deleteContact(String id) to delete a contact.

88.3.1. Contact picker

The API above reads the whole address book, so it needs the broad contacts permission. If all you need is a contact the user chose, use ContactPicker [https://www.codenameone.com/javadoc/com/codename1/contacts/ContactPicker.html] instead. It shows the platform's own picker, and the app only ever sees the contacts the user tapped and only the fields it asked for.

```
ContactPicker picker = new ContactPicker();
```

```
picker.setRequestedFields(ContactPicker.NAME | ContactPicker.PHONE);
picker.pick(ev -> {
    Contact[] picked = ContactPicker.getPickedContacts(ev);
    if(picked.length > 0) {
        numberField.setText(picked[0].getPrimaryPhoneNumber());
    }
});
```

From 2027-01-27 Google Play requires an app that targets Android 17 (API level 37) or later and requests `READ_CONTACTS` to pass a Play Console declaration explaining why the picker isn't enough. An app that only picks never requests that permission, so it never files that declaration. The build only adds `READ_CONTACTS` for the broad API, so mixing the two in one app puts the permission back.

Ask for as little as you can. On Android the requested fields also decide which contacts the picker offers, and the platform returns nothing you didn't ask for. `setMultiSelect(boolean)` lets the user pick several contacts, `setSelectionLimit(int)` caps how many, and `setRequireAllRequestedFields(boolean)` hides contacts that are missing one of them.

The contacts you get back are snapshots. There's no continuing access behind them, so anything you need later has to be copied out of the `Contact` and stored by your app.

`ContactPicker.isSupported()` tells you whether the platform has a picker at all. Android, iOS and the simulator do; where a platform doesn't, `pick` reports an empty selection rather than falling back to reading the address book, because that fallback would need the permission you were avoiding. A cancelled pick reports the same empty selection, so `getPickedContacts` is the only thing your listener has to check.

Android 17 and newer show the system picker, and serve every field. Older releases fall back to the contacts app's own single-row picker, which needs no permission either but returns one contact carrying one kind of data: the name plus whichever of phone, email and postal address was requested first. A photo, a birthday or a web site is best-effort there, a multiple selection comes back as a single contact, and `setRequireAllRequestedFields` has no effect. Nothing about that escalates into a permission prompt - the fields you can't have simply come back null, so read every one you asked for defensively.

88.4. Localization & internationalization (L10N & I18N)

Localization (l10n) means adapting to a locale which is more than translating to a specific language but also to a specific language within environment for example: `en_US!= en_UK`. Internationalization (i18n) is the process of creating one application that adapts to all locales and regional requirements.

Codename One supports automatic localization and seamless internationalization of an application using Java properties bundles.

Place locale-specific properties files inside an `l10n` directory directly under your module's `main` directory (for example: `common/src/main/l10n`). Each file inside this directory is treated as a resource

bundle and will be packaged automatically with your app, allowing you to version translations alongside the rest of your source code.

When you're iterating on translations you can also use the simulator to capture bundles automatically. Open the Simulator menu and enable **Auto Update Default Bundle** so that running your app in the Codename One simulator will create any missing resource bundles on the fly as you interact with the UI, which makes it simple to populate keys without manually editing files during development. The resource is keyed by the properties file's base name rather than by the directory holding it, so the archetype's `common/src/main/l10n/Bundle.properties` becomes `Bundle`. The locale comes from the `_xx` suffix, and a file without one is filed under the empty locale, so ask for that when the device's language has no bundle of its own:

```
// the bundle id is the .properties base name, not the directory: the
// archetype ships common/src/main/l10n/Bundle.properties
Hashtable<String, String> bundle = res.getL10N("Bundle", local);
if (bundle == null) {
    // a file with no _locale suffix is filed under the empty locale,
    // and getL10N is an exact lookup that will not fall back for you
    bundle = res.getL10N("Bundle", "");
}
UIManager.getInstance().setBundle(bundle);
```

The device language (as an ISO 639 two-letter code) could be retrieved with this:

```
String local = L10NManager.getInstance().getLanguage();
```

Once installed a resource bundle takes over the UI and every string set to a label (and label like components) will be automatically localized based on the bundle. You can also use the localize method of UIManager [https://www.codenameone.com/javadoc/com/codename1/ui/plaf/UIManager.html] to perform localization on your own:

```
UIManager.getInstance().localize( "KeyInBundle", "DefaultValue");
```

The list of available languages in the resource bundle could be retrieved like this. Notice that this a list that was set by you and doesn't need to confirm to the ISO language code standards:

```
Resources res = fetchResourceFile();
Enumeration locales = res.listL10NLocales("Bundle");
```

An exception for localization is the `TextField`/`TextArea` components both of which contain user data, in those cases the text won't be localized to avoid accidental localization of user input.

You can export and import resource bundles as standard Java properties files, CSV and XML. The formats are pretty standard for most localization shops, the XML format Codename One supports is the one used by Android's string bundles which

> means most localization specialists should localize it

The resource bundle is a map between keys and values for example: the code below displays "`This Label is localized`" on the `Label` with the hardcoded resource bundle. It would work the same with a resource bundle loaded from a resource file:

```
Form hi = new Form("L10N", new BoxLayout(BoxLayout.Y_AXIS));
HashMap<String, String> resourceBudle = new HashMap<String, String>();
resourceBudle.put("Localize", "This Label is localized");
UIManager.getInstance().setBundle(resourceBudle);
hi.add(new Label("Localize"));
hi.show();
```

Figure 363. Localized label

88.4.1. Localization manager

The L10NManager [https://www.codenameone.com/javadoc/com/codename1/l10n/L10NManager.html] class includes a multitude of features useful for common localization tasks.

It allows formatting numbers/dates & time based on platform locale. It also provides a great deal of the information you need such as the language/locale information you need to pick the proper resource bundle:

```
Form hi = new Form("L10N", new TableLayout(16, 2));
L10NManager l10n = L10NManager.getInstance();
// the parsers take locale-formatted input -- a hard coded "34.35" is
// read as 3435 anywhere "." groups digits -- so round-trip the
// formatters' own output
String localeDouble = l10n.format(34.35);
String localeCurrency = l10n.formatCurrency(33.77);
hi.add("format(double)").add(l10n.format(11.11)).
    add("format(int)").add(l10n.format(33)).
    add("formatCurrency").add(l10n.formatCurrency(53.267)).
    add("formatDateLongStyle").add(l10n.formatDateLongStyle(new Date())).
    add("formatDateShortStyle").add(l10n.formatDateShortStyle(new Date())).
    add("formatDateTime").add(l10n.formatDateTime(new Date())).
    add("formatDateTimeMedium").add(l10n.formatDateTimeMedium(new Date())).
    add("formatDateTimeShort").add(l10n.formatDateTimeShort(new Date())).
    add("getCurrencySymbol").add(l10n.getCurrencySymbol()).
    add("getLanguage").add(l10n.getLanguage()).
    add("getLocale").add(l10n.getLocale()).
    add("isRTLLocale").add("" + l10n.isRTLLocale()).
    add("parseCurrency").add(l10n.formatCurrency(l10n.parseCurrency(localeCurrency))).
    add("parseDouble").add(l10n.format(l10n.parseDouble(localeDouble))).
    add("parseInt").add(l10n.format(l10n.parseInt("56"))).
    add("parseLong").add("" + l10n.parseLong("4444444"));
```

```
hi.show();
```

Figure 364. Localization formatting/parsing and information

88.4.2. RTL/Bidi

RTL stands for right to left, in the world of internationalization it refers to languages that are written from right to left (Arabic, Hebrew, Syriac, Thaana).

Most western languages are written from left to right (LTR), but some languages are written from right to left (RTL) speakers of these languages expect the UI to flow in the opposite direction otherwise it seems weird like reading this word would be to most English speakers: "drieW."

The problem posed by RTL languages is known as BiDi (Bi-directional) and not as RTL since the "true" problem isn't the reversal of the writing/UI but rather the mixing of RTL and LTR together. For example: numbers are always written from left to right (like in English) so in an RTL language the direction is from right to left and once you reach a number or English text embedded in the middle of the sentence (such as a name) the direction switches for a duration and is later restored.

The main issue in the Codename One world is in the layouts, which need to reverse on the fly. Codename One supports this through an RTL flag on all components that's derived from the global `RTL` flag in UIManager [https://www.codenameone.com/javadoc/com/codename1/ui/plaf/UIManager.html].

Resource bundles can also include special case constant @rtl, which indicates if a language is written from right to left. This allows everything to automatically reverse.

When in `RTL` mode the UI will be the exact mirror so `WEST` will become `EAST`, `RIGHT` will become `LEFT` and this would be true for paddings/margins as well.

If you have a special case where you don't want this behavior you will need to wrap it with an `isRTL` check. You can also use `setRTL` on a per `Component` basis to disable RTL behavior for a specific `Component`.

Most UI APIs have special cases for BiDi instead of applying it globally for example: AWT introduced constants such as `LEADING` instead of making `WEST` mean the opposite direction. You think that was a mistake since the cases where you wouldn't want the behavior of automatic reversal are rare.

Codename One's support for bidi includes the following components:

- **Bidi algorithm** - allows converting between logical to visual representation for rendering
- **Global RTL flag** - default flag for the entire application indicating the UI should flow from right to left
- **Individual RTL flag** - flag indicating that the specific component/container should be presented as an RTL/LTR component (for example: for displaying English elements within an RTL UI).
- **RTL text field input**

Most of Codename One's RTL support is under the hood, the LookAndFeel [https://www.codenameone.com/javadoc/com/codename1/ui/plaf/LookAndFeel.html] global RTL flag can be enabled using:

```
UIManager.getInstance().getLookAndFeel().setRTL(true);
```

Once RTL is activated all positions in Codename One become reversed and the UI becomes a mirror of itself. For example: Adding a `Toolbar` command to the left will actually make it appear on the right. Padding on the left becomes padding on the right. The scroll moves to the left etc.

This applies to the layout managers (except for group layout) and most components. Bidi is seamless in Codename One but a developer still needs to be aware that his UI might be mirrored for these cases.

88.4.3. Localizing native iOS strings

Some strings in iOS need to be localized using iOS's native mechanisms - namely providing **.lproj* directories with *.strings* files. For example, if you want the app to have a different bundle display name for each language, or you want to translate the "UsageDescription" strings of your Info.plist into many languages, you would need to use iOS' native localization facilities [https://developer.apple.com/localization/].

Example: Localizing the app name

The app name, as it's displayed to the user, is defined in using the *CFBundleDisplayName* key of the app's Info.plist file., this will be automatically set to your app's display name, as defined in your *codenameone_settings.properties* file. This works fine if your app will have the same name in every locale, but suppose you want your app to take on a different name in French than in English. For example: You want your app to be called "Hello App" for English-speaking users, and "Bonjour App" for French-speaking users.

In this case, you need to add iOS localization bundles "en.lproj" and `fr.lproj`, each with a file named `InfoPlist.strings`. If you're using Maven, then you can add these directly inside the *ios/src/main/strings* directory of your project.

You will need to create the *strings* directory manually, if it doesn't exist yet.

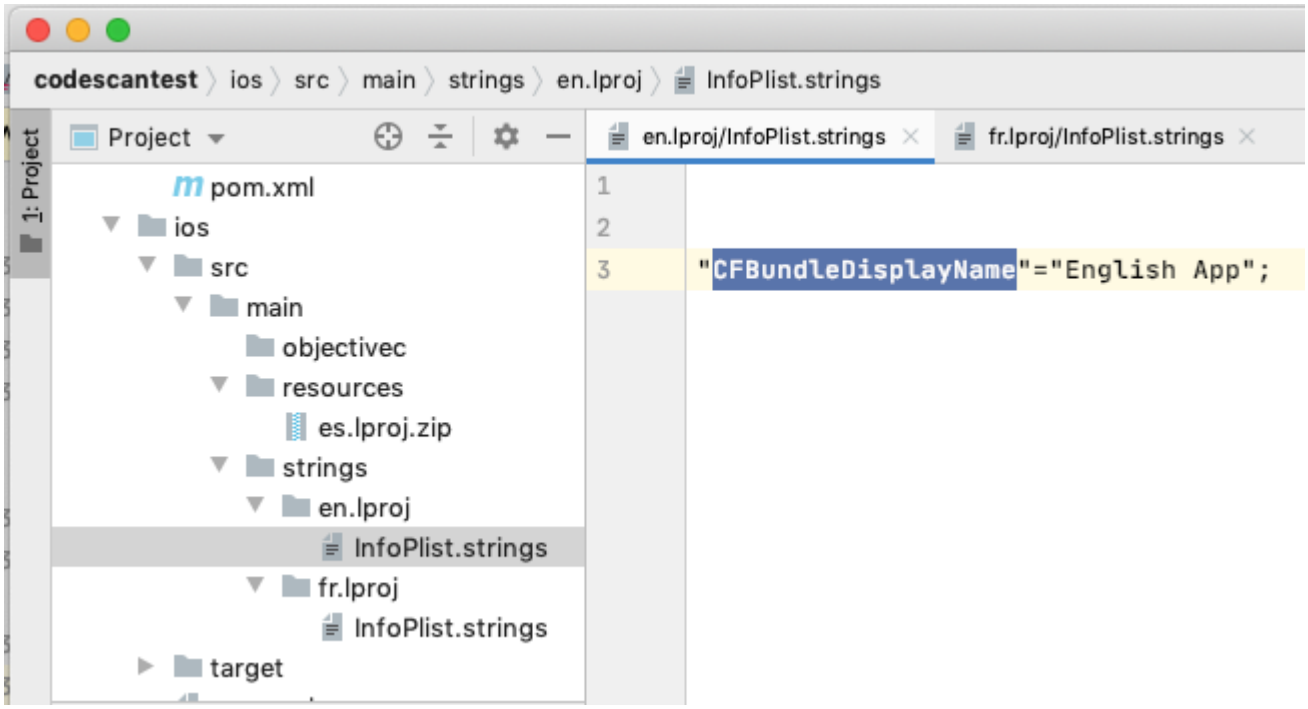

Figure 365. Maven project with English, French, and Spanish localizations for Info.plist. English and French language bundles are contained in the ios/src/main/strings directory. The Spanish bundle is included as a zip file in ios/src/main/resources. Both methods are supported (zipped in resources and unzipped in strings).

Listing 21. ios/src/main/strings/en.lproj/InfoPlist.strings

```
"CFBundleDisplayName"="Hello App";
```

Listing 22. ios/src/main/strings/en.lproj/InfoPlist.strings

```
"CFBundleDisplayName"="Bonjour App";
```

The *strings* format is like the *properties* file format, except that both the "key" and the "value" must be wrapped in quotes. And if there are many strings, then they must be delimited by a semi-colon `;`.

Legacy Ant Projects

Legacy Ant projects have a different directory structure. They have no equivalent location to the Maven *ios/src/main/strings* directory, but the legacy `ios/src/main/resources` content can be replicated under *native/ios*. To include native iOS localizations in those projects, place zipped versions of your .lproj directories inside the `native/ios` directory. For example, *en.lproj.zip*, *fr.lproj.zip*, etc.

Whenever possible, migrate legacy builds to Maven to take advantage of the modern workflow. See Chapter 2, *Maven Project Workflow* for automated migration options.

Example: Localization app usage description strings

iOS requires you to supply usage descriptions for many features that will be displayed to the user when the app requests permission to use the feature. For example, the NSCameraUsageDescription [https://developer.apple.com/documentation/bundleresources/information_property_list/nscamerausagedescription?language=objc] string must be provided if your app needs to use the camera. You can specify these values as build hints using the pattern `ios.NSXXXUsageDescription=This feature is needed blah blah`. In the `NSCameraUsageDescription` case, you might include the build hint:

```
ios.NSCameraUsageDescription=This app needs to use your camera to scan bar codes
```

These descriptions are embedded in your app's Info.plist file, so they can be localized the same way you localize other Info.plist values - in the localized `InfoPlist.strings` file.

See the above example for instructions on localizing values in the Info.plist file. Then add translations to the `InfoPlist.strings` file for your usage descriptions.

Listing 23. ios/src/main/strings/en.lproj/InfoPlist.strings

```
"CFBundleDisplayName"="Hello App";
"NSCameraUsageDescription"="This app needs to use your camera to scan bar codes";
```

Listing 24. ios/src/main/strings/en.lproj/InfoPlist.strings

```
"CFBundleDisplayName"="Bonjour App";
"NSCameraUsageDescription"="Cette application doit utiliser votre appareil photo pour scanner les codes à barres";
```

88.4.4. Localizing the app icon

Codename One can ship a different launcher icon per locale on iOS and Android by detecting specially named PNG files during the build. Drop your per-locale artwork into `common/src/main/resources` using the convention:

```
cn1_icon_<lang>[_<country>].png
```

`<lang>` is a two-letter ISO 639-1 language code and the optional `<country>` is a two-letter ISO 3166-1 country code. Language is treated as case-insensitive; the country component is normalized to uppercase. A few valid examples:

- `cn1_icon_fr.png`: French (any region)
- `cn1_icon_en_GB.png`: British English
- `cn1_icon_es_MX.png`: Mexican Spanish

Supply a square source image at least 432×432 pixels (the largest size emitted for Android adaptive icons; 1024×1024 is recommended, matching the main app icon); the build resizes it to every target density. A smaller source would be upscaled and look blurry, so the build now fails with a clear

error when it detects an undersized localized icon rather than shipping a soft one. The default app icon continues to be controlled by your `codenameone_settings.properties` file and is used whenever the device locale doesn't match any of the localized variants.

These icons live under `src/main/resources` and Maven copies them into `target/classes` incrementally — it **doesn't** delete the copy when you remove or rename the source file. If you replace a localized icon and still see the old (often blurry) one, run `mvn clean` to clear the stale resource from `target/classes` before rebuilding. The build also fails when it finds an undersized `cn1_icon_*.png` in the compiled output that's about to be bundled and sent to the build server.

At runtime the builders look for a `<lang>_<COUNTRY>` match first, then fall back to a bare `<lang>` match. Providing both (for example `cn1_icon_en.png` plus `cn1_icon_en_GB.png`) lets you give British users a country-specific icon while every other English locale still receives the generic English icon.

Android behavior

On Android the build generates locale-qualified drawable resources at every density so the platform picks the right icon automatically based on the device's current locale:

- `drawable-<lang>[-r<COUNTRY>][-<dpi>]/icon.png` at 36, 48, 72, 96, 128, 144 and 192 pixels for legacy launchers.
- When `android.enableAdaptiveIcons=true` the same variants are also written as `mipmap-<lang>[-r<COUNTRY>]-<dpi>/ic_launcher.png` and `ic_launcher_foreground.png`. The default adaptive background and the `mipmap-anydpi-v26/ic_launcher.xml` definition are reused as-is.

No code changes are required—Android's resource framework switches icons when the locale changes.

When you supply a region-qualified icon (such as `cn1_icon_ar_AE.png`) without a matching language-only variant, the build also emits the **default** (non-localized) icon into `drawable-<lang>/` and the matching `mipmap-*-<lang>/` directories. This barrier is required because Android's resource resolver (API 24+) walks every child of the parent locale when it can't find an exact or parent-language match, and would otherwise pick `ar-rAE` for, say, an `ar-PK` device. The barrier short-circuits that lookup so only devices whose region matches the supplied variant receive the localized icon. If you also ship a language-only file (for example `cn1_icon_ar.png`) it's used as the barrier instead, so you keep full control of the fallback icon for Arabic speakers outside AE.

iOS behavior

iOS doesn't localize launcher icons natively, so Codename One wires up alternate app icons [https://developer.apple.com/documentation/uikit/uiapplication/2806818-setalternateiconname] for you:

- For each detected locale the build generates an `AppIcon_<lang>_<COUNTRY>.appiconset` inside `Images.xcassets` containing the 120×120, 180×180, 152×152 and 167×167 (iPad Pro) PNGs along with a matching `Contents.json`.
- The build adds the matching `ASSETCATALOG_COMPILER_ALTERNATE_APPICON_NAMES` Xcode build setting so `actool` emits a coherent partial `Info.plist` covering both `CFBundlePrimaryIcon` and

`CFBundleAlternateIcons`. The user's `Info.plist` is left untouched; injecting `CFBundleIcons` manually would be dropped during the actool merge and is therefore avoided.

- The `CodenameOne_GLAppDelegate` is patched to call `-[UIApplication setAlternateIconName:completionHandler:]` at launch. The delegate reads `[NSLocale preferredLanguages]`, tries the full `<lang>_<COUNTRY>` key first, then falls back to the language-only key, and clears the alternate icon (reverting to the default) if no variant matches.
- The injection is idempotent and runs before the `ios.afterFinishLaunching` hook, so any custom code you supply via that build hint is unaffected.

IOS displays a system alert the first time an app switches to an alternate icon. This is platform-standard behavior—Codename One can't suppress it.

Tips and troubleshooting

- File names are matched case-insensitively. `cn1_icon_EN_uk.png` is treated the same as `cn1_icon_en_UK.png`.
- Names that don't fit the `<2-letter lang>[_<2-letter country>]` pattern are logged and skipped; the rest of the build continues.
- The original `cn1_icon_*.png` files are removed after processing so they aren't shipped as stray bundle resources.
- To override the default (non-localized) icon, keep using the `Icon` setting in `codenameone_settings.properties` or the `icon` image in `CN1Resource.res`. This feature only adds **alternate** icons for specific locales.

88.5. Location - GPS

The Location [https://www.codenameone.com/javadoc/com/codename1/location/Location.html] API allows you to track changes in device location or the current user position.

The Simulator includes a Location Simulation tool that you can launch to determine the current position of the simulator and debug location events

The most basic usage for the API allows you to fetch a device Location, notice that this API is blocking and can take a while to return:

```
Location position = LocationManager.getLocationManager().getCurrentLocationSync();
```

In order for location to work on iOS you **MUST** define the build hint `ios.locationUsageDescription` and describe why your application needs access to location. Otherwise you won't get location updates!

The `getCurrentLocationSync()` method is good for cases where you need to fetch a current location once and not repeatedly query location. It activates the GPS then turns it off to avoid excessive battery usage. For example, if an application needs to track motion or position over time it should

use the location listener API to track location as such:

Notice that there is a method called `getCurrentLocation()` which will return the current state and might not be right for some cases:

```
class MyListener implements LocationListener {
    public void locationUpdated(Location location) {
        // update UI etc.
    }

    public void providerStateChanged(int newState) {
        // handle status changes/errors appropriately
    }
}
LocationManager.getLocationManager().setLocationListener(new MyListener());
```

On Android location maps to low-level APIs if you disable the usage of Google Play Services. By default location should perform well if you leave the Google Play Services on

88.5.1. Location in the background - geofencing

Polling location is expensive and requires a special permission on iOS. Its also implemented rather differently both in iOS and Android. Both platforms place restrictions on the location API usage in the background.

Because of the nature of background location the API is non-trivial. It starts with the venerable `LocationManager` but instead of using the standard API you need to use `setBackgroundLocationListener`.

Instead of passing a `LocationListener` instance you need to pass a `Class` object instance. This is important because background location might be invoked when the app isn't running and an object would need to be allocated.

Notice that you **shouldn't** perform long operations in the background listener callback. IOS wake-up time is limited to about 10 seconds and the app could get killed if it exceeds that time slice.

Notice that the listener can also send events when the app is in the foreground, so it's recommended to check the app state before deciding how to process this event. You can use `Display.isMinimized()` to determine if the app is running or in the background.

When implementing this make sure that:

- The class passed to the API is a public class in the global scope. Not an inner class or anything like that!
- The class has a public no-argument constructor
- You need to pass it as a class literal for example: `MyClassName.class`. Don't use

`Class.forName("my.package.MyClassName")`!
Class names are problematic since device builds are obfuscated, you should use literals which the obfuscator detects and handles.

The following code demonstrates usage of the `Geofence` API:

```
Geofence gf = new Geofence("test", loc, 100, 100000);

LocationManager.getLocationManager()
        .addGeoFencing(GeofenceListenerImpl.class, gf);
```

The listener it registers looks like this:

```
public class GeofenceListenerImpl implements GeofenceListener {
    @Override
    public void onExit(String id) {
    }

    @Override
    public void onEntered(String id) {
        if(Display.getInstance().isMinimized()) {
            // backgrounded, so there is no form to show a dialog on
            LocalNotification ln = new LocalNotification();
            ln.setId("geofence-welcome");
            ln.setAlertTitle("Welcome");
            ln.setAlertBody("Thanks for arriving!");
            Display.getInstance().scheduleLocalNotification(ln,
                    System.currentTimeMillis() + 10, LocalNotification.REPEAT_NONE);
        } else {
            Display.getInstance().callSerially(() -> {
                Dialog.show("Welcome", "Thanks for arriving", "OK", null);
            });
        }
    }
}
```

Android background location permissions (API 30+)

On Android 11 (API level 30) and higher, requesting background location permission requires a two-step process. First, foreground location permissions must be granted. Then, the app must request background location access, which will direct the user to the system settings to select `Allow all the time`. Codename One handles this flow automatically when you use `LocationManager`.

For Android 11+ (API 30+), Codename One detects if background location is needed and presents a dialog explaining the need before redirecting the user to the app settings. You can customize both dialogs through localization keys under `android.permission.ACCESS_BACKGROUND_LOCATION`. The first one, offering to open the settings screen, takes its body from the bare key and its title and buttons from `.title`, `.settings` and `.cancel`. The second, shown after the user comes back, uses

`.explanation_title`, `.explanation_body` and `.ok`:

```
// the port reads these through UIManager.localize(). There is only one
// bundle, so add to the installed one rather than replacing it -- a
// fresh map here would drop every other localized string in the app.
// setBundle keeps whatever map it was handed, so the installed one may
// be immutable -- copy before adding
java.util.Map<String, String> installed = UIManager.getInstance().getBundle();
java.util.Map<String, String> bundle = installed == null
        ? new java.util.HashMap<String, String>()
        : new java.util.HashMap<String, String>(installed);
// the bare key is the body of the first prompt; the suffixed ones
// dress the follow-up dialog that sends the user to settings
bundle.put("android.permission.ACCESS_BACKGROUND_LOCATION",
        "Reminders need your location while the app is closed.");
bundle.put("android.permission.ACCESS_BACKGROUND_LOCATION.title",
        "Location needed");
bundle.put("android.permission.ACCESS_BACKGROUND_LOCATION.explanation_body",
        "Choose \"Allow all the time\" so reminders still arrive when the app is closed.");
bundle.put("android.permission.ACCESS_BACKGROUND_LOCATION.explanation_title",
        "One more step");
bundle.put("android.permission.ACCESS_BACKGROUND_LOCATION.settings", "Open settings");
bundle.put("android.permission.ACCESS_BACKGROUND_LOCATION.ok", "Done");
bundle.put("android.permission.ACCESS_BACKGROUND_LOCATION.cancel", "Not now");
UIManager.getInstance().setBundle(bundle);
```

88.5.2. One-time location - the location button

Google Play draws a line between two ways an application uses precise location. Tracking, navigation and geofencing are ongoing, and an application that does them holds `ACCESS_FINE_LOCATION` and declares why. A transactional use is different: finding restaurants nearby, filling in an address, tagging a photo. For those, applications that target Android 17 (API level 37) must let the user share their location through a button that the **system** draws, and the deadline is January 27, 2027.

`LocationButton` is that control:

```
LocationButton locationButton =
        new LocationButton(LocationButton.TEXT_USE_PRECISE_LOCATION);
locationButton.addLocationSharedListener(loc -> {
    if (loc == null) {
        status.setText("Location not shared");
    } else {
        status.setText(loc.getLatitude() + ", " + loc.getLongitude());
    }
    status.getParent().revalidate();
});
root.add(locationButton);
```

The listener is called once the user has answered, with a `Location` or with `null`. `null` means the user declined, or that no fix arrived before the button's timeout. A platform control that fails to open isn't reported this way: the component replaces it with the ordinary button, so the user is asked again there rather than told no. `isSystemRendered()` is how to see that happened.

Where the system draws it, and where it doesn't

On Android 17 and later this component **is** the system's control. Another process renders it, and the application can neither change its wording nor intercept its taps. That's the point: a tap on a button the system drew is what earns the session-scoped grant, so the application never has to hold precise location permanently.

Everywhere else — on Android below API level 37, on iOS, on the desktop and in the simulator — the component is an ordinary Codename One button that asks for the location permission the usual way, styled through the `LocationButton` UIID like any other component. Your code is the same either way. `isSystemRendered()` on the button tells you which of the two it ended up with, for an application that wants to word something differently around it. It answers for that button rather than for the platform, so it's also false on an Android 17 device where the system control failed to open and the component fell back. To ask the platform question before you build anything, use `Display.getInstance().isLocationButtonSupported()`.

The label comes from the text type you pass to the constructor, one of `TEXT_NONE`, `TEXT_PRECISE_LOCATION`, `TEXT_USE_PRECISE_LOCATION`, `TEXT_SHARE_PRECISE_LOCATION`, `TEXT_NEAR_MY_PRECISE_LOCATION` or `TEXT_NEAR_YOUR_PRECISE_LOCATION`. `setButtonBackgroundColor()` and `setButtonTextColor()` reach the system control; the fallback button follows the theme.

Permissions

Nothing to configure. Referencing `LocationButton` makes the Android build add `USE_LOCATION_BUTTON` to the manifest, which the platform requires before it will render the control.

The build also decides how to declare `ACCESS_FINE_LOCATION`. An application that uses the button and nothing else from the location or maps packages gets it declared `onlyForLocationButton`, which means the system grants precise location through the button and never any other way: no "allow precise location" question, nothing held between taps, and nothing to justify to Google Play. An application that also tracks, navigates or geofences needs the ordinary grant and gets the ordinary declaration. The class scan the build already runs answers this, so neither case needs a build hint.

The one thing it can't see is native Android code reaching the platform's location APIs directly, because Gradle compiles that after the decision is made. An application like that declares itself:

```
codename1.arg.android.locationButton.exclusive=false
```

`true` forces the restriction on and `false` forces it off; the default, `auto`, infers it. Force it off when native code needs the ordinary grant — the failure is otherwise silent, with location requests coming back approximate rather than refusing.

One consequence is worth knowing. The restriction is what it says: precise location comes through the button and no other way. On an application that carries it, the fallback described above can't

recover precise location — if the system control fails to open, the ordinary button that replaces it asks a question the system won't answer with precise access, and the listener receives an approximate location or none. That's the bargain the restriction makes, and it's the right one for an application whose only use of precise location is the button; it's another reason not to force it on for an application that reaches precise location some other way.

88.6. Background music playback

Codename One supports playing music in the background (for example: when the app is minimized) which is useful for developers building a music player style application.

This support isn't totally portable since the Android and iOS approaches for background music playback differ a great deal. To get this to work on Android you need to use the API: `MediaManager.createBackgroundMedia()`.

You should use that API when you want to create a media stream that will work even when your app is minimized.

For iOS you will need to use a special build hint: `ios.background_modes=music`.

Which should allow background playback of music on iOS and would work with the `createBackgroundMedia()` method.

88.7. Capture - photos, video, audio

The capture API allows you to use the camera to capture photographs or the microphone to capture audio. It even includes an API for video capture.
The API itself couldn't be simpler:

```
String filePath = Capture.capturePhoto();
```

Just captures and returns a path to a photo you can either open it using the Image [https://www.codenameone.com/javadoc/com/codename1/ui/Image.html] class or save it somewhere.

The returned file is a temporary file, you shouldn't store a reference to it and instead copy it locally or work with the `Image` object

For example: you can copy the `Image` to `Storage` using:

```
String filePath = Capture.capturePhoto();
if(filePath != null) {
    Util.copy(FileSystemStorage.getInstance().openInputStream(filePath), Storage.getInstance().createOutputStream
(myImageFileName));
}
```

When running on the simulator the `Capture` API opens a file chooser API instead of physically capturing the data. This makes debugging device or situation specific

> issues simpler

You can capture an image from the camera using an API like this:

```
Form hi = new Form("Capture", new BorderLayout());
hi.setToolbar(new Toolbar());
Style s = UIManager.getInstance().getComponentStyle("Title");
FontImage icon = FontImage.createMaterial(FontImage.MATERIAL_CAMERA, s);

ImageViewer iv = new ImageViewer(icon);

hi.getToolbar().addCommandToRightBar("", icon, (ev) -> {
    String filePath = Capture.capturePhoto();
    if(filePath != null) {
        try {
            DefaultListModel<Image> m = (DefaultListModel<Image>)iv.getImageList();
            Image img = Image.createImage(filePath);
            if(m == null) {
                m = new DefaultListModel<>(img);
                iv.setImageList(m);
                iv.setImage(img);
            } else {
                m.addItem(img);
            }
            m.setSelectedIndex(m.getSize() - 1);
        } catch(IOException err) {
            Log.e(err);
        }
    }
});

hi.add(BorderLayout.CENTER, iv);
hi.show();
```

Figure 366. Captured photos previewed in the ImageViewer

You show video capture in the MediaManager section.

The sample below captures audio recordings (using the 'Capture' API) and copies them locally

under unique names. It also demonstrates the storage and organization of captured audio:

```
Form hi = new Form("Capture", BoxLayout.y());
hi.setToolbar(new Toolbar());
Style s = UIManager.getInstance().getComponentStyle("Title");
FontImage icon = FontImage.createMaterial(FontImage.MATERIAL_MIC, s);

FileSystemStorage fs = FileSystemStorage.getInstance();
String recordingsDir = fs.getAppHomePath() + "recordings/";
fs.mkdir(recordingsDir);
try {
    for(String file : fs.listFiles(recordingsDir)) {
        MultiButton mb = new MultiButton(file.substring(file.lastIndexOf("/") + 1));
        mb.addActionListener((e) -> {
            try {
                Media m = MediaManager.createMedia(recordingsDir + file, false);
                m.play();
            } catch(IOException err) {
                Log.e(err);
            }
        });
        hi.add(mb);
    }

    hi.getToolbar().addCommandToRightBar("", icon, (ev) -> {
        try {
            String file = Capture.captureAudio();
            if(file != null) {
                SimpleDateFormat sd = new SimpleDateFormat("yyyy-MMM-dd-kk-mm");
                String fileName =sd.format(new Date());
                String filePath = recordingsDir + fileName;
                Util.copy(fs.openInputStream(file), fs.openOutputStream(filePath));
                MultiButton mb = new MultiButton(fileName);
                mb.addActionListener((e) -> {
                    try {
                        Media m = MediaManager.createMedia(filePath, false);
                        m.play();
                    } catch(IOException err) {
                        Log.e(err);
                    }
                });
                hi.add(mb);
                hi.revalidate();
            }
        } catch(IOException err) {
            Log.e(err);
        }
    });
} catch(IOException err) {
    Log.e(err);
```

```
}
hi.show();
```

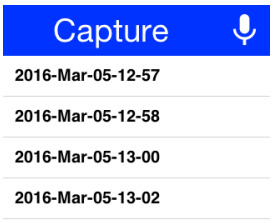

Figure 367. Captured recordings in the demo

You can also record audio through `MediaRecorderBuilder`, which describes a recording by path, MIME type, sample rate, bit rate and channel count instead of handing the job to the platform's own capture UI.

Build it with `MediaRecorderBuilder.build()`, which passes the whole builder to the platform implementation.

`MediaManager.createMediaRecorder(MediaRecorderBuilder)` accepts the same object, and what it does with it depends on the destination. A builder with `redirectToAudioBuffer(true)` is delegated straight to `build()`, so every setting survives. A builder recording to a file is reduced to its path and MIME type, which drops the sample rate, bit rate and channel count set on it and leaves the platform's defaults in place. A stereo request isn't refused so much as ignored, and what you get is whatever that platform would have recorded anyway.

Call `build()` yourself when those settings matter, bearing in mind how far each port carries them. Android, iOS, the JavaScript port and the simulator implement the builder overload in full. The native Linux and Windows ports implement it too but read only the sampling rate and channel count, their WAV recorders fixing the MIME type and ignoring the bit rate; they also take no notice of `redirectToAudioBuffer(true)`, so asking those two for live PCM writes a file at the builder's path instead. Anywhere else the framework's own fallback reduces the builder to a path and a MIME type again.

How far the settings then travel depends on the port, and on the format. The JavaScript port takes only the path when recording to a file, so a web file recording uses the browser's defaults; recording into an audio buffer it does ask for the sampling rate — though not always. It skips the request on iOS whatever the browser, and on any browser that doesn't advertise the `sampleRate` constraint, so those recordings arrive at the platform's own rate. Elsewhere the whole builder reaches the port, which applies what its codec supports: Android sets the sampling rate and bit rate when encoding AAC and leaves both to the encoder for AMR, and the simulator never reads the bit rate at all.

Treat the builder's numbers as preferences rather than guarantees. An `AudioBuffer` reports `getSampleRate()` for the data it holds — the recorder fills that in from the rate the audio actually arrived at, or from the rate it resampled the audio to, so the figure describes the samples in your

hands.

`getNumChannels()` reports the layout the recorder built, and on the JavaScript port that much is exact: it emits channel 0 alone for a mono request and interleaves left and right for a stereo one, so the count always matches the PCM you hold and you can split the channels by it. It says nothing about the capture, though — the port never submits a channel count to the browser, so a stereo request depends on the input device already providing two channels.

88.7.1. Capture asynchronous API

The `Capture` API also includes a callback based API that uses the `ActionListener` interface to implement capture. For example: you can adapt the previous sample to use this API as such:

```
hi.getToolbar().addCommandToRightBar("", icon, (ev) -> {
    Capture.capturePhoto((e) -> {
        if(e != null && e.getSource() != null) {
            try {
                DefaultListModel<Image> m = (DefaultListModel<Image>)iv.getImageList();
                Image img = Image.createImage((String)e.getSource());
                if(m == null) {
                    m = new DefaultListModel<>(img);
                    iv.setImageList(m);
                    iv.setImage(img);
                } else {
                    m.addItem(img);
                }
                m.setSelectedIndex(m.getSize() - 1);
            } catch(IOException err) {
                Log.e(err);
            }
        }
    });
});
```

88.8. Gallery

The gallery API allows picking an image and/or video from the cameras gallery (camera roll).

Like the `Capture` API the image returned is a temporary image that should be copied locally, this is due to device restrictions that don't allow direct modifications of the gallery

You can adapt the `Capture` sample above to use the gallery as such:

```
Form hi = new Form("Capture", new BorderLayout());
hi.setToolbar(new Toolbar());
Style s = UIManager.getInstance().getComponentStyle("Title");
FontImage icon = FontImage.createMaterial(FontImage.MATERIAL_CAMERA, s);
```

```
ImageViewer iv = new ImageViewer(icon);

hi.getToolbar().addCommandToRightBar("", icon, (ev) -> {
    Display.getInstance().openGallery((e) -> {
        if(e != null && e.getSource() != null) {
            try {
                DefaultListModel<Image> m = (DefaultListModel<Image>)iv.getImageList();
                Image img = Image.createImage((String)e.getSource());
                if(m == null) {
                    m = new DefaultListModel<>(img);
                    iv.setImageList(m);
                    iv.setImage(img);
                } else {
                    m.addItem(img);
                }
                m.setSelectedIndex(m.getSize() - 1);
            } catch(IOException err) {
                Log.e(err);
            }
        }
    }, Display.GALLERY_IMAGE);
});

hi.add(BorderLayout.CENTER, iv);
```

No need for a screenshot as it will look identical to the capture image screenshot above

The last value is the type of content picked which can be one of: `Display.GALLERY_ALL`, `Display.GALLERY_VIDEO` or `Display.GALLERY_IMAGE`.

88.9. Analytics integration

Analytics now has its own chapter. It covers the provider SPI, consent and privacy handling, the built-in providers (the Codename One first-party service, Google Analytics 4, Matomo, Firebase and a logging provider), and how to write your own. See the Analytics chapter.

The `AnalyticsService` class documented here previously is deprecated but still works — it delegates to the new API. The migration table at the end of the Analytics chapter maps each old call to its replacement.

88.10. Social sign-in (Facebook, Google, …)

The legacy Facebook and Google OAuth2 sign-in flows that used to live here drove an embedded `WebBrowser`, which the providers no longer permit. The full sign-in stack — system-browser-based OpenID Connect for any provider, plus Facebook / Google / Microsoft / Apple / Auth0 / Firebase helpers — now lives in the Authentication and Identity chapter.

88.11. Lead Component

Codename One has two basic ways to create new components:

1. Subclass a `Component` override `paint`, implement event callbacks etc.
2. Compose many components into a new component, by subclassing a `Container`.

Components such as Tabs [https://www.codenameone.com/javadoc/com/codename1/ui/Tabs.html] subclass `Container` which make a lot of sense for that component since it's physically a `Container`.

For example, components like MultiButton [https://www.codenameone.com/javadoc/com/codename1/components/MultiButton.html], SpanButton [https://www.codenameone.com/javadoc/com/codename1/components/SpanButton.html] & SpanLabel [https://www.codenameone.com/javadoc/com/codename1/components/SpanLabel.html] don't necessarily seem like the right candidate for compositing but they're all `Container` subclasses.

Using a `Container` provides you a lot of flexibility in layout & functionality for a specific component. `MultiButton` is a great example of that. It's a `Container` internally that's composed of 5 labels and a `Button`.

Codename One makes the `MultiButton` "feel" like a single button through the use of `setLeadComponent(Component)` which turns the button into the "leader" of the component.

When a `Container` hierarchy is placed under a leader all events within the hierarchy are sent to the leader, so if a label within the lead component receives a pointer pressed event this event will be sent to the leader.

For example: for the `MultiButton` the internal button will receive that event and send the action performed event, change the state etc.

This creates some potential issues for instance in `MultiButton`:

```
myMultiButton.addActionListener((e) -> {
    if(e.getComponent() == myMultiButton) {
        // this won't occur since the source component is really a button!
    }
    if(e.getActualComponent() == myMultiButton) {
        // this will happennull
    }
});
```

The leader also determines the style state, so all the elements being lead are in the same state. For example: if the button is pressed all elements will display their pressed states, notice that they will do so with their own styles but they will each pick the pressed version of that style so a `Label` UIID within a lead component in the pressed state would return the Pressed state for a `Label` not for the `Button`.

This is convenient when you need to construct more elaborate UI's and the cool thing about it's that you can do this entirely in the designer which allows assembling containers and defining the lead

component inside the hierarchy.

For example: the `SpanButton` class is like this code:

```
public class SpanButton extends Container {
    private Button actualButton;
    private TextArea text;

    public SpanButton(String txt) {
        setUIID("Button");
        setLayout(new BorderLayout());
        text = new TextArea(getUIManager().localize(txt, txt));
        text.setUIID("Button");
        text.setEditable(false);
        text.setFocusable(false);
        actualButton = new Button();
        addComponent(BorderLayout.WEST, actualButton);
        addComponent(BorderLayout.CENTER, text);
        setLeadComponent(actualButton);
    }

    public void setText(String t) {
        text.setText(getUIManager().localize(t, t));
    }

    public void setIcon(Image i) {
        actualButton.setIcon(i);
    }

    public String getText() {
        return text.getText();
    }

    public Image getIcon() {
        return actualButton.getIcon();
    }

    public void addActionListener(ActionListener l) {
        actualButton.addActionListener(l);
    }

    public void removeActionListener(ActionListener l) {
        actualButton.removeActionListener(l);
    }

}
```

88.11.1. Blocking lead behavior

The `Component` class has two methods that allow you to exclude a component from lead behavior: `setBlockLead(boolean)` & `isBlockLead()`.

Effectively when you have a `Component` within the lead hierarchy that you would like to treat differently from the rest you can use this method to exclude it from the lead component behavior while keeping the rest in line...

This should have no effect if the component isn't a part of a lead component.

The sample below is based on the `Accordion` component which uses a lead component internally:

```
f.getToolbar().addMaterialCommandToRightBar("", FontImage.MATERIAL_ADD, e -> addEntry(accr));
addEntry(accr);
f.add(BorderLayout.CENTER, accr);
f.show();
```

This allows you to add/edit entries but it also allows the delete button above to actually work. Without a call to `setBlockLead(true)` the delete button would cat as the rest of the accordion title.

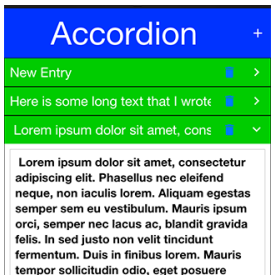

Figure 368. Accordion with delete button entries that work despite the surrounding lead

88.12. Pull to refresh

Pull to refresh is the common UI paradigm that Twitter popularized where the user can pull down the form/container to receive an update. Adding this to Codename One couldn't be simpler!

Just invoke `addPullToRefresh(Runnable)` on a scrollable container (or form) and the runnable method will be invoked when the refresh operation occurs.

Pull to refresh is implicitly implements in the `InfiniteContainer`

```
Form hi = new Form("Pull To Refresh", BoxLayout.y());
hi.getContentPane().addPullToRefresh(() -> {
    hi.add("Pulled at " + L10NManager.getInstance().formatDateTimeShort(new Date()));
});
hi.show();
```

`setPullToRefresh(Runnable)` is provided as a more discoverable alias for the same single-task slot — both names route to the same field, and a second call replaces whatever runnable was

previously registered.

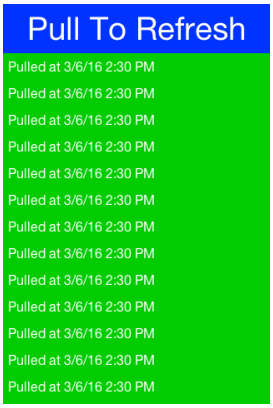

Figure 369. Pull to refresh demo

88.12.1. Modern arc-spinner pull-to-refresh

The legacy pull-to-refresh visual is the classic "rotating arrow + text" stack. Modern Material 3 / iOS apps instead show a thin circular arc that grows as the user pulls and spins once the task fires. This is shipped as an opt-in path via the `pullToRefreshModernBool` theme constant; the iOS Modern and Android Material themes enable it by default so apps shipping against those themes get the spec-accurate look without any extra wiring.

To enable in a custom theme:

```
#Constants {
    pullToRefreshModernBool: true;
    pullToRefreshIndicatorDiameterMm: 8;       /* 8mm circle           */
    pullToRefreshIndicatorStrokeMm: "0.6";     /* 0.6mm stroke thickness */
}

TabIndicator {
    /* The pull-to-refresh arc shares its color with the animated tab
       indicator -- both follow the brand's accent. */
    color: #007aff;
    background-color: transparent;
    padding: 0;
    margin: 0;
}
```

Behavior:

- During the pull gesture the arc sweep grows from 0° to ~330° proportional to how far the user has pulled past the threshold.
- When the refresh task fires the arc rotates continuously at ~360°/sec until the task completes.
- All sizing is in millimetres so the indicator stays physical-size-accurate across device densities; no rasterized images involved.

The legacy `addPullToRefresh` API is unchanged — the same `Runnable` is invoked at the same moment;

only the visual rendering differs.

88.13. Running 3rd party apps using display's execute

The Display [https://www.codenameone.com/javadoc/com/codename1/ui/Display.html] class's `execute` method allows you to invoke a URL which is bound to a particular application.

This works rather well assuming the application is installed. Apple's URL scheme reference [https://developer.apple.com/library/archive/featuredarticles/iPhoneURLScheme_Reference/Introduction/Introduction.html] lists the schemes iOS handles itself, for common applications and built-in functionality.

Some URLs might not be supported if an app isn't installed, on Android there isn't much that can be done but iOS has a `canOpenURL` method for Objective-C.

On iOS you can use the `Display.canExecute()` method which returns a `Boolean` instead of a `boolean` which allows you to support 3 result states:

1. `Boolean.TRUE` - the URL can be executed
2. `Boolean.FALSE` - the URL isn't supported or the app is missing
3. `null` - you've no idea whether the URL will work on this platform.

The sample below launches a "godfather" search on IMDB when this is sure to work (on iOS currently). You can actually try to search for null as well but this sample plays it safe by using the http link which is sure to work:

```
Boolean can = Display.getInstance().canExecute("imdb:///find?q=godfather");
if(can != null && can) {
    Display.getInstance().execute("imdb:///find?q=godfather");
} else {
    Display.getInstance().execute("http://www.imdb.com");
}
```

88.14. Automatic build hint configuration

You try to make Codename One "seamless," this expresses itself in small details such as the automatic detection of permissions on Android etc. The build servers go a long way in setting up the environment as intuitive. However, it isn't enough, build hints are often confusing and obscure. It's hard to abstract the mess that's native mobile OSes and the odd policies from Apple/Google...

A good example for a common problem developers face is location code that doesn't work in iOS. This is due to the `ios.locationUsageDescription` build hint that's required. The reason that build hint was added is a need by Apple to provide a description for every app that uses the location service.

To solve this sort of used case you have two APIs in `Display`:

```
void ensureLocationUsageDescription() {
```

```
    // Both calls only work in the simulator, and setProjectBuildHint throws
    // anywhere else -- so this belongs behind an isSimulator() check, run
    // once during development rather than on every launch.
    if (!Display.getInstance().isSimulator()) {
        return;
    }

    Map<String, String> hints = Display.getInstance().getProjectBuildHints();
    if (hints == null) {
        // No codename1_settings.properties beside the running project, or
        // it could not be read. Nothing to check against, and nothing to
        // write into.
        return;
    }

    String description = hints.get("ios.locationUsageDescription");
    if (description == null || description.length() == 0) {
        Display.getInstance().setProjectBuildHint("ios.locationUsageDescription",
                "Used to show nearby results on the map");
    }
}
```

Both of these allow you to detect if a build hint is set and if not (or if it's set incorrectly) set its value...

If you use the location API from the simulator and you didn't define `ios.locationUsageDescription` Codename One will implicitly define a string there. The cool thing is that you will now see that string in your settings and you would be able to customize it.

For example, this gets way better than that trivial example!

The real value is for 3rd party cn1lib authors. For example: Google Maps or Parse. They can inspect the build hints in the simulator and show an error in case of a misconfiguration. They can even show a setup UI. Demos that need special keys in place can force the developer to set them up before continuing.

88.15. Easy thread

Working with threads is ranked as one of the least intuitive and painful tasks in programming. This is such an error prone task that some platforms/languages took the route of avoiding threads entirely. A typical scenario: you need to convert some code to work on a separate thread but you still want the ability to communicate and transfer data from that thread.

This is possible in Java but non-trivial, the thing is that this is easy to do in Codename One with tools such as `callSerially` that let arbitrary code run on the EDT. Why not offer that to any random thread?

That's why `EasyThread` exists: it takes some concepts of Codename One's threading and makes them more accessible to an arbitrary thread. This way you can move things like resource loading into a

separate thread and synchronize the data back into the EDT as needed...

Easy thread can be created like this:

```
EasyThread e = EasyThread.start("ThreadName");
```

You can send a task to the thread using:

```
e.run(() -> doThisOnTheThread());
```

However, it gets better, say you want to return a value:

```
// the result callback runs on the EasyThread, not the EDT, so anything
// that touches the UI has to be marshalled back explicitly
e.run((success) -> success.onSucess(doThisOnTheThread()),
      (myResult) -> Display.getInstance().callSerially(() -> onEDTGotResult(myResult)));
```

Lets break that down. `(success) → success.onSucess(doThisOnTheThread())` runs on the `EasyThread`, off the EDT, and the result callback runs there too: `EasyThread` hands your `SuccessCallback` straight to the worker and never marshals it. Anything that touches the UI has to be sent back with `callSerially`, which is what the second lambda does.

These asynchronous calls make things a bit painful to wade through, so the API wraps them in a simplified synchronous version:

```
EasyThread e = EasyThread.start("Hi");
int result = e.run(() -> {
    System.out.println("This is a thread");
    return 3;
});
// the worker stays alive waiting for more work, so release it when the
// thread has nothing left to do
e.killWhenIdle();
```

There are a few other variants like `runAndWait` and there is a `kill()` method which stops a thread and releases its resources.

88.16. Mouse cursor

Codename one can change the mouse cursor when hovering over specific areas to show resizability, movability etc. For obvious reasons this feature is available in the desktop and JavaScript ports as the other ports rely on touch interaction. The feature is off by default and needs to be enabled on a `Form` by using `Form.setEnableCursors(true);`. If you're writing a custom component that can use cursors such as `SplitPane` you can use:

```
@Override
protected void initComponent() {
    super.initComponent();
    getComponentForm().setEnableCursors(true);
}
```

Once this is enabled you can set the cursor over a specific region using `cmp.setCursor()` which accepts one of the cursor constants defined in `Component`.

88.17. Working with git

A generated Maven project ships a `.gitignore` for its build output — `target`, `build`, and the RAD schema generated under `common/src/main/rad`. It says nothing about your editor, and that's deliberate, because most of what sits in those directories belongs to the project rather than to you. The archetype generates `.idea` and `.vscode` itself, including run configurations for the debug proxy, on-device debugging and the certificate wizard, and a CodeRAD project needs `common/.settings/org.eclipse.m2e.apt.prefs` before Eclipse will run the annotation processor. Commit those.

The part worth ignoring is the narrow set that records what you personally had open, chiefly `.idea/workspace.xml`, `.idea/shelf/` and `*.iml`. That set is the same in every project you work on, which makes it a good fit for a global ignore file rather than a per-project one — `git config --global core.excludesFile ~/.gitignore_global`, with the patterns in the file it names.

The theme used to be the hard part here, because a `.res` is a binary that git can't diff, and two people editing one produce a conflict no merge tool can resolve. A Maven project doesn't have that problem. The theme's source is `common/src/main/css/theme.css`, and the `.res` is compiled out of it into `target/classes` on each build, so what's under version control is text and the binary is an artifact the `.gitignore` above already excludes.

That leaves the resource editor's **File → XML Team Mode**, which writes a matching `res/theme.xml` tree beside a resource file so its contents diff and merge like source. It's on by default, but it only fires for the older Ant layout, because `saveXML` wants the resource's own directory to be named `src` with `codenameone_settings.properties` beside it, and no Maven source path looks like that. Expect to meet it in an inherited project rather than to adopt it in a new one.

AI and agents

Chapter 89. AI, Chat UI, and Speech

Codename One ships a portable LLM client, a streaming chat component, speech-to-text and text-to-speech APIs, built-in vision and language services, and a portable LiteRT inference API. The builders add native frameworks and dependencies when application bytecode references the corresponding entry point.

This chapter introduces every piece in turn:

- `com.codename1.ai` — provider-agnostic chat, embeddings, tool calls, and image generation.
- `com.codename1.components.ChatView` — a theme-aware chat surface that streams tokens in place.
- `com.codename1.media.SpeechRecognizer` and `com.codename1.media.TextToSpeech` — on-device speech-to-text and speech synthesis.
- `com.codename1.security.SecureStorage` non-prompting overloads — silent reads for secrets the network layer needs on every call, such as LLM API keys.
- `com.codename1.ai.vision` — OCR, barcode, face, labeling, pose, segmentation, document correction, and camera-frame pipelines.
- `com.codename1.ai.inference` — reusable LiteRT sessions for `.tflite` models.
- `com.codename1.ai.language` — language identification, translation, and smart reply.

Each async call in this chapter returns an `com.codename1.util.AsyncResource`. Use `.ready(…)` for the success path, `.except(…)` for errors, and `.cancel()` to abort an in-flight request. The streaming chat call also dispatches deltas through a `StreamingListener`; both listener callbacks and `ready` callbacks fire on the EDT.

89.1. The `com.codename1.ai` package

The `LlmClient` class is the single entry point. Static factories return a configured client for each supported provider. Every client speaks the same `ChatRequest` and `ChatResponse` value types, so the call site does not change when you swap providers:

```
// OpenAI (also drives Ollama, vLLM, llama.cpp, and other
// OpenAI-compatible endpoints).
LlmClient openai = LlmClient.openai(apiKey);

// Local Ollama on the default port (http://localhost:11434).
LlmClient ollama = LlmClient.ollama("llama3.2");

// Any OpenAI-compatible endpoint (Together, Groq, Fireworks, vLLM, null).
LlmClient together = LlmClient.localOpenAiCompatible(
        "https://api.together.xyz/v1",
        apiKey,
        "meta-llama/Llama-3.3-70B-Instruct-Turbo");

// Anthropic and Google Gemini, both via their OpenAI-compatible
```

```
// endpoints. The wire format is identical; only the base URL,
// default model, and auth differ.
LlmClient anthropic = LlmClient.anthropic(apiKey);
LlmClient gemini = LlmClient.gemini(apiKey);
```

All five factories return the same `LlmClient` API. OpenAI, Ollama, vLLM, and `llama.cpp` share the canonical wire format. Anthropic's `https://api.anthropic.com/v1/chat/completions` and Google's `https://generativelanguage.googleapis.com/v1beta/openai/chat/completions` implement the same shape, so the framework speaks to all three through one network layer. Default models pick a sensible production-grade target per provider (`gpt-4o-mini`, `claude-sonnet-4-5`, `gemini-2.0-flash`, `llama3.2`); override per request with `ChatRequest.builder().model(…)`.

89.1.1. A first chat

`ChatRequest` is a builder. The bare minimum is a model identifier and one user message:

```
ChatRequest req = ChatRequest.builder()
        // No model named: the request uses the client's default, which
        // LlmClient#setDefaultModel sets and the simulator's Ollama
        // redirect sets for you. Naming a cloud model here would ask a
        // local server for one it has never heard of.
        .addMessage(ChatMessage.system("Reply in haiku."))
        .addMessage(ChatMessage.user("Describe a Codename One app."))
        .temperature(0.7f)
        .maxTokens(200)
        .build();

openai.chat(req).ready(resp -> {
    Dialog.show("Reply", resp.getText(), "OK", null);
}).except(err -> {
    Log.e(err);
});
```

`ChatResponse.getText()` concatenates every text part of the assistant message. `getFinishReason()` returns one of `"stop"`, `"length"`, `"tool_calls"`, `"content_filter"`, or `"error"`. `getUsage()` returns prompt, completion, and total token counts when the provider reports them; the fields return -1 when the provider omits them.

89.1.2. Streaming tokens

`chatStream(…)` opens an SSE connection and dispatches deltas through a `StreamingListener` on the EDT. The returned `AsyncResource` resolves to the final aggregated `ChatResponse` when the stream completes; calling `cancel()` on the resource closes the underlying socket:

```
StringBuilder buffer = new StringBuilder();

// Open the assistant bubble first. appendToLastMessage() writes to
// whichever bubble is newest, which is nothing at all on a fresh view
```

```
// and the user's own message once one has been added.
ChatBubble streaming = chatView.beginAssistantStream();

openai.chatStream(req, new StreamingListener.Adapter() {
    @Override
    public void onContentDelta(String delta) {
        buffer.append(delta);
        streaming.appendText(delta);
    }

    @Override
    public void onError(Throwable t) {
        Log.e(t);
    }
}).ready(resp -> {
    // getUsage() is null when the provider omits token accounting, which
    // OpenAI-compatible endpoints commonly do.
    if (resp.getUsage() != null) {
        Log.p("Total tokens: " + resp.getUsage().getTotalTokens());
    }
});
```

The decoder reassembles fragmented SSE deltas before invoking the listener, so `onContentDelta` always receives a complete token chunk. Tool-call fragments are reassembled the same way and surfaced through `onToolCallDelta(index, id, name, argumentsFragment)`; `name` is non-null on the first fragment and `id` is present on the first call.

89.1.3. Tool calling

`Tool` describes a callable function with a JSON schema. Pass a `ToolHandler` to make it executable; the model can then call the tool and the handler returns the JSON result that gets fed back into the conversation:

```
Tool weather = new Tool(
        "get_weather",
        "Return the current weather for a city.",
        "{\"type\":\"object\",\"properties\":{" +
            "\"city\":{\"type\":\"string\"}}," +
            "\"required\":[\"city\"]}",
        argumentsJson -> {
            Map<String, Object> args = JSONParser.parseJSON(argumentsJson);
            // Serialize rather than concatenate: the city is a value the
            // model produced, and a quote or backslash in it would emit
            // malformed JSON that cannot be sent back as a tool result.
            Map<String, Object> result = new HashMap<String, Object>();
            result.put("tempC", Integer.valueOf(22));
            result.put("city", args.get("city"));
            return JSONParser.toJson(result);
        });
```

```
ChatRequest req = ChatRequest.builder()
        // No model named: the client's default applies, which the
        // simulator's Ollama redirect sets for you. Naming a cloud model
        // asks a local server for one it does not have.
        .addMessage(ChatMessage.user("What is the weather in Tel Aviv?"))
        .tools(Collections.singletonList(weather))
        .toolChoice(ToolChoice.AUTO)
        .build();

openai.chat(req).ready(resp -> {
    if (resp.getToolCalls().isEmpty()) {
        // ToolChoice.AUTO lets the model answer without reaching for a
        // tool, and that answer is this response. There is nothing to
        // send back.
        Log.p(resp.getText());
        return;
    }

    // Otherwise the response is the model asking for the tools, not the
    // answer. Run every call it asked for, then send the conversation
    // back once with a result for each: the assistant message names all
    // of them, and a follow-up carrying only some is rejected as an
    // incomplete tool-call sequence.
    ChatRequest.Builder followUp = ChatRequest.builder()
            .addMessage(ChatMessage.user("What is the weather in Tel Aviv?"))
            .addMessage(resp.getAssistantMessage());
    for (ToolCall call : resp.getToolCalls()) {
        try {
            String result = call.execute(Collections.singletonList(weather));
            followUp.addMessage(ChatMessage.toolResult(call.getId(), result));
        } catch (Exception err) {
            // execute() runs your own handler, so it can fail for any
            // reason, and this callback has nowhere to propagate to.
            // The turn still needs a result for this id.
            Log.e(err);
            followUp.addMessage(ChatMessage.toolResult(call.getId(),
                    "{\"error\": \"the tool failed\"}"));
        }
    }
    openai.chat(followUp.build()).ready(answer -> Log.p(answer.getText()));
});
```

`ToolChoice` covers the four standard modes:

- `ToolChoice.AUTO` — the model picks at will (default).
- `ToolChoice.NONE` — the model must not call any tool.
- `ToolChoice.REQUIRED` — the model must call exactly one tool.
- `ToolChoice.named("get_weather")` — force a specific tool.

89.1.4. Structured output

Constrain a response to JSON with `ResponseFormat.JSON_OBJECT`. The client adds the provider-specific flag, and `ChatResponse.getText()` returns a string the runtime can hand to `JSONParser`:

```
ChatRequest req = ChatRequest.builder()
        // No model named: the client's default applies, and the
        // simulator's Ollama redirect sets that for you. Naming a
        // cloud model asks a local server for one it lacks.
        .responseFormat(ResponseFormat.JSON_OBJECT)
        .addMessage(ChatMessage.system(
            "Return a JSON object with keys city and population."))
        .addMessage(ChatMessage.user("Tel Aviv"))
        .build();
```

89.1.5. Multi-modal messages

Attach an image to a user message by adding an `ImagePart`. The part accepts either inline bytes plus a MIME type or a remote HTTPS URL:

```
ImagePart photo = new ImagePart(receiptBytes, "image/jpeg");
ChatMessage msg = ChatMessage.userWithImage(
        "Extract the line items from this receipt.", photo);

ChatRequest req = ChatRequest.builder()
        // No model named: the client's default applies, and the
        // simulator's Ollama redirect sets that for you. This request
        // carries an image, so whichever default is in play has to
        // accept one -- the redirect's own default is text-only, so
        // point cn1.ai.ollamaModel at a vision-capable model to run
        // this locally.
        .addMessage(msg)
        .build();
```

89.1.6. Embeddings

`embed(EmbeddingRequest)` returns one `Embedding` vector per input. Use the vectors for semantic search, deduplication, or downstream clustering:

```
EmbeddingRequest req = EmbeddingRequest.builder()
        // Embeddings need an embedding model, and the client carries a
        // single default that is normally a chat one -- so name it here.
        // Against a local Ollama, name an embedding model you pulled.
        .model("text-embedding-3-small")
        .addInput("a cat sat on the mat")
        .addInput("a feline rested on the rug")
        .build();
```

```
openai.embed(req).ready(resp -> {
    float[] v0 = resp.getData().get(0).getVector();
    float[] v1 = resp.getData().get(1).getVector();
    // Compute cosine similarity, persist to Storage, etc.
});
```

89.1.7. Image generation

`ImageGenerator` mirrors the LLM client shape. The OpenAI factory drives DALL-E 3 today; the on-device factory routes through the optional `cn1-ai-stablediffusion` cn1lib (when present in the consumer project):

```
// Through your own endpoint, as the credentials section requires:
// ImageGenerator.openai(apiKey) would put the billable provider key on
// the device. ImageGenerator.onDevice() is the other option, and needs
// the cn1-ai-stablediffusion cn1lib.
ImageGenerator gen = ImageGenerator.openAiCompatible(
        "https://api.example.com/ai/v1", sessionToken);
GenerateImageRequest req = new GenerateImageRequest(
        "A pastel watercolor of a Tel Aviv beach at sunset");
req.setSize("1024x1024");
req.setQuality("hd");

gen.generate(req).ready(image -> {
    Label preview = new Label(image);
    Display.getInstance().getCurrent().add(preview).revalidate();
});
```

DALL-E 3 supports `count = 1` only. Larger batches require a different underlying model; pass it via `setModel(…)`.

89.1.8. Conversation persistence

`ConversationStore` wraps `Storage` to serialize a list of `ChatMessage` values to JSON under a named key:

```
ConversationStore store = new ConversationStore("chat-history");
List<ChatMessage> history = store.load();        // empty list on first call

history.add(ChatMessage.user("Hello"));
ChatResponse resp = openai.chat(
        ChatRequest.builder().messages(history).build())
    .get();                                       // blocking helper, EDT-safe
history.add(resp.getAssistantMessage());
store.save(history);
```

`Tokenizer.estimateMessages(history)` returns a rough token count so you can trim the oldest turns

before the conversation outgrows the model's context window.

89.1.9. Prompt templates

`PromptTemplate` does simple `{placeholder}` substitution. Unknown placeholders pass through unchanged so partially-filled templates are safe to log:

```
PromptTemplate t = PromptTemplate.of(
        "Translate the following from {source} to {target}: {text}");
t.put("source", "English");
t.put("target", "French");
t.put("text", "good morning");

ChatMessage user = t.asUser();                    // wraps the rendered string
```

89.1.10. Retry policy

`RetryPolicy.exponentialBackoff()` returns a sensible default (four attempts, 500ms initial delay, 30s cap, jitter). Wrap any chat call in a retry loop yourself, or attach the policy to a higher-level wrapper. `LlmException.getRetryAfterSeconds()` returns the provider's `Retry-After` header value when present, or -1, so the policy can honor rate-limit hints.

89.1.11. Simulator redirect for offline development

The JavaSE simulator pings `localhost:11434` at startup. When Ollama is running, the simulator exports the flag `cn1.ai.ollamaDetected=true`. A second system property, `cn1.ai.simulatorRedirect`, controls whether the simulator transparently routes `LlmClient.openai(…)` calls to the local Ollama endpoint instead:

Value	Behavior
`disabled`	The default on a device. Calls go to the configured provider, even in the simulator.
`auto`	The default in the simulator. If Ollama is reachable, route OpenAI calls through it. Otherwise behave like `disabled`.
`ollama`	Force redirect to Ollama. Use this in offline-only development environments.

The redirect target is also configurable: `cn1.ai.ollamaUrl` defaults to `http://localhost:11434/v1`, and `cn1.ai.ollamaModel` defaults to `llama3.2`. Unchanged production code therefore runs offline against a local model without any conditional wiring at the call site.

89.1.12. Storing the API key

Never put a provider API key on the device at all — not hard-coded, not in a bundled resource, and not fetched at runtime and cached. Mobile binaries are trivially reverse-engineered, and a key the running app can read is a key its user

> can extract; `SecureStorage` protects data at rest and can't change that. A leaked provider key is billable by whoever holds it, against your account, with no way to scope the damage to one user.

Keep the key on your server and proxy the provider calls through it. The device then authenticates to **your** endpoint with a short-lived, user-scoped token, which expires on its own and can be revoked for one user without touching anyone else. That token is worth caching with the non-prompting `SecureStorage` overloads:

```
// Your server keeps the provider key and proxies the calls. The device
// holds only a short-lived, user-scoped token for your own endpoint, so
// a stolen one expires and can be revoked for that user alone.
SecureStorage store = SecureStorage.getInstance();
boolean saved = store.set("ai.session.token", sessionTokenFromServer);

// Treat the store as a cache, not as the source of truth. When the write
// fails -- no secure storage on this port, or the keychain refused it --
// reading back gives either nothing or the previous, now expired, token.
// The one just issued is the good one, so use it and let persistence be
// best effort.
String token = saved ? store.get("ai.session.token") : sessionTokenFromServer;
if (token == null) {
    token = sessionTokenFromServer;
}
LlmClient client = LlmClient.localOpenAiCompatible(
        "https://api.example.com/ai/v1", token, "gpt-4o-mini");
```

89.2. The `ChatView` component

`ChatView` is a scrollable, theme-aware chat surface that handles the list of bubbles, the streaming append, the typing indicator, and the input strip in one component. Drop it into a `Form` with a single `BorderLayout.CENTER`:

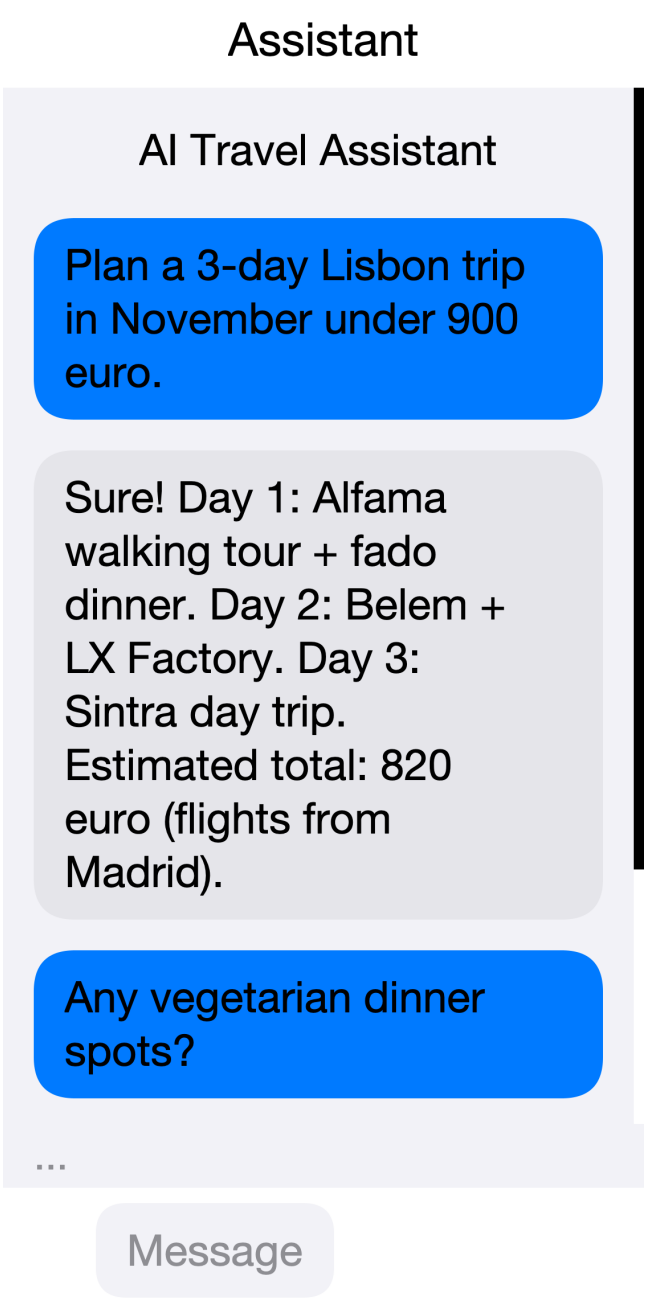

Figure 370. `ChatView` *rendered in the JavaSE simulator under the iOS Modern theme*

The component exposes thread-safe `addMessage`, `appendToLastMessage`, and `setTypingIndicatorVisible` methods, so background callbacks from `chatStream(…)` can mutate the view directly:

```
Form chat = new Form("Assistant", new BorderLayout());
ChatView view = new ChatView();
chat.add(BorderLayout.CENTER, view);

view.addMessage(ChatMessage.assistant("How can I help?"));

// One request at a time. A second send while the first is still
// streaming builds its request without the first reply, and the two
// completions then append to the history in whatever order they finish,
// producing turns like user A, user B, assistant B, assistant A.
```

```
boolean[] sending = {false};

view.setOnSend(e -> {
    if (sending[0]) {
        return;
    }
    sending[0] = true;
    String text = view.getInput().getText();
    view.getInput().clear();
    view.addMessage(ChatMessage.user(text));
    view.setTypingIndicatorVisible(true);

    // Snapshot the history before opening the assistant bubble. The view
    // records streamed text as it arrives, so completed replies are
    // already in there; the one thing to leave out is the empty
    // placeholder that beginAssistantStream() is about to append.
    //
    // No model named: the client's default applies, and the simulator's
    // Ollama redirect sets that for you.
    ChatRequest req = ChatRequest.builder()
            .messages(new ArrayList<ChatMessage>(view.getHistory()))
            .build();

    ChatBubble streaming = view.beginAssistantStream();
    // The proxy client from the credentials section: on a device
    // LlmClient.openai(apiKey) would need the billable provider key to
    // be present there, which that section says not to do.
    client.chatStream(req, new StreamingListener.Adapter() {
        @Override public void onContentDelta(String d) {
            // Append to the bubble this send opened, not to whichever is
            // newest: a second send while this one is still streaming
            // would otherwise divert this response into that bubble.
            streaming.appendText(d);
        }
    }).ready(resp -> {
        sending[0] = false;
        view.setTypingIndicatorVisible(false);
    }).except(err -> {
        // Without this the indicator stays up for good on a failure, and
        // the guard above would block every later send.
        sending[0] = false;
        view.setTypingIndicatorVisible(false);
        Log.e(err);
    });
});
chat.show();
```

`ChatBubble` and `ChatInput` are public, so subclass them for custom rendering. Override `ChatView.createBubble(message)` to swap in a custom subclass when the view builds the message list.

89.2.1. Theming

`ChatView` exposes the following UIIDs out of the box:

UIID	Applies to
`ChatView`	The outer container.
`ChatViewMessages`	The scrollable message column.
`ChatBubbleUser`	The container for a user message.
`ChatBubbleAssistant`	The container for an assistant message.
`ChatBubbleSystem`	The container for a system message.
`ChatBubbleText`	The inner `TextArea` of every bubble.
`ChatTypingIndicator`	The animated typing dots.
`ChatInput`	The input strip.
`ChatInputField`	The text field inside the strip.
`ChatSendButton`	The send button.
`ChatAttachButton`	The attach button.
`ChatVoiceButton`	The voice button.

Style them from `theme.css` to align with the rest of the app. Hide the voice or attach button by leaving its listener unset; the corresponding `Button` instance is hidden when no `ActionListener` is registered.

89.2.2. One-call binding to an LLM

`LlmChatBinding.bind(view, client, baseRequest)` wires the input bar directly to `chatStream(…)`. Every send replays the conversation history, dispatches the response into the view, and updates the typing indicator. Use it for prototypes, or as a reference implementation when you need a custom send pipeline:

```
LlmChatBinding.bind(view,
        // The proxy client from the credentials section, not
        // LlmClient.openai(apiKey): a shipped build must not carry the
        // provider key on the device.
        client,
        // The template's messages are sent ahead of the conversation on
        // every request, so this is where a system prompt belongs.
        // build() also rejects an empty message list.
        ChatRequest.builder()
                .addMessage(ChatMessage.system("You are a helpful assistant."))
                .build());
```

89.3. Speech recognition and TextToSpeech

The new media APIs route through `Display` and into the implementation hooks on `CodenameOneImplementation`, so the call surface is identical on every platform. The default implementation returns `false` from `isSupported()` and is a no-op for `recognize`/`speak`.

89.3.1. SpeechRecognizer

iOS uses `SFSpeechRecognizer`, Android uses `android.speech.SpeechRecognizer`, and the JavaSE simulator stays unsupported unless the optional `cn1-ai-whisper` cn1lib is on the classpath. Call `stop()` to end an active session early; partial results stop firing immediately.

89.3.2. TextToSpeech

```
if (TextToSpeech.isSupported()) {
    TtsOptions opts = new TtsOptions()
            .setLanguageTag("fr-FR")
            .setRate(1.0f);
    TextToSpeech.speak("Bonjour", opts);
}
```

iOS uses `AVSpeechSynthesizer`, Android uses `android.speech.tts.TextToSpeech`, and the JavaSE simulator falls back to `say` on macOS, `espeak` on Linux, and the platform `SAPI` bridge on Windows. `getAvailableVoices()` returns the platform-specific voice identifiers when the OS exposes them; `setVoiceId(…)` accepts any of those strings, or `null` to use the default voice for the configured language.

89.4. On-device vision

The vision API is three layers deep, and most applications only need the first one. Start with the finished screen, drop to a component when the screen has to look like your own, and drop to a single analyzer when you are working on one image at a time.

89.4.1. Scanning a barcode or QR code

`CodeScanner` is an entire scanner screen in one call. It opens the camera, decodes, restores the form you came from, and hands back the code. This is the replacement for the `cn1-codescan` cn1lib:

```
if (!CodeScanner.isSupported()) {
    ToastBar.showErrorMessage("This device cannot scan codes");
    return;
}

CodeScanner.scan().ready(code -> {
    if (code == null) {
        return;                         // the user backed out
    }
```

```
    resultLabel.setText(code.getValue());
}).except(error -> Log.e(error));
```

The result completes with `null` when the user backs out — the cn1lib's `scanCanceled()` — and fails through `except` when the camera can't be opened, which is its `scanError()`. There is no third callback to implement.

`CodeScannerOptions` rewords the screen and restricts which symbologies end the scan, so a stray product barcode in the frame doesn't complete a QR scan:

```
CodeScanner.scan(new CodeScannerOptions()
        .title("Boarding pass")
        .hint("Hold the pass flat inside the frame")
        .formats(BarcodeFormat.PDF417, BarcodeFormat.AZTEC))
    .ready(code -> {
        if (code != null) {
            checkIn(code.getValue());
        }
    })
    .except(error -> Log.e(error));
```

The `BarcodeFormat` constants are the portable symbology names every backend maps onto, so no format literals are needed.

Three classes share the name `CodeScanner`. Import `com.codename1.ai.vision.CodeScanner`. The other two are the `cn1-codescan` cn1lib's `com.codename1.ext.codescan.CodeScanner` and the long-deprecated `com.codename1.codescan.CodeScanner` in core, whose `getInstance()` returns `null` on current targets.

89.4.2. Analyzing the live camera

`VisionCameraView` is a component that owns the camera and runs an analyzer over its frames. It handles the session, the frame conversion, the dropping of frames that inference has fallen behind, and the hop back to the EDT; the application implements one listener. It works with every analyzer, not just barcodes:

```
FaceDetector detector = new FaceDetector();
VisionCameraView<Face[]> view = new VisionCameraView<>(detector);
view.setFacing(CameraFacing.FRONT);
view.setListener(new VisionPipelineListener<Face[]>() {
    @Override
    public void result(Face[] faces, VisionImage source) {
        shutter.setEnabled(faces.length == 1);
        statusLabel.setText(faces.length == 1
                ? "Looking good"
                : "Fit exactly one face in the frame");
```

```
    }

    @Override
    public void error(Throwable error) {
        Log.e(error);
    }
});

Form form = new Form("Selfie", new BorderLayout());
form.add(BorderLayout.CENTER, view);
form.add(BorderLayout.SOUTH, BoxLayout.encloseY(statusLabel, shutter));
form.show();
// The camera is opened when the form is shown and released when the
// user navigates away. Call view.close() when the screen is finished
// with for good, which also releases the detector.
```

The analyzer is constructed by the application rather than named by a feature constant. That's deliberate: the builders decide which native vision dependency to package from the analyzer classes an application references, so building the analyzer in your own code is what keeps a face-detection app from also carrying the barcode and pose models.

The camera opens when the view is shown and is released when the user navigates away, so a form transition can't leave the hardware held. `close()` additionally releases the analyzer, for a screen that's finished with for good.

`setScaleType(…)`, and the mirroring a front camera asks for, are honored in the simulator. The iOS and Android previews render fixed at fill-and-crop and unmirrored, because neither port implements the preview-scaling hook on `CameraImpl` yet. Treat both as requests rather than guarantees on a device.

The preview is a native view, and Codename One components can't be painted over it on every platform — iOS renders native peers behind the Codename One layer, Android renders them in front. Put a reticle, hints, and buttons around the preview rather than on top of it. Result geometry can still be drawn over a **still** image, as below.

89.4.3. The analyzers

Each analyzer takes a `VisionImage` and returns a typed result. Create one, reuse it across a sequence of images, and close it when finished. Check `isSupported()` before offering the feature: availability depends on the target, the linked backend, and the OS version.

`VisionImage` accepts JPEG, PNG, NV21, or RGBA8888 data. `VisionImage.fromFile(path)` reads a gallery or captured photo, `VisionImage.fromImage(image)` takes one already in memory — passing an `EncodedImage`'s original bytes straight through rather than re-encoding — and `VisionImage.fromCameraFrame(frame)` copies a live frame's callback-owned buffers and preserves its rotation.

`BarcodeScanner` decodes codes from a still image:

```
BarcodeScanner scanner = new BarcodeScanner();
scanner.process(VisionImage.fromFile(photoPath)).ready(codes -> {
    for (Barcode code : codes) {
        if (BarcodeFormat.matches(code, BarcodeFormat.EAN_13,
                BarcodeFormat.UPC_A)) {
            lookUpProduct(code.getValue());
        }
    }
    scanner.close();
}).except(error -> {
    Log.e(error);
    scanner.close();
});
```

`TextRecognizer` reads text. Over a file:

```
TextRecognizer recognizer = new TextRecognizer();
recognizer.process(VisionImage.fromFile(photoPath)).ready(result -> {
    textArea.setText(result.getText());
    recognizer.close();
}).except(error -> {
    Log.e(error);
    recognizer.close();
});
```

Or from the live camera, stopping at the first block that looks like the value being hunted for:

```
VisionCameraView<TextRecognitionResult> view =
        new VisionCameraView<>(new TextRecognizer());
view.setListener(new VisionPipelineListener<TextRecognitionResult>() {
    @Override
    public void result(TextRecognitionResult text, VisionImage source) {
        for (TextRecognitionResult.TextBlock block : text.getBlocks()) {
            // Every frame is analyzed until one block looks like the
            // value being hunted for.
            if (block.getText().startsWith("SN-")) {
                accept(block.getText());
                return;
            }
        }
    }

    @Override
    public void error(Throwable error) {
        Log.e(error);
    }
});
```

`FaceDetector` returns bounds, head angles, and named landmarks. Cropping a photo to the face it contains:

```
Image photo = EncodedImage.create(jpegBytes);
FaceDetector detector = new FaceDetector();
detector.process(VisionImage.fromImage(photo)).ready(faces -> {
    if (faces.length > 0) {
        Rectangle box = faces[0].getBounds()
                .toBounds(0, 0, photo.getWidth(), photo.getHeight());
        preview.setIcon(photo.subImage(box.getX(), box.getY(),
                box.getWidth(), box.getHeight(), true));
    }
    detector.close();
}).except(error -> {
    Log.e(error);
    detector.close();
});
```

Read individual landmarks with `face.getLandmark(…)` and the `FaceLandmarks` constants. Not every backend fills in every field: `getSmilingProbability()` and `getTrackingId()` are negative when unavailable, and Apple Vision reports neither.

`ImageLabeler` classifies what an image contains:

```
ImageLabeler labeler = new ImageLabeler(new VisionOptions()
        .minimumConfidence(0.6f)
        .maximumResults(5));

labeler.process(VisionImage.fromFile(photoPath)).ready(labels -> {
    StringBuilder summary = new StringBuilder();
    for (ImageLabel label : labels) {
        summary.append(label.getText())
               .append(" (")
               .append(Math.round(label.getConfidence() * 100))
               .append("%)\n");
    }
    resultLabel.setText(summary.toString());
    labeler.close();
}).except(error -> {
    Log.e(error);
    labeler.close();
});
```

The label text is the portable part. `ImageLabel.getIndex()` is a model class index that differs between backends and is -1 on Apple Vision, so branch on `getText()`.

`PoseDetector` locates body joints. Backends detect different subsets of the skeleton, so look joints up by name and handle a missing one:

```
VisionCameraView<Pose> view = new VisionCameraView<>(new PoseDetector());
view.setListener(new VisionPipelineListener<Pose>() {
    private boolean wasUp;

    @Override
    public void result(Pose pose, VisionImage source) {
        Pose.Landmark wrist = pose.getLandmark(PoseLandmarks.RIGHT_WRIST);
        Pose.Landmark shoulder =
                pose.getLandmark(PoseLandmarks.RIGHT_SHOULDER);
        if (wrist == null || shoulder == null
                || wrist.getConfidence() < 0.6f) {
            return;                    // this frame did not see the arm
        }
        // Y grows downwards, so "above" is the smaller value.
        boolean up = wrist.getPosition().getY()
                < shoulder.getPosition().getY();
        if (up && !wasUp) {
            reps++;
            statusLabel.setText(String.valueOf(reps));
        }
        wasUp = up;
    }

    @Override
    public void error(Throwable error) {
        Log.e(error);
    }
});
```

`SelfieSegmenter` separates a person from the background. `SegmentationMask.cutOut(…)` applies the mask to the source image and rescales it, since the mask has the model's resolution rather than the frame's:

```
EncodedImage photo = EncodedImage.create(jpegBytes);
SelfieSegmenter segmenter = new SelfieSegmenter();

segmenter.process(VisionImage.encoded(jpegBytes)).ready(mask -> {
    // Below 60% foreground confidence becomes transparent, so whatever
    // is painted behind this image shows through.
    Image person = mask.cutOut(photo, 0.6f);
    preview.setIcon(person);
    segmenter.close();
}).except(error -> {
    Log.e(error);
    segmenter.close();
});
```

`SegmentationMask.toMaskImage(rgb)` renders the mask itself as a translucent tint, for highlighting the

subject rather than cutting it out.

`DocumentScanner` flattens a photographed page:

```
DocumentScanner scanner = new DocumentScanner();
if (!scanner.isSupported()) {
    // Google's Android document scanner is an interactive flow rather
    // than an analyzer, so Android reports this unsupported.
    scanner.close();
    return;
}
scanner.process(VisionImage.fromFile(photoPath)).ready(result -> {
    List<Image> pages = new ArrayList<>();
    for (int i = 0; i < result.getPageCount(); i++) {
        pages.add(EncodedImage.create(result.getPage(i)));
    }
    show(pages);
    scanner.close();
}).except(error -> {
    Log.e(error);
    scanner.close();
});
```

89.4.4. Drawing the results

Bounds and points are normalized to the range 0 through 1 rather than pixels, so one observation maps onto an image of any size. `VisionRect.toBounds(component)` and `VisionPoint.toPoint(component)` convert them into the absolute coordinates a `paint` method draws in:

```
class FaceOverlay extends Label {
    private Face[] faces = new Face[0];

    FaceOverlay(Image photo) {
        super(photo);
    }

    void setFaces(Face[] value) {
        faces = value;
        repaint();
    }

    @Override
    public void paint(Graphics g) {
        super.paint(g);
        g.setColor(0x34c759);
        for (Face face : faces) {
            // Results are normalized to 0..1, so the same observation maps
            // onto whatever size this component happens to be.
```

```
            Rectangle r = face.getBounds().toBounds(this);
            g.drawRect(r.getX(), r.getY(), r.getWidth(), r.getHeight(), 3);
        }
    }
}
```

The mapping stretches the whole normalized range across the destination, which is right when the destination has the same aspect ratio as the analyzed image. A live preview scaled with `ScaleType.CROP` doesn't, which is the other half of why overlays belong on still images.

89.4.5. Scripting results in the simulator

The desktop has no on-device vision models. Rather than report every analyzer as unsupported — which would leave a scanner screen impossible to build without a device — the simulator returns whatever you script under **Simulate** > **Vision**:

- **Vision Supported** turns the whole API off, so the `isSupported()` branch can be exercised.
- **Analysis outcome** switches between the scripted result, an empty result, `VisionException.UNSUPPORTED`, and a backend error. Every screen needs the "nothing found" and "it failed" paths, and this is how to reach them.
- The remaining items set the scripted values: the decoded code and its format, the recognized text, the image labels, how many faces are found and whether they're smiling, and whether a body pose is detected.

The scripted results carry plausible geometry, so overlay and debounce code can be written and debugged before the app ever reaches a device. Nothing in this section applies to a device build.

89.4.6. Backends and options

An image whose stored pixels aren't already upright needs its rotation declared: `VisionImage.encoded(bytes, rotationDegrees)`. The one-argument overload, and `fromFile(…)`, assume the pixels are upright and don't inspect EXIF metadata; `fromCameraFrame(…)` takes the rotation from the frame. `VisionOptions.minimumConfidence(…)` clamps finite and infinite values to the range 0 through 1 and rejects NaN.

Android uses ML Kit. iOS and Mac native builds default to Apple Vision and Core Image. iOS can select ML Kit explicitly:

```
VisionOptions options = new VisionOptions()
        .backend(VisionBackends.mlKitTextRecognition())
        .minimumConfidence(0.5f);

new TextRecognizer(options)
        .process(VisionImage.encoded(jpegBytes))
        .ready(result -> Log.p(result.getText()))
        .except(error -> Log.e(error));
```

89.4.7. Reading non-Latin text

`TextRecognizer` reads the Latin script by default. Select a writing system with `VisionOptions.textScript(…)` to read Chinese, Devanagari, Japanese, or Korean:

```
TextRecognizer recognizer = new TextRecognizer(new VisionOptions()
        .textScript(TextScript.japanese()));

recognizer.process(VisionImage.encoded(jpegBytes))
        .ready(result -> Log.p(result.getText()))
        .except(error -> Log.e(error));
```

The selector names a script rather than a language, because that's what the underlying recognizers are organized by. One script covers every language written in it, and each script model also reads the Latin characters mixed into the same page. Recognize one script per analyzer; create a second analyzer when a screen needs both.

Android maps each script to the matching ML Kit recognizer. Apple platforms map it to the Vision recognition languages for that script, asking the OS which languages it supports rather than assuming a list. When the OS recognizes none of them, the analysis fails with `VisionException.UNSUPPORTED` rather than returning Latin OCR of the page. Select `VisionBackends.mlKitTextRecognition()` to use ML Kit's model for that script on iOS instead.

Each script is a separate model, and referencing `TextScript.japanese()` is what adds it: the ML Kit script bundle on Android, and on iOS the matching pod when the ML Kit backend was also selected. An application that never names a script carries only the Latin model, and one that names Japanese doesn't carry the Korean or Devanagari models.

On an iOS simulator, the Apple barcode backend uses Vision barcode request revision 1. Newer simulator runtimes can otherwise complete a barcode request without reporting valid QR codes. Physical devices use the latest revision supplied by the OS. Test newer symbologies such as Micro QR on a device, or select the matching ML Kit backend.

Create and reuse an analyzer when processing a sequence. Call `close()` when the analyzer is no longer needed. Before showing a feature, call its `isSupported()` method: availability can depend on the target, linked backend, and OS version.

`VisionPipeline` attaches an analyzer to a `CameraSession` frame stream and keeps only the newest pending frame. Live OCR and pose detection therefore can't build an unbounded queue when inference is slower than the camera. While an analysis is busy, the pipeline reuses the pending buffer when newer same-sized frames replace it. Results and errors are delivered on the Codename One EDT.

`CameraFrame.getRawBytes()` can be `null` even after requesting NV21 or RGBA8888 when a port can't expose that format. JPEG bytes remain available; `VisionImage.fromCameraFrame(…)` automatically selects that fallback.

`DocumentScanner` currently performs still-image rectangle correction on Apple platforms. Google's Android document scanner is an interactive camera flow rather than an analyzer for an existing

`VisionImage`, so the Android backend reports it as unsupported rather than launching a UI flow.

89.4.8. Vision feature and dependency selection

The Java package is always part of core. The builders scan the concrete analyzer classes and retain only the native adapter and dependency for each class the application actually uses:

API	Android	Apple default / optional backend
`TextRecognizer`	ML Kit text recognition	Vision / `GoogleMLKit/TextRecognition`
`TextScript` (non-Latin)	ML Kit bundle for that script	Vision recognition languages / `GoogleMLKit/TextRecognition<Script>`
`BarcodeScanner`, `CodeScanner`	ML Kit barcode scanning	Vision / `GoogleMLKit/BarcodeScanning`
`FaceDetector`	ML Kit face detection	Vision / `GoogleMLKit/FaceDetection`
`ImageLabeler`	ML Kit image labeling	Vision / `GoogleMLKit/ImageLabeling`
`PoseDetector`	ML Kit pose detection	Vision / `GoogleMLKit/PoseDetection`
`SelfieSegmenter`	ML Kit selfie segmentation	Vision / `GoogleMLKit/SegmentationSelfie`
`DocumentScanner`	Unsupported for still images	Core Image perspective correction

`CodeScanner` selects the same barcode dependency `BarcodeScanner` does, because it builds one internally; an application that references only the ready-made screen still gets the decoder. `CodeScanner` and `VisionCameraView` additionally select the camera natives, so neither has to be paired with a `com.codename1.camera` reference to work.

The optional iOS ML Kit pod is added only when both the analyzer and its feature-specific selector are referenced. For example, `VisionBackends.mlKitBarcodeScanning()` adds only the barcode pod. Current Google ML Kit iOS pods require iOS 15.5. Selecting one of these optional backends automatically raises the effective application and CocoaPods deployment target to 15.5 when the configured target is lower. Referencing one Android analyzer doesn't compile or package the other five adapters.

89.5. Portable LiteRT inference

`InferenceSession` loads `.tflite` data from bytes, a bundled resource, or a private file. Android uses LiteRT and can request NNAPI. iOS uses TensorFlow Lite Objective-C and may request the Core ML delegate. Both mobile implementations fall back to CPU unless `allowFallback(false)` is set. Android and iOS reject strict `Accelerator.NPU` sessions: NNAPI can mix delegated and CPU operations, and the Core ML delegate can schedule work across the Neural Engine, GPU, and CPU. Neither reports that the entire graph ran on the requested NPU. With fallback enabled, NPU selection is a best-effort accelerator preference. On iOS, strict `Accelerator.CORE_ML` sessions are also rejected because the delegate doesn't report whether unsupported model operations remained on LiteRT's CPU path. The JavaSE simulator and targets without a native LiteRT runtime, including Mac native, return `false` from `InferenceSession.isSupported()`.

```
InferenceSession.open(
        ModelSource.resource("/models/classifier.tflite"),
        new InferenceOptions().accelerator(
                InferenceOptions.Accelerator.AUTO))
    .ready(session -> {
        Tensor input = Tensor.floats("serving_default_input",
                new int[] {1, 224, 224, 3}, pixels);
        session.run(new Tensor[] {input})
                .ready(outputs -> {
                    try {
                        consume(outputs[0]);
                    } finally {
                        session.close();
                    }
                })
                .except(error -> {
                    try {
                        Log.e(error);
                    } finally {
                        session.close();
                    }
                });
    })
    .except(error -> Log.e(error));
```

Open is asynchronous because model initialization can allocate native resources. A session is reusable and supports multiple named inputs, multiple outputs, and `resizeInput(…)`. A session serializes its mutable native interpreter: while `run(…)` is pending, another run, input resize, or input/output metadata query throws `IllegalStateException`. Tensor data is copied across the port boundary. Always close the session.

Bundle small models as resources. For larger models use `ModelCache.fetch(url, cacheKey, sha256)`, which downloads over HTTPS, verifies the supplied SHA-256 digest, and reuses the app-private cached file. The initial URL must use HTTPS. Ports that expose redirect responses reject a redirect to HTTP and discard the temporary download. iOS follows redirects below the portable network layer, so iOS requires the SHA-256 argument and rejects the unpinned two-argument overload. Supply the digest on every platform for every third-party or remotely mutable model. Interrupted downloads restart through a temporary `.download` file and are never promoted to the cache until verification succeeds. Concurrent calls for the same cache key and content identity share one download but receive independent asynchronous resources. Canceling one caller suppresses only that caller's notification; it doesn't cancel the shared download or the other callers. When a cache key already has an active download, a request with a conflicting URL or digest fails instead of sharing the temporary file.

89.6. On-device language services

`LanguageIdentifier`, `Translator`, and `SmartReply` share `LanguageOptions`. Its minimum-confidence threshold clamps to 0 through 1 and rejects NaN. Translation models are downloaded and cached

by ML Kit when a language pair is first used. Android and iOS builders select `language-id`, `translate`, and `smart-reply` independently, so using language identification alone doesn't package the other two SDKs.

```
LanguageOptions options = new LanguageOptions()
        .backend(LanguageBackends.mlKitTranslation());
if (Translator.isSupported(options)) {
    Translator.translate("Where is the station?", "en", "fr",
            options)
        .ready(value -> Log.p(value))
        .except(error -> Log.e(error));
}
```

`LanguageBackends.auto()` selects ML Kit on Android and Apple's Natural Language framework for language identification on iOS. The Apple default keeps arm64 simulator builds native and adds no third-party dependency. `LanguageBackends.mlKitLanguageIdentification()` opts identification into the ML Kit iOS pod. iOS translation and Smart Reply are explicit opt-ins: use `LanguageBackends.mlKitTranslation()` or `LanguageBackends.mlKitSmartReply()` respectively. Merely referencing `Translator` or `SmartReply` doesn't add a pod or exclude the arm64 simulator. Selecting one of those ML Kit backends requires the x86_64 simulator slice and raises an iOS deployment target below 15.5.

The static language methods are convenient for one operation and close their temporary backend after either success or failure. For repeated work, call `LanguageIdentifier.open(…)`, `Translator.open(…)`, or `SmartReply.open(…)`, reuse the returned feature session, and close it when the last pending operation completes. Reusable sessions retain backend state and, on Android, cache ML Kit clients and translation clients per language pair. Mac native and the other unsupported targets return `false` from the language service `isSupported()` checks. Completion and failure callbacks arrive on the EDT.

89.7. Platform availability

The public API and the unsupported fallback are present on every Codename One target. Vision has native implementations on Android, iOS, and macOS; Apple Vision is the default on Apple targets and Android uses ML Kit. Language services and LiteRT inference have native implementations on Android and iOS. JavaSE, JavaScript, native Windows, native Linux, watchOS, and tvOS report unsupported for these new APIs; Mac native reports unsupported for language and LiteRT. No target sends data to a cloud inference service. Large portable runtimes or model payloads for the remaining targets remain appropriate opt-in libraries.

No build hints or cn1lib coordinates are required for the built-in mobile implementations. The local Maven plugin and BuildDaemon use the same `PlatformFeatureCatalog`, so local and cloud builds make the same dependency decisions.

89.8. Migrating from the AI cn1libs

The old `com.codename1.ai.mlkit.*` and `com.codename1.ai.tflite` packages aren't compatibility

aliases. Remove those dependencies and move directly to `com.codename1.ai.vision`, `com.codename1.ai.language`, or `com.codename1.ai.inference`. Result coordinates are normalized floats rather than packed platform-specific integer arrays. `cn1-ai-whisper` and `cn1-ai-stablediffusion` remain cn1libs because their native payloads and models are intentionally large.

Remove the retired cn1lib dependency before adding the built-in class. During migration, the builders deduplicate identical CocoaPods names and preserve an explicitly declared user version constraint. Removing the old library is still required because compatibility aliases would keep its old native-interface and packaging contracts alive.

89.8.1. Putting it all together

The pieces compose well. The following loop captures a photo, extracts text with the multi-modal `gpt-4o` model, speaks the result, and streams the same text into a `ChatView`:

```
Capture.capturePhoto(evt -> {
    // A cancelled capture arrives as a null event or a null source
    // depending on the port, and reading either would fail rather than
    // simply returning the user to the app.
    if (evt == null || !(evt.getSource() instanceof String)) {
        return;
    }
    String path = (String) evt.getSource();
    byte[] bytes = readAllBytes(path);
    if (bytes == null || bytes.length == 0) {
        // Nothing to describe. Sending an empty ImagePart produces a
        // data URL with no payload, which the provider rejects.
        return;
    }
    ImagePart img = new ImagePart(bytes, "image/jpeg");

    ChatRequest req = ChatRequest.builder()
            // No model named here: the request uses whatever default the
            // client carries. Whichever it is, it has to accept images.
            .addMessage(ChatMessage.userWithImage(
                "Describe the photo in one sentence.", img))
            .build();

    chatView.addMessage(req.getMessages().get(0));
    ChatBubble streaming = chatView.beginAssistantStream();
    StringBuilder full = new StringBuilder();

    // The same proxy client as the credentials sample above: on a device
    // LlmClient.openai(apiKey) would need the billable provider key to be
    // present here, which is exactly what that section says not to do.
    client.chatStream(req, new StreamingListener.Adapter() {
        @Override public void onContentDelta(String d) {
            full.append(d);
            // Append to the bubble this capture opened: a second photo
            // started mid-stream would otherwise take this text.
```

```
            streaming.appendText(d);
        }
    }).ready(resp -> {
        TextToSpeech.speak(full.toString());
    });
});
```

This sample sends an image, so whichever model the client reaches has to accept one — for a shipped app, whatever your proxy is configured with.

Note that the simulator's Ollama redirect doesn't apply here. It wraps the public-provider factories, and `localOpenAiCompatible` returns its client directly, which is the point: a proxy is a real endpoint and isn't something to swap out behind your back. To try this against a local model, build the client with `LlmClient.ollama(…)` and name a vision-capable model you've pulled.

The photo leaves the device either way. Nothing here runs a model on the phone, so cover that in your privacy policy — and note that the client is the proxy client from the previous section, not `LlmClient.openai(apiKey)`, because that one needs the billable provider key to be present on the device.

Chapter 90. MCP Headless API

The Model Context Protocol (MCP) headless API lets an application expose itself to a large language model agent. An agent such as Claude Desktop, Claude Code, Codex, or opencode can read the current screen, drive the user interface, and call tools the application publishes.

The API reuses the accessibility semantics tree. The same immutable tree that describes the screen to VoiceOver and TalkBack also describes it to the agent, so any application is drivable without extra code. Application specific data and actions are exposed through the existing `com.codename1.ai.Tool` contract.

The socket transport runs anywhere the port can bind the loopback interface, which includes an application running on a device, so an agent can attach to a build on a phone as well as to the simulator. It's blocked on a release build; see Development builds only. The stdio transport needs process standard input and so is supported by the JavaSE port, which powers the simulator and the desktop tooling.

90.1. The MCP menu

Every desktop Codename One tool, including the simulator and Codename One Settings, gets a native `MCP` pull-down menu. The menu is added by the JavaSE port, so a tool gets it without any code of its own. It's the main way a user turns a tool into something an agent can drive.

The menu has these items:

- **Expose This Tool To Agents** starts and stops the loopback MCP server for the running tool.
- **Install in MCP Hosts** registers this tool with the MCP hosts detected on the machine: Claude Desktop, Claude Code, and Codex. After a host restarts, the tool appears as an MCP server the agent can use. A detected host whose configuration format isn't supported yet is reported rather than written to.
- **Remove From MCP Hosts** removes that registration.
- **Detect MCP Hosts** lists the hosts found on the machine and where their configuration lives.
- **Debug Logging** controls how much of the MCP conversation is echoed to the log.

Install writes a command that launches `MCPStdioLauncher`, a small bridge that relays the host's standard input and output to the running tool's socket. Hosts speak stdio and the tool serves a socket, so the bridge lets a stdio host such as Claude Desktop drive the already-running, human-visible tool.

90.2. Starting the server

Invoking the API is the switch. There is no build hint or property to set. The socket server lets an agent attach to a session a person is watching, which is the usual choice in the simulator:

```
MCP.startSocketServer(8765);
```

A tool that a host launches as a subprocess can serve over standard input and output instead:

```
MCP.startStdioServer();
```

The stdio transport is the standard MCP local transport, exchanging newline delimited JSON-RPC messages. While it runs, application logging is redirected away from standard output so it can't corrupt the protocol stream. The stdio transport lives in the JavaSE port because it needs process standard input, which isn't available on every target.

90.3. Attaching to an application on a device

The socket transport binds the loopback interface, and it binds the loopback interface of whatever machine the application is running on. In the simulator that's your own, so an agent connects to `127.0.0.1` and there's nothing else to arrange. On a phone the port belongs to the phone, and reaching it needs a forward.

The native Linux port supports the portable socket transport through an IPv4 listener bound to `127.0.0.1`. Stopping the listener wakes a waiting listener, and closing a connection wakes its blocked input/output operations. This capability doesn't enable wildcard-bound server sockets or change the release-build guard. Native Linux builds still require the explicit, controlled-development opt-in described below.

For a Linux application running in a container, run the MCP client in that same container or network namespace. Publishing a container port doesn't make a listener bound to its internal loopback address reachable from the host. A local headless test can use Xvfb; when its launcher runs in Docker, use `--init` so the launcher's readiness signals are delivered normally. Native window-manager behavior still needs a desktop session.

On Android, `adb forward tcp:8765 tcp:8765` maps a port on the development machine onto the same port inside the device, so an agent connects to `127.0.0.1:8765` as before. Remove it with `adb forward --remove tcp:8765` when the session ends. The `cn1:android-on-device-debugging` goal already installs and launches a debuggable build, and its `waitForAttach=false` option is the one to use when the point of the session is the agent rather than a breakpoint, since the application then boots straight into a drivable state instead of blocking for a debugger. On iOS the same setting isn't a convenience but a requirement, because `ios.onDeviceDebug.waitForAttach` defers the callback that boots the application until a debugger attaches — so a starter in the application's own code never runs, and there is nothing listening on the port to reach.

The native iOS simulator shares the host's network stack, so the application's loopback port is the host's loopback port and no forwarding applies. A physical iPhone doesn't: the port sits on the device's own loopback, reachable only over the USB multiplexing channel, and `iproxy` from libimobiledevice is the usual relay. Codename One ships no goal for it, so an agent-driven session against a real iPhone depends on external tooling in a way the Android one doesn't.

None of this is a second security boundary. A forward is something you asked for, and the reason the server refuses a release build is that the loopback interface on a device is shared with every other application installed on it — see Development builds only.

90.4. Development builds only

The socket server refuses to bind on a release build and throws an `IllegalStateException` instead.

The reason is what an attached agent can do. It reads the screen and drives the user interface, and the loopback interface is shared by everything on the device rather than being private to one application. On a phone that means any other installed application can connect to the port and drive yours. That's a reasonable trade while you're developing, because it's how an agent attaches to a running build, and a poor one in an application a user installs.

A development build is a debuggable Android package or a development provisioned iOS build. Any other target counts as a release build, so a port that can't tell the difference withholds the server rather than exposing it.

The JavaSE port is the exception, and it's worth understanding before you rely on this. That port runs the simulator, the designer and the desktop tooling, and it can't distinguish those from a desktop application packaged for distribution: there's no debuggable flag and no provisioning profile to read. It reports a development build in every case, because reporting otherwise would take the MCP menu away from every desktop tool. A packaged desktop application is therefore not gated by this, and one that needs to withhold the server from its own release build has to supply that signal itself.

Nothing binds a port unless the application calls a starter, and an application that never calls one has no server at all. The gate matters for the case where a starter is left in the code by accident, which is the way a debugging facility usually reaches production.

The same distinction is available to application code, so a starter can be left in place and simply not fire in a shipped build:

```
if (Display.getInstance().isDebuggableBuild()) {
    MCP.startSocketServer(8765);
}
```

A build that ships to devices you control, such as a kiosk fleet, a test lab, or a managed enterprise deployment, can lift the block:

```
MCP.setAllowOnReleaseBuilds(true);
MCP.startSocketServer(8765);
```

Treat that call the way you'd treat any other decision to expose a control surface, because the device itself becomes the boundary.

90.5. Built-in user interface tools

Every server registers a small set of tools that read and drive the screen through the accessibility tree. An agent calls `ui_snapshot` to get the semantics tree of the focused top-level container as JSON, including the identifier, role, label, value, and state of each node, and the identifiers of the actions

each node supports.

The agent drives the screen with `ui_perform_action`, which performs an action such as `activate` or `setText` on a node from the snapshot. The convenience tools `ui_activate` and `ui_set_text` wrap the common cases, and `ui_find` locates nodes by identifier, by label, or by screen coordinate.

Call `ui_windows` to list the main form and desktop windows, with their `windowId`, `title`, `visible`, `focused` and `blocked` fields. The snapshot, find and action tools accept an optional `windowId`: omit it to use the focused top-level container, use `0` for the current main form, or use a positive ID from `ui_windows` for a visible desktop window. This allows an agent to inspect and operate a native Codename One dialog explicitly. Actions against a window blocked by a modal dialog are rejected. Operating-system file pickers are outside the Codename One semantics tree.

Actions run on the Codename One EDT, so an agent never touches the live component tree directly. A completed action returns `success` and a fresh `snapshot`, with `pending:false`. If an action opens a blocking modal dialog, its nested event loop can return a snapshot with `pending:true` and `success:null` while the original handler is still running. This keeps the MCP connection available: use subsequent calls to inspect and dismiss the dialog, then verify the resulting state. A pending response isn't confirmation that the original action completed successfully.

90.6. Publishing application tools

An application publishes its own data and actions as MCP tools. A `Tool` has a name, a description, a JSON schema for its parameters, and a handler:

```
MCP.addTool(new Tool(
        "current_user",
        "Returns the signed in user",
        "{\"type\":\"object\",\"properties\":{}}",
        new ToolHandler() {
            @Override
            public String invoke(String argumentsJson) {
                return "{\"name\":\"" + signedInUser + "\"}";
            }
        }));
```

The server merges these tools with the built-in tools when a host lists the available tools, and routes each call to the matching handler. The same `Tool` type is used by the Codename One AI client, so a tool defined once serves both a hosted agent and an in-application model.

90.7. Screenshots and the simulator

The server exposes a screenshot of the focused top-level container as an MCP image resource, so a vision capable model can see the screen alongside the semantic tree. The resource is enabled by default and can be disabled per server.

The JavaSE simulator drives the same MCP menu described above, so an application can be exposed and driven from the running simulator during development.

90.8. Simulator keyboard, touches and recording

The simulator adds tools of its own, prefixed `sim_`, that exist only on the desktop. Together with the user interface tools they let an agent script a video of a feature from start to finish.

The on-screen keyboard. With **Simulate** > **Virtual Keyboard** (or `sim_keyboard_set`) turned on, editing a text field slides up a keyboard drawn in the style of the skin's platform, or of the platform you force. The layout follows the field's constraint: letters, an email layout with `@`, or a number pad. The return key reads **Next** while another field follows and **Done** on the last one, and **Next** moves editing to the following field without hiding the keyboard. What the application sees follows each port:

- iOS: the screen keeps its size, `Display.getInvisibleAreaUnderVKB()` returns the keyboard height, a form in bottom padding editing mode is padded by it, and the field scrolls into view.
- Android in resize mode: the application gets `sizeChanged` with the height above the keyboard.
- Android in pan mode: the size stays the same and the whole screen shifts up until the field clears the keyboard.

The recording below was made by an agent through these tools: it turned the iOS keyboard on, started a recording, tapped the email field, typed into both fields, moved between them with **Next** and **Done**, and stopped the recording.

[The simulated iOS keyboard sliding up while a sign up form scrolls its email and password fields into view] | *img/simulator-virtual-keyboard.gif*

By default Android chooses between resize and pan for each field, the same way the Android port does. The **Android: Resize** and **Android: Pan** items, or `androidSoftInput`, force one mode. Virtual keyboard listeners fire on show and hide in both cases.

Touches. `sim_tap` and `sim_drag` press the screen through the same path as a mouse click, so they reach the simulated keyboard and appear as touch indicators, which `ui_activate` doesn't. `sim_touch_indicators` sets the style (`none`, `dot` or `ripple`), color, size and drag trails. **Simulate** > **Show Touches** also draws them in the simulator window.

Recording. `sim_record_start` records the screen to MP4, MOV, WebM or an animated GIF, either the screen alone or inside the device skin. Frames are taken on a fixed clock, so the video plays back in real time even while the screen is still. The options cover the frame rate and scale, the touch indicator style, a click sound mixed into the audio track at every tap, and the audio source. By default the recording carries what the application plays: sound effects, game sounds, music and video soundtracks, taken from the simulator's own audio output so nothing else playing on the computer gets in. `audio` can also be `microphone`, `app_and_microphone` for narration over the application's sound, or `none`. `sim_record_caption` overlays a caption on the video for a few seconds, and `sim_record_stop` finishes the file and returns its path and length. **Simulate** > **Start Recording** offers the same options in a dialog. Recording needs `ffmpeg`. Without it, the recorder writes numbered PNG frames and says so in its result.

A typical script calls these tools in order:

1. `sim_keyboard_set` with `{"mode": "auto"}` to use the skin's keyboard.

2. `sim_record_start` with `{"path": "/tmp/signup.mp4", "tapSound": true}`.
3. `sim_record_caption` with `{"text": "Sign up in one step"}`.
4. `sim_tap` with the `nodeId` of the email field, found with `ui_find`.
5. `sim_keyboard_type` with `{"text": "ada@example.com"}`, then `sim_keyboard_key` with `{"key": "next"}`.
6. `sim_keyboard_type` with `{"text": "42"}`, then `sim_keyboard_key` with `{"key": "done"}`.
7. `sim_wait` with `{"ms": 800}` to let the last frame settle.
8. `sim_record_stop`, which returns the file's path and length.

`sim_rotate` switches between portrait and landscape, and `sim_keyboard_state` reports whether the keyboard is showing, its height, the layout, and the screen size the application currently sees.

90.9. Restyling the application

The simulator also lets an agent change the application's look through its `theme.css`, with every change staged so a person can review it and undo it.

`sim_style_get` reads one rule as written. `sim_style_set` sets a property in a rule, adding the declaration or the rule when it's missing; an empty value removes the declaration. The change goes straight into `theme.css`, so live CSS reload shows it on the simulated screen within a second. The tools keep the text the file had before the first change, and answer each call with a unified diff of everything staged since:

1. `sim_style_audit` lists drift in the theme, the same findings as the `css-audit` Maven goal.
2. `sim_style_set` with `{"selector": "Button", "property": "color", "value": "var(--brand)"}`.
3. `sim_style_diff` shows the staged changes.
4. `sim_style_approve` keeps them, or `sim_style_reject` restores the earlier text and the old theme reloads.

The tools edit only top-level rules, never rules inside `@media` blocks, and accept no value that could close the declaration or the rule. If the file is saved in an editor while changes are staged, they refuse to write until the agent approves, or rejects with `force`, so a stale snapshot never overwrites a person's edits.

90.10. Debug logging

Because an agent drives the tool on its own, it helps to watch what it does. The server echoes the MCP conversation to the Codename One log at a level chosen through the menu's **Debug Logging** item or in code:

```
MCP.setVerbosity(MCPVerbosity.FULL);
```

The levels of `MCPVerbosity` are, from quietest to loudest: `OFF`, `ERRORS` (only failed calls), `SUMMARY` (one line per call), and `FULL` (every request and response). Each level includes the one below it.

90.11. Registering with installed hosts

The Install and Remove items in the MCP menu call `MCPClientRegistrar`, which detects the MCP hosts installed on the machine and writes a server entry into each host configuration, so an end user doesn't edit configuration by hand. Detection and registration are available to any Codename One tool, and they run inside the runtime because they use the portable `FileSystemStorage`.

A caller describes the server with an `MCPClientDescriptor` (a name and the command that launches it) and registers it with the detected hosts. Hosts whose configuration format isn't yet supported are reported so the user can add the entry manually. `opencode` is the one that's left: it nests its servers in an `mcp` block whose entries have a shape of their own.

Claude Desktop and Claude Code keep their servers in a JSON `mcpServers` object. Codex keeps its own in `~/.codex/config.toml`, as one `[mcp_servers.<name>]` table per server, and that file is shared by the ChatGPT desktop app, the Codex CLI, and the Codex IDE extension, so registering once reaches all three.

The default path is the one that's used. If you've moved your Codex configuration with `CODEX_HOME`, add the entry there by hand: the registrar runs inside the Codename One runtime, which has no `System.getenv`, so it can't follow the variable.

The TOML file is edited as text rather than parsed and written back. Only the lines belonging to the one server are replaced, so every other server, setting, comment, and choice of formatting in the file survives the edit exactly as the user left it, and the file keeps its own line endings. Registering again replaces the entry instead of adding a second one, and removing takes the server's `env` sub-table with it.

A configuration the editor can't make sense of is left untouched, and the reason is logged. That covers a file that isn't valid TOML, and the shapes it won't rewrite: the server declared through a dotted key or an inline table, `mcp_servers` declared as an array of tables, or the same server declared twice. Losing a Codex configuration is a worse outcome than not registering.

The host reads its configuration at startup, so a host that's already running needs a restart before the new server appears.

Security and identity

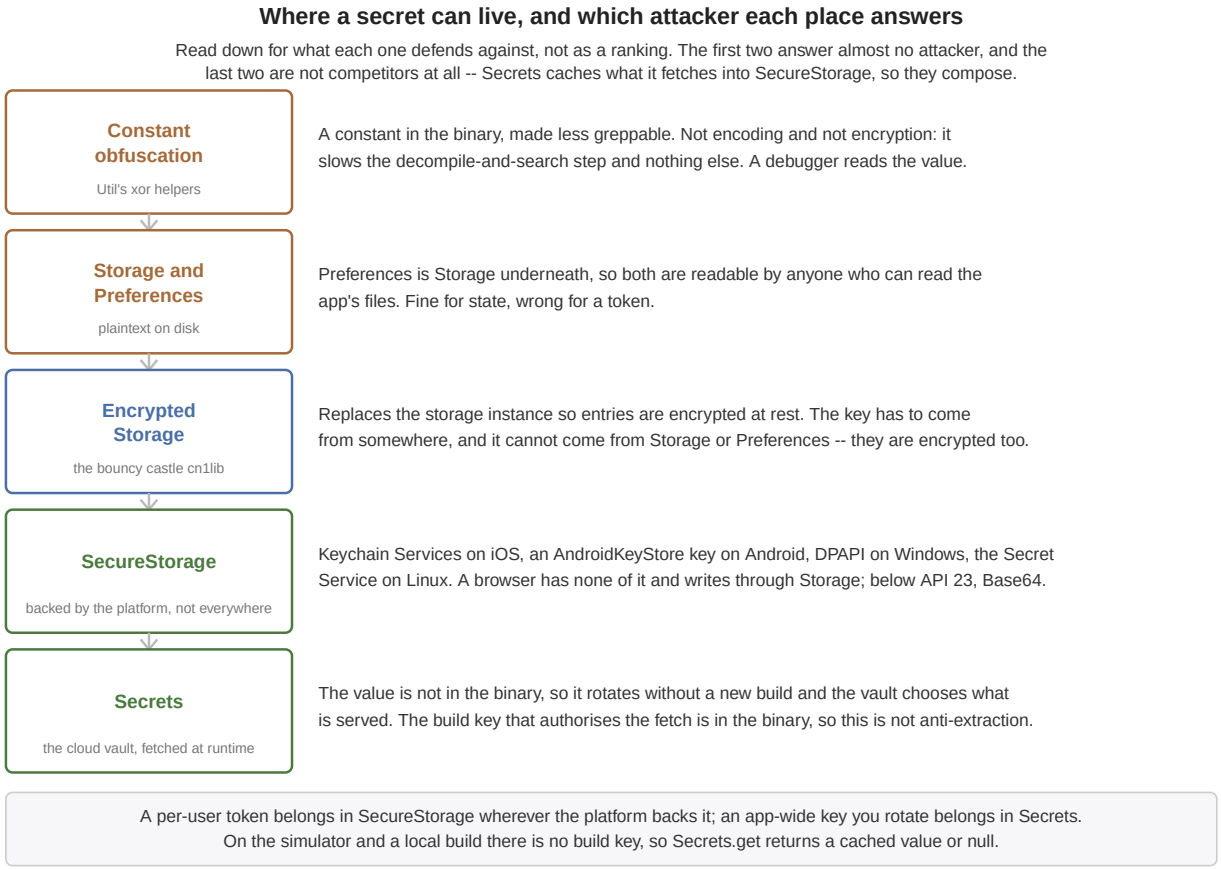
Chapter 91. Security

Security is a "big word." It implies many things and that's also true for the mobile app development so before you get started lets try to define the scope of security.

You will deal with application security and its communication mechanisms while ignoring everything beyond that scope. Start with a simple fact:

> Codename One applications are secure on the devices by the nature of the mobile OS security.

For most intents and purposes this will be enough, unless you're specifically concerned about security this section isn't for you. Mobile OSes isolate applications from one another so it's hard for an application to damage the OS or even damage/spy on a different app.



The restrictions laid on apps are here to make them extra secure and on top of that Codename One lays a few big advantages in security:

- Codename One code is compiled (unlike for example, PhoneGap/Cordova)
- Android release builds are obfuscated by default with R8, which makes the binaries harder to reverse engineer. On the other ports the shipped code is compiled or translated (the iOS/native ports go through ParparVM to C) rather than renamed. Enterprise accounts can turn on cross-platform hardening — name obfuscation, string encryption and more — for every port; see the App Hardening chapter
- Codename One compiles the UI to native code too which means typical reverse engineering code will have a harder time following
- Codename One disables debug flags so a hacker won't be able to debug your production app on the device

Despite that you still need to keep in mind that the binary could still be reverse engineered and so it's important to avoid storing keys in the client side code. For example, if you have an API key to access a service (for example, Google Cloud key) it needs to be stored in your server and not as a constant in your app!

Each section below discusses some attack vectors against applications and how they can be stopped. Pretty much all these attacks require a sophisticated attacker which will exist for high value targets (for example, bank apps, government etc.).

The sections that follow work through the places a value can be kept. They aren't interchangeable and they aren't a single ranking: each one answers a different attacker, the first two barely answer any, and the last two compose rather than compete — `Secrets` caches what it fetches in `SecureStorage`. A per-user token belongs in the keychain; an app-wide key you want to rotate without a release belongs in the vault.

91.1. Constant obfuscation

One of the first things a hacker will do when compromising an app is look at it. For example, an attacker wanting to exploit a bank's login UI would look at the label next to the login and then search for it in the decompiled code. If the UI has the String "enter username and password" they can search for that.

It won't lead directly to a hack or exploit, but it will narrow down the area of the code where you should look and it makes the first step that much easier. Obfuscation helps as it removes descriptive method names but it can't hide the Strings you use in constants. If an app has a secret key within obfuscating it can make a difference (albeit a slight difference).

Notice that this is a temporary roadblock as any savvy hacker would compile the app and connect a debugger eventually (although this is blocked in release builds) and would be able to inspect values of variables/flow. But the road to reverse engineering the app would be harder even with a simple xor obfuscation.

This isn't encoding or encryption — it's a simple obfuscation of the data.

The `Util` class has two static methods for it: `xorEncode(String)` turns a string into the obfuscated form, and `xorDecode(String)` turns it back.

They use a simple xor based obfuscation to make a String less readable. For example, if you've code like this:

```
private static final String SECRET = "Don't let anyone see this/* omitted */";
```

You might be concerned about the secret, then this would make it slightly harder to find out:

```
// Don't let anyone see this/* omitted */
```

Notice that this **isn't secure**, if you have a crucial value that must not be found you need to store it in the server. No alternative exists because everything that's sent to the client can be compromised by a determined hacker.

Use the comment to help you find the string in the code

Codename One's built-in user-specific constants are obfuscated with this method. For example, an app built with Codename One carries some internal data such as the user who built the app, which is now obfuscated. The following small app encodes strings so you can copy and paste them into your app:

```
Form hi = new Form("Encoder", BoxLayout.y());
TextField bla = new TextField("", "Type Text Here", 20, TextArea.ANY);
TextArea encoded = new TextArea();
SpanLabel decoded = new SpanLabel();
hi.addAll(bla, encoded, decoded);
bla.addDataChangedListener((a, b) -> {
    String s = bla.getText();
    String e = Util.xorEncode(s);
    encoded.setText(e);
    decoded.setText(Util.xorDecode(e));
    hi.getContentPane().animateLayout(100);
});

hi.show();
```

This allows you to type in the first text field and the second text area shows the encoded result. A text area is used so copy/paste is easy.

91.2. Storage encryption

Codename One had support for bouncy castle encryption for quite a while but it isn't as intuitive as you'd like it to be. This makes securing/encrypting your app more painful than it should.

Codename One supports full encryption of the `Storage` (notice the distinction, `Storage` isn't `FileSystemStorage`). This is available by installing the bouncy castle cn1lib from the extensions menu then using one line of code

You would want that code within your `init(Object)` method

Notice that you can't use storage or preferences to store this data as it would be encrypted (`Preferences` uses `Storage` internally). You can use a password for this key and it would make it way more secure **but** if a user changes his password you might have a problem. In that case you might need the old password to migrate to a new password.

This works through a new mechanism in storage where you can replace the storage instance with another instance using:

```
Storage.setStorageInstance(new MyCustomStorageSubclass());
```

You can leverage that knowledge to change the encryption password on the encryption storage. The key is installed for the whole of `Storage`, so every entry has to move together: read them all under the old key, install the new one, write them all back. `EncryptedStorage` comes from the bouncy castle cn1lib, so this listing isn't part of the compiled examples:

```
EncryptedStorage.install(oldKey);
Map<String, byte[]> all = new LinkedHashMap<>();
for (String name : Storage.getInstance().listEntries()) {
    try (InputStream is = Storage.getInstance().createInputStream(name)) {
        all.put(name, Util.readInputStream(is));
    }
}

EncryptedStorage.install(newKey);
for (Map.Entry<String, byte[]> e : all.entrySet()) {
    try (OutputStream o = Storage.getInstance().createOutputStream(e.getKey())) {
        o.write(e.getValue());
    }
}
```

The `try`-with-resources is deliberate: `Util.cleanup` swallows a close failure, and on the write side a swallowed close means an entry was never finalized under the new key. Let it throw.

This isn't crash-safe, and it can't be made crash-safe from the outside. If the process dies part way through the second loop, some entries are under each key and neither opens the whole store. `Storage` has no rename, so there is no way to stage the converted copies and swap them in atomically, and the recovery data lives only in that in-memory map.

Which is the real argument for not rotating the storage key at all. Encrypt `Storage` with a random key your app generates once, keep that key wrapped under the password-derived one in a single record outside `Storage`, and a password change re-wraps that one small record instead of rewriting every entry. Nothing else moves, so there is no half-converted state to recover from. If you do rewrite the store in place, do it once at startup with nothing else touching `Storage`, and treat the possibility of an interrupted run as something your app has to survive rather than something this loop prevents.

It isn't a good idea to replace storage objects when an app is running so this is purely for this special case...

If you use preferences it might be a good idea to set their built-in location to a different path using something like `Preferences.setPreferencesLocation("EncryptedPreferences");`.

This is useful as it prevents the encrypted preferences from colliding with the regular preferences.

91.3. Secure storage and secrets

Some values are too sensitive for `Storage` or `Preferences`, which are plaintext on disk: auth tokens, refresh tokens, and API keys. Codename One gives you two complementary tools for them.

91.3.1. SecureStorage (the platform keychain)

`com.codename1.security.SecureStorage` keeps small string values in the operating system's secure keychain (iOS Keychain Services and the Android Keystore) so they're protected by the platform's secure enclave instead of being written to app storage. The quiet, no-prompt API is three calls:

```
SecureStorage ss = SecureStorage.getInstance();
ss.set("auth.token", token);
String token = ss.get("auth.token");   // null if absent
ss.remove("auth.token");
```

What backs it differs by port, and a `null` read isn't the only thing to watch for. The native ports mostly put the value behind something real: Keychain Services on iOS, an `AndroidKeyStore` key on Android from API 23, DPAPI on Windows and the Secret Service on Linux. Below API 23 the Android path falls back to Base64 in `SharedPreferences` and warns about itself, so it's a store and not a protection. The base implementation returns `false` / `null` where there's nothing to use, so treat that as "not available" and fall back accordingly. The browser port now encrypts what it writes: the value goes into origin-private storage as AES-GCM ciphertext under a `CryptoKey` created with `extractable: false` and held in IndexedDB, which is a key the page can use and can't read out. That protects a copied storage file, a profile backup and a stolen database, and it doesn't protect the value from script running on the origin, which calls `get` exactly as your code does. Outside a secure context there is no Web Crypto at all, so writing over plain `http:` is refused rather than stored in the clear. The simulator's non-prompting tier still describes itself as obfuscation rather than security. Don't let a successful read in either of those stand in for a test on a device.

91.3.2. Secrets (fetched from the cloud, never shipped in the binary)

Baking an API key (for example a Google Maps key) into your app means it's in the binary forever, and rotating it means shipping a new build. `com.codename1.security.Secrets` keeps the value out of the binary and lets you rotate it server-side. Be clear about what that does and doesn't buy you: the fetch is authenticated with the build key, which **is** in the binary, so a determined attacker who extracts it can call the vault the same way your app does. What you gain is rotation without a release, and a vault that decides what a client may ever read — not secrecy against someone reverse engineering the binary. You define the secret once in the Codename One Cloud vault, and

the app fetches it at runtime and caches it in `SecureStorage`:

```
// off the EDT -- the first call may hit the network:
String mapsKey = Secrets.get("googlemaps.key");
```

`get` returns the keychain-cached value when present, otherwise it fetches from the vault over TLS, caches it, and returns it. `refresh(name)` forces a fresh fetch (after you rotate the value server-side) and `clear(name)` drops the cached copy.

To publish a secret, open the **Secrets** page of the build console and add it under the app-readable namespace (the `app.` prefix; you reference it by its bare name from `Secrets.get`). Only secrets in that namespace are ever served to a device, so your server-only credentials (such as the store API keys used by commerce validation) stay in the vault and can't be fetched from a client. Authentication uses the build key every cloud build already carries, so there's nothing to wire up; on the simulator or a local build there's no build key, so `get` returns the cached value if any and otherwise `null`.

Build hint	Default	Description
`secrets.cloud.endpoint`	*(Codename One cloud)*	Base URL of the secrets service. Override only if you self-host.

91.4. Vaults: One password, every device

`SecureStorage` answers one question — where does this device keep a small secret — and it answers it per device. `com.codename1.security.vault.Vault` answers the harder one: how does the same user read the same encrypted data on their phone and in a browser, without a server ever being able to read it, and without typing a password on every page load.

One random 32-byte **data key** protects everything a vault holds. The data key is never stored. What's stored are wrapped copies of it: one sealed under a key derived from the user's password, optionally one sealed under a recovery code, and, if the user asked to be remembered, one sealed by this device's key store — the keychain on iOS, the keystore on Android, a non-extractable `CryptoKey` in a browser. Unlocking means unwrapping one of those copies. Changing the password rewrites one wrap and re-encrypts no data at all.

That shape is what makes synchronization work. The record describing a vault is ciphertext, and so is every record the vault seals, so a sync server can store both and read neither.

91.4.1. Setting one up

```
Vault vault = Vault.named("notes");
VaultOptions options = new VaultOptions()
        .policy(rememberThisDevice ? UnlockPolicy.REMEMBER_DEVICE
                : UnlockPolicy.SESSION_ONLY)
        .autoLockAfter(5 * 60 * 1000);
vault.configure(options);
```

```
vault.enroll(password, options).ready(ready -> Log.p("vault ready"));
```

On every later run, try the remembered key first and fall back to asking:

```
Vault vault = Vault.named("notes");
vault.unlockRemembered()
        .except(notRemembered -> vault.unlockWithPassword(password)
                .except(wrong -> Log.p("that password did not open the vault")));
```

`KEY_MISSING` from `unlockRemembered` is the ordinary case, not an error to show anyone: it's how you learn this device was never remembered, or has been forgotten.

91.4.2. Storing things

Small secrets go in by name. Values are `char[]` rather than `String` so you can clear them — a `String` is immutable and lives in the heap until it's collected, which is an unbounded window in a heap dump.

```
vault.putSecret("api.token", token);
vault.getSecret("api.token").ready(value -> {
    useToken(value);
    // The caller owns the characters and can clear them; a String could not be.
    java.util.Arrays.fill(value, '\0');
});
```

Larger data is sealed rather than stored, so you decide where it lives:

```
vault.seal("note-7", note).ready(sealed -> upload("note-7", sealed));
// The vault record itself is safe to upload too: it carries the data key only in
// wrapped form, so a server holding it can neither read the notes nor help anyone else.
upload("vault", vault.exportSyncState());
```

A second device enrolls from the first device's exported state and the same password:

```
Vault vault = Vault.named("notes");
vault.importSyncState(syncState, password)
        .ready(ok -> vault.open("note-7", sealedNote).ready(this::showNote))
        .except(failure -> Log.p("could not enroll this device: " + failure.getMessage()));
```

Keep the credentials the user signs into your sync server with separate from the vault password. A server that can verify the login must not be able to derive the vault key, and it can if they're the same string.

91.4.3. Unlock policies

Three, and the choice belongs to the user rather than to you.

Policy	What it means
`SESSION_ONLY`	The password is required every launch, and every page load in a browser. Nothing that can reopen the vault is written to the device.
`REMEMBER_DEVICE`	The data key is additionally wrapped under this device's key store, so the vault reopens with no prompt. That's unattended access: anyone who can run the app on this device reopens the vault without the password.
`REQUIRE_USER_VERIFICATION`	Reaching the key needs the user to verify themselves. Choosing this **deletes** the unattended wrap, because a policy that promises a prompt while a wrap that skips it sits alongside promises nothing.

In a browser the third one isn't the second with a flag on it — it's a different mechanism. `REMEMBER_DEVICE` wraps the data key under a non-extractable `CryptoKey` in IndexedDB; `REQUIRE_USER_VERIFICATION` wraps it under key material a **passkey** derives, through the WebAuthn PRF extension.

That distinction is the one thing a browser can offer that the stored key can't: **the key material doesn't exist until the user verifies**. A copied browser profile carries the credential id, which isn't a secret, and can't derive anything without the authenticator and a person in front of it. The stored `CryptoKey`, by contrast, travels with the profile and works in the copy.

A passkey may be synced, and that's your choice to make. By default the browser offers whatever authenticators it has, so on a Mac the credential can land in iCloud Keychain and reach every device on that Apple account; a Google-account passkey on Android behaves the same way. Where that happens, "remember this device" amounts to "remember this account" — still a genuine protection, because it needs the account **and** a biometric, but not device-binding.

For a note-taking app that's usually what the user wants: a new laptop unlocks with a face scan and no password. For something holding a second factor it's the opposite, which is why this is a choice:

```
VaultOptions options = new VaultOptions()
        .policy(UnlockPolicy.REQUIRE_USER_VERIFICATION);
if (mustNotLeaveThisDevice) {
    // Excludes security keys and every synced passkey. Enrolment fails with
    // POLICY_NOT_MET where no authenticator can meet it, so have a fallback.
    options.requireDeviceBoundPasskey();
}
Vault vault = Vault.named("payments").configure(options);
vault.enroll(password, options).except(failure -> offerPasswordOnly());
```

`requireDeviceBoundPasskey()` checks the credential's **backup-eligibility flag**, which is the part that actually decides. Asking for platform attachment alone isn't enough — an iCloud Keychain passkey is platform-attached and syncs anyway. A browser that won't report the flag counts as **may leave this device**, so an unknown answer is never rounded up into a guarantee.

What it costs: hardware security keys are excluded, and a user whose only authenticator syncs can't enroll at all — enrollment fails with `POLICY_NOT_MET` rather than keeping a credential that doesn't meet the requirement. Offer the weaker policy as a fallback, or don't require it.

Checked on real hardware and not only against a virtual authenticator: macOS Touch ID in Chrome derives 32 bytes, and derives the same 32 bytes again after the browser has been quit and reopened — which is the property the whole scheme rests on, since a passkey that derived fresh bytes each time would make the wrapped data key unrecoverable.

A passkey signature isn't an encryption key, and it's worth being clear why, because the obvious shortcut is wrong: signatures are randomized, so signing a fixed challenge gives different bytes every time. PRF is the part of WebAuthn that actually derives a key — the authenticator evaluates its own HMAC secret over a salt, so the same credential and salt give the same 32 bytes forever.

Not every authenticator implements it. Enrollment checks `prf.enabled` from the creation ceremony and refuses to keep a credential that can't derive, so `capabilities().supports(…)` tells you the truth rather than offering a prompt with nothing behind it. And note that **WebAuthn doesn't work on an IP-address origin at all** — a relying-party id has to be a domain. For local development that means serving from `localhost`, not `127.0.0.1`.

91.4.4. Measured browser support

Run by hand against the shipped bridge on macOS, with Touch ID as the platform authenticator:

Browser	**Device key**	**Passkey PRF**	`storage.persisted()`
Chrome 152	yes	yes	false
Safari 26.6	yes	yes	false
Firefox 155	yes	yes	false

"Device key" is the whole `REMEMBER_DEVICE` path: a non-extractable `CryptoKey` structured-cloned into IndexedDB, a wrap round trip, and a wrong binding correctly failing its tag. That's the one that mattered — it's the default, and had Safari refused the clone, remembered vaults would have been broken on every iPhone and Mac.

PRF derived 32 stable bytes in all three, and in Chrome the same bytes after the browser was quit and reopened.

What this doesn't cover: mobile Safari, Chrome on Android, Windows Hello, hardware security keys, and older versions of all three. The runtime detection above is what protects those — the table says what was seen, not what's guaranteed. Every one of these browsers reported `storage.persisted()` as false on a fresh profile, which is why `PERSISTENT` is reported from storage working rather than from that call.

Reproduce any row with `node scripts/verify-javascript-vault-passkey.mjs`, which serves a page running the same bridge an application does.

`REQUIRE_USER_VERIFICATION` isn't available everywhere. Ask `vault.capabilities().supports(policy)` before you offer the switch, because a "remember this device" toggle on a platform that can't

remember is worse than no toggle.

91.4.5. Asking what actually protects it

Protections are independent flags with three answers each — yes, no, and **can't say** — rather than a security level. The third is a real answer: no browser will tell you whether a key ended up in a secure element, and a report that guessed would be inventing a guarantee.

```
ProtectionReport report = vault.protection();
if (report.answer(Protection.HARDWARE_BACKED) == ProtectionReport.UNKNOWN) {
    // Not "no". This platform will not say, and a screen that rendered that as "no"
    // would understate an authenticator that does use a secure element.
    return "Encrypted on this device; hardware backing could not be confirmed.";
}
return report.provides(Protection.HARDWARE_BACKED)
        ? "Encrypted with a hardware-backed key."
        : "Encrypted with a software key.";
```

When you need a protection rather than a description of one, require it. The vault then refuses instead of storing with less:

```
VaultOptions options = new VaultOptions()
        .policy(UnlockPolicy.REMEMBER_DEVICE)
        .require(Protection.OS_PROTECTED);
Vault vault = Vault.named("payments").configure(options);
vault.enroll(password, options).except(failure -> {
    if (failure instanceof VaultException
            && ((VaultException) failure).getError() == VaultError.POLICY_NOT_MET) {
        // The browser reaches this: there is no OS key store in a page. Offer the
        // session-only policy instead of pretending the requirement was met.
        Log.p("this device cannot hold the key in the OS key store");
    }
});
```

`UNKNOWN` never satisfies a requirement.

91.4.6. What a vault protects against

Threat	Protected
A stolen database file, a stolen backup, a copied storage pool	Yes. Everything at rest is authenticated ciphertext under a key that isn't stored beside it.

Threat	Protected
A copied browser profile, vault locked	Yes under `SESSION_ONLY`. **No** under `REMEMBER_DEVICE` in a browser: the copy contains the IndexedDB the wrapping key lives in, and the key works in the copy.
A copied profile, vault unlocked	No. The data key is in memory.
Script running on your own origin, vault unlocked	**No.** It calls the same decrypt your code calls. Non-extractable keys and Web Workers don't change this.
Script on your origin, vault locked	It can't read the data. It can wait, and read the password when the user next types it.
A browser extension, or malware on the device	No.
A compromised server that serves new application code	No. New code runs in your origin and inherits everything your application has.
Data already copied elsewhere	No. `forgetDevice()` and `destroyLocalData()` remove local access; they can't reach a copy.

The second row is the one that gets misread. "The database file alone is useless" and "a copy of the whole profile is useless" are different claims, and only the first holds for a browser with a remembered device. Say that to users in those words.

91.4.7. Keys you can use and can't read

`operationalKey` hands back a `KeyHandle` — a key with no byte accessor at all. There's no `getEncoded()` on it and no method that adds one, and it stops working the moment the vault locks.

```
vault.operationalKey("cache").ready(key -> {
    // There is no getEncoded() on a KeyHandle, and no method that adds one.
    key.seal(payload, null).ready(sealed -> storeInCache(sealed));
});
```

91.4.8. Encrypted databases

SQLCipher keys from bytes, on the device and in the browser's WebAssembly build alike, so a database can't be keyed by a handle. `DatabaseConfig.vault(…)` therefore produces real key bytes, and says so rather than exporting a handle behind your back:

```
// The vault must be unlocked here: the key does not exist until it is. Locking the
// vault afterwards does not close the connection -- the engine already has the key.
```

```
return Database.openOrCreate("notes", DatabaseConfig.vault(vault, "notes"));
```

While the database is open the key is in the process and stays there; locking the vault doesn't close the connection. What the vault adds over `DatabaseConfig.managed()` is that the key doesn't exist at all until the user unlocks — which in a browser is the difference between a page that holds a database key from the moment it loads and one that doesn't. If you can't accept the exposure, call `VaultOptions.requireOpaqueKeysOnly()`, which makes that call fail with `POLICY_NOT_MET` and means this vault can't key a database.

`rotateDataKey` and importing a rotation both change the current database key. Record `vault.getDataKeyVersion()` alongside the database when creating it, and use `DatabaseConfig.vault(vault, alias, recordedVersion)` to open that file even after a later rotation arrives. The vault retains the retired keys across restarts; `vault.databaseKey(alias, version)` also exposes them for database engines you manage directly.

To change the database key, open the file at its recorded version, call `database.changeKey(DatabaseConfig.vault(vault, alias, newVersion))`, and update the recorded version only after that succeeds. Keep both version numbers in a local migration journal until reopening succeeds, so a crash between changing the key and updating that record is recoverable. There is no automatic key change.

If import policy setup fails, an untouched import is rolled back. `VaultError.IMPORT_COMMITTED` means the import reached committed state and rollback would risk existing data or couldn't be confirmed. The session is locked; reread the persisted sync state before retrying policy setup.

91.4.9. Cross-platform interoperability

Everything about the format is pinned so the same password opens the same data everywhere:

- AES-256-GCM with a 12-byte nonce and a 128-bit tag, in a versioned envelope whose header — version, cipher suite, KDF parameters, key id — is authenticated rather than merely present. Rewriting the iteration count fails the tag instead of steering the decryption.
- PBKDF2-HMAC-SHA256, 600,000 iterations by default, with the count carried in the envelope so it can be raised without breaking what's already written. It's the one password KDF a browser has, and a KDF one of the three platforms has to emulate in application code isn't a portable one.
- UTF-8 encoded by Codename One rather than by the platform, because runtimes disagree about unpaired surrogates. No normalization is applied: if you want to accept two spellings of the same accented password, normalize before you call.
- Every envelope is bound to its application, vault, record and purpose. Ciphertext moved from one record to another fails to authenticate rather than decrypting into the wrong slot.

91.4.10. Deploying the browser build

The vault needs a secure context. Served over plain `http:` on anything but `localhost` there's no Web Crypto, and writes are refused rather than stored in the clear.

The SQLite engine — about 1.5 MB of WebAssembly and its loader — is copied into the build only when the application can actually reach it. It's fetched on first use rather than at page load, so it never cost startup time for anyone; it cost deployment size in an artifact you upload to static hosting. The decision is made from the translated output, and it fails toward shipping: if the build can't tell, the engine goes in, because a database that won't open is a worse outcome than a download nobody makes.

The JavaScript build writes its own deployment configuration into a `cn1-security` directory: a `_headers` file for Netlify and Cloudflare Pages, configuration for nginx and for Apache, and a README explaining them. It's written beside the bundle directory and named after it — `MyApp-js-cn1-security` next to `MyApp-js` — because the bundle directory is the web root you upload. Host configuration doesn't belong there, and a directory that sits outside the bundle can't be published by accident. A Maven build copies it, and the suspension report beside it, into `target/`. Nothing here is active until you copy the file your host reads to where it reads it. That's on purpose: Netlify and Cloudflare read `_headers` automatically, and an application that never asked for a policy shouldn't acquire one on its next deploy. Read the README first: the policy restricts `connect-src` to this origin, so an app that calls a backend elsewhere has to add it. The Content-Security-Policy in them is generated from the page that was actually emitted — each inline block is hashed — so it doesn't go stale against a template.

Three of those protections exist only as response headers and are ignored in a `<meta>` tag: `frame-ancestors`, `X-Frame-Options` and `Strict-Transport-Security`. A deployment that puts the policy in the page and skips the host configuration has no clickjacking protection and no HSTS, whatever the rest of it says.

Give the application its own origin where you can. Storage, IndexedDB, the vault's key and cookies are all keyed by origin and not by path, so a second application on the same host under a different path shares every one of them.

91.5. Disabling screenshots

One of the common security features some apps expect is the ability to block a screenshot. In the past apps like snapchat required that you touch the screen to view a photo to block the ability to grab a screenshot (on iOS). This no longer works…

Blocking screenshots is implemented by classifying the app window as secure on Android. You can enable this via the build hint `android.disableScreenshots=true`. Once that's added screenshots should no longer work for the app, this might impact other things as well such as the task view which will no longer show the screenshot either.

On iOS, you can't prevent a user from taking a static screenshot, but you can block screen capture/recording while it's active. This uses `UIScreen.isCaptured` and its change notification to hide the app contents while a capture session is active. Enable this behavior with the build hint `ios.disableScreenshots=true`.

91.6. Blocking copy & paste

Blocking copy & paste is useful for cases where a device might have spyware installed that monitors

the clipboard. This also prevents a user from using a password manager (which rely on the clipboard), those managers could be compromised and thus if you're building a secure app this might be necessary.

You can block copy & paste on Android & iOS. Blocking of copy & paste can be implemented globally or on a specific field.

To block copy & paste globally use:

```
Display.getInstance().setProperty("blockCopyPaste", "true");
```

To block copy & paste on a specific field do:

```
textCmp.putClientProperty("blockCopyPaste", Boolean.TRUE);
```

Notice that the inverse of using `false` might not work as expected

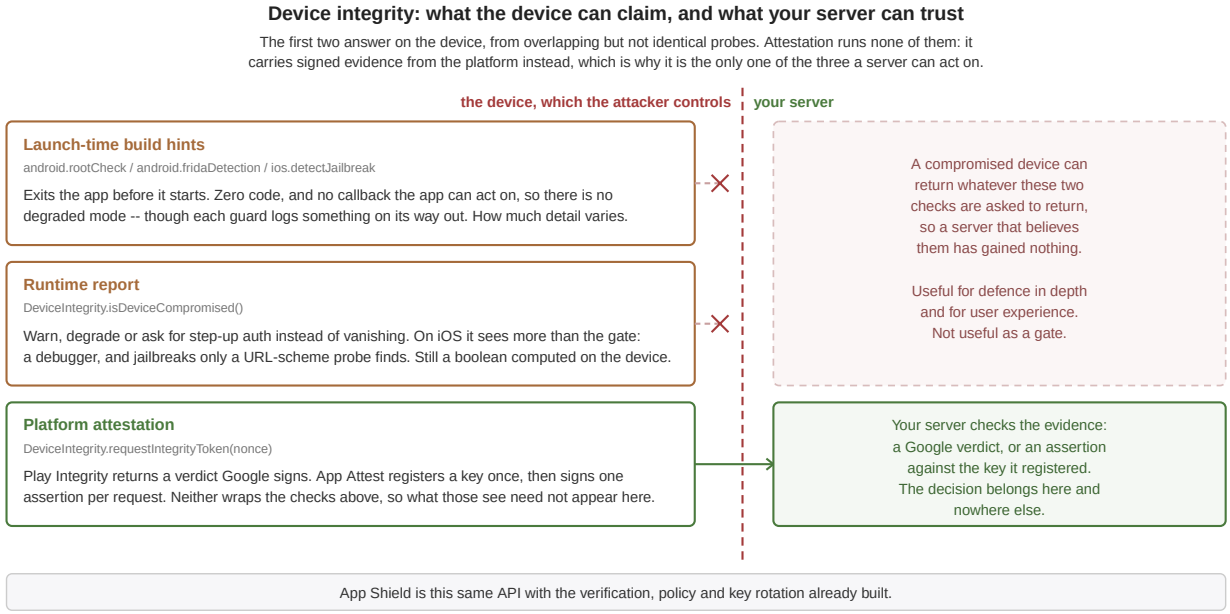
91.7. Blocking jailbreak

iOS & Android are walled gardens which is both a blessing and a curse. Looking at the bright side the walled garden aspect of locked down devices means the devices are more secure by nature. For example, on a PC that was compromised you can detect the banking details of a user logging into a bank. But on a phone it would be much harder due to the deep process isolation.

This isn't true for jailbroken or rooted devices. In these devices security has often been compromised with good intentions (opening up the ecosystem) but it can also be used as a step in a serious attack on an application!

For obvious reasons it's hard to accurately detect a jailbroken or rooted device but when possible if you have a high security app you might want to block the functionality or even raise a "silent alarm" in such a case. To detect this you can use the `isJailbrokenDevice` method as such:

```
if(Display.getInstance().isJailbrokenDevice()) {
    // probably jailbroken or rooted
} else {
   // probably not
}
```



Notice that this isn't right, you can't be 100% sure as there are no official ways to detect jailbreak. That's why it's crucial to encrypt everything and assume the device was compromised to begin with when dealing with sensitive data. Still it's worthwhile to use these APIs to make the life of an attacker a little bit harder.

91.8. Device integrity, RASP & attestation

The `isJailbrokenDevice` check above is a single, coarse signal. For high-security apps (banking, payments, healthcare) Codename One exposes a richer, cross-platform device-integrity API in `com.codename1.security.DeviceIntegrity`. It groups three families of runtime self-protection (RASP) primitives, each available both as a **zero-code build hint** (an automatic launch-time guard) and as a **runtime API** (so your app can make granular, per-transaction decisions). The build hints are wired into the build server, so enabling a feature is just a settings entry away.

Every on-device check is bypassable on a sufficiently compromised device — that's an industry truth, not a Codename One limitation. Use the on-device checks for defense-in-depth and UX (warn, degrade, require step-up auth), but gate genuinely sensitive server actions on the **server-verified attestation token** described below, never on a boolean computed on the device itself.

91.8.1. Detecting rooted / jailbroken / tampered devices (RASP)

Codename One ships several launch-time hard gates that terminate the app on a compromised device. They're enabled through build hints and need no code:

- `android.rootCheck=true` — bundles the RootBeer library and exits at launch on a rooted device (`su` binaries, test-keys / custom ROM signals, Magisk indicators, dangerous system properties).
- `android.fridaDetection=true` — detects the Frida dynamic-instrumentation toolkit (the core RASP threat) and exits.
- `ios.detectJailbreak=true` — exits at launch on a jailbroken iOS device (MobileSubstrate / Liberty / FridaGadget dylibs, Cydia/apt paths, sandbox-escape probes).

When you'd rather respond in-app than be hard-killed — for example to block only a single risky operation, raise a silent alarm, or require additional authentication — use the non-exiting runtime report instead:

```
if (DeviceIntegrity.isDeviceCompromised()) {
    // root / jailbreak / Frida / emulator detected -- do not hard-exit,
    // instead degrade: disable the transfer button, require step-up auth, etc.
    for (String reason : DeviceIntegrity.getCompromiseReasons()) {
        // reason is a machine-readable code: "root", "frida", "emulator", "jailbreak"
        Log.p("Device compromise signal: " + reason);
    }
}
```

`isDeviceCompromised()` covers the root, jailbreak and Frida ground the launch gates do, plus emulator heuristics, but it isn't the same set and never terminates the app. On iOS it reports more than the gate enforces: the launch guard exits only on the file, path, mount and hooking signals, leaving out the one that fires when a debugger is attached, by design, so a device launched from Xcode still runs, while the runtime report includes it and also probes for the package managers a jailbreak leaves behind. Don't read a passed launch as covering whatever your runtime policy checks. On unsupported ports it returns `false`. The simulator returns `false` too until you set a signal under **Simulate** > **App Shield**, which is how you exercise your warning, degradation and step-up branches without a compromised device.

If your security policy mandates a specific commercial Mobile Threat Defense (MTD) / RASP vendor (Zimperium, Promon SHIELD, etc.), you integrate that vendor's SDK through the standard `android.gradleDep` / `ios.pods` build hints — Codename One's built-in checks complement, but don't claim to replace, a dedicated MTD product.

91.8.2. Platform attestation: Google Play Integrity & Apple App Attest

The trustworthy way to verify device and app integrity is hardware-backed attestation: Google Play Integrity on Android and Apple App Attest on iOS. Both produce a **signed token** that your backend verifies with Google / Apple. This is the mechanism to use when you must, for example, block an outward transfer to a newly added beneficiary on a device that fails integrity.

Enable it with a build hint, which bundles the SDK (Android) or links the entitlement (iOS):

- `android.playIntegrity=true` — bundles the Play Integrity SDK and enables the runtime token API. Optionally add `android.playIntegrity.verifyUrl=https://backend.example.com/integrity` to **also** attest at launch on a background thread and exit if your backend rejects the token. `android.playIntegrityVersion` overrides the bundled SDK version.
- `ios.appAttest=true` — enables App Attest (DeviceCheck.framework) and the runtime token API. `ios.appAttest.environment` is `development` (debug builds) or `production` (release) by default.

The runtime API is identical on both platforms — request a token bound to a fresh server nonce, then POST it to your backend for verification:

```
// serverNonce is generated by, and round-tripped from, your backend so it can
// detect replay. The returned token is opaque and MUST be verified server-side.
DeviceIntegrity.requestIntegrityToken(serverNonce).onResult((token, err) -> {
```

```
    if (err != null) {
        // Attestation unavailable -- treat the device as untrusted /
        // require an additional verification step before allowing the transfer.
        return;
    }
    // POST `token` to your backend. The backend decrypts/validates the verdict
    // with Google / Apple and decides whether to authorize the transfer.
    authorizeTransferAfterServerVerification(token);
});
```

`DeviceIntegrity.isAttestationSupported()` reports whether attestation is available and was bundled into this build. On the simulator, on unsupported ports, or when the build hint is off, `requestIntegrityToken()` completes with an error rather than throwing.

The block-the-transfer decision lives in **your backend**, gated on the verified verdict. Codename One's job is to reliably deliver the attested token; the policy enforcement — for example blocking new-beneficiary transfers when integrity fails and biometric controls aren't enabled — is application + server logic that consumes this API.

`DeviceIntegrity` hands you the raw platform blob and leaves verification, policy, replay protection, key management and rotation to you. If you'd rather not build that, Chapter 93, *App Shield* is the managed layer on top of exactly this API: the attestation is verified server-side against Apple and Google, evaluated against a policy you control, and turned into a short-lived signed token your backend checks with a few lines of middleware. Both remain available and this API keeps working unchanged.

91.8.3. Defending against accessibility-service abuse (Android)

A common Android malware technique is to abuse the accessibility services API for overlays, remote control, and on-screen text extraction (including reading text destined for text-to-speech). Codename One lets you detect untrusted accessibility services and lock down sensitive screens.

The `android.accessibilityGuard=true` build hint checks the enabled accessibility services at launch and, by default, exits when an untrusted one is active. Tune it with:

- `android.accessibilityGuard.allow=com.google.android.marvin.talkback,com.example.trusted` — a comma-separated allow-list of accessibility-service **packages** the user legitimately relies on (such as a screen reader). Any enabled service outside this list trips the guard.
- `android.accessibilityGuard.mode=exit|warn` — `exit` (default) terminates the app; `warn` only logs, leaving the decision to your runtime code.

At runtime you get the same information for granular control:

```
// Enumerate the enabled accessibility services (component ids "pkg/.Service").
String[] services = DeviceIntegrity.getEnabledAccessibilityServices();

// True if any enabled service is outside your trusted allow-list.
```

```
if (DeviceIntegrity.hasUntrustedAccessibilityService("com.google.android.marvin.talkback")) {
    // Likely accessibility-abusing malware -- block the sensitive action.
}
```

For the screens that actually matter (PIN entry, transfer confirmation), mark them secure so the OS blocks screenshots, screen recording, and accessibility screen scraping while they're displayed:

```
// Entering a sensitive screen (Android FLAG_SECURE; no-op on iOS):
DeviceIntegrity.setSecureScreen(true);
// null leaving it:
DeviceIntegrity.setSecureScreen(false);
```

Accessibility-service enumeration and `setSecureScreen()` are Android concepts; on iOS they're no-ops (iOS has no equivalent third-party accessibility-service threat model). Use `ios.disableScreenshots=true` to block screen capture on iOS as described in Section 91.5, "Disabling screenshots".

91.8.4. Defending against tapjacking and screen overlays (Android)

Tapjacking is the other half of the same attack. Instead of driving your app through an accessibility service, a malicious app draws its own window on top of yours — a fake PIN pad, a fake confirmation button, or an invisible layer — so the user believes they're tapping your UI while the tap is being framed, or harvested, by someone else. It's the classic way a banking transfer gets confirmed by a user who thought they were dismissing a notice.

Android exposes this as flags on each touch event, and Codename One turns that into a policy you set once:

- `android.tapjackingGuard=true` — switches on protection at launch with no code. By default it blocks obscured touches and asks Android 12+ to hide overlay windows.
- `android.tapjackingGuard.mode=block|strict|report` — `block` (default) drops any gesture that starts while another window covers the touched point. `report` observes without changing behavior, which is the safe way to measure how often this happens in your user base first. `strict` also drops touches where only part of the window is covered; read the warning below before choosing it.
- `android.tapjackingGuard.hideOverlays=true|false` — whether to also call `setHideOverlayWindows()`. Defaults to `true`.

The runtime API gives you the same control plus a notification:

```
// Switch on tapjacking protection once, during startup. BLOCK drops any gesture
// that begins while another app's window covers the touched point.
DeviceIntegrity.setTapjackingProtection(TapjackingPolicy.BLOCK);

// A blocked gesture never reaches your components, so this listener is how the
// app learns the tap happened. It fires when the state changes, not per touch.
```

```
//
// Read the state off the event, not from isScreenObscured(). The callback is
// delivered on the EDT while the state is updated on the platform's input thread,
// so a busy EDT can let a later clean touch land first -- and re-reading the
// global state would then skip the warning for the event that caused it.
DeviceIntegrity.addTapjackingListener(e -> {
    if (Boolean.TRUE.equals(e.getSource())) {
        Dialog.show("Security warning",
                "Another app is drawing over this screen. Close it before continuing.",
                "OK", null);
    }
});

// On a sensitive screen, remove the overlay instead of merely filtering its taps.
// This is Android 12+ only, and unlike the touch filter it also protects native
// peer components such as BrowserComponent.
if (DeviceIntegrity.isHideOverlayWindowsSupported()) {
    DeviceIntegrity.setHideOverlayWindows(true);
}
DeviceIntegrity.setSecureScreen(true);
```

Two properties of this API are worth being precise about, because getting them wrong leads to a false sense of coverage.

Detection is touch-driven, not a live window query. Android reports obscuring as a flag on a delivered `MotionEvent`, so `isScreenObscured()` means "the most recently observed touch arrived obscured." If an overlay appears and the user never touches the screen, nothing is observed. That's a platform limitation, not an implementation gap.

A blocked gesture is dropped in full. Swallowing only the press and delivering the release would leave the framework holding half a gesture, so once a gesture starts obscured, everything through to the matching release is discarded. Your components see nothing at all — which is exactly why the listener exists, and why an app that blocks should register one rather than rely on polling.

`setHideOverlayWindows(true)` is the strongest of the three defenses and the only one that also covers native peer components such as `BrowserComponent` and native text fields, because it removes the offending window instead of filtering the touches it enables. Pair it with `setSecureScreen(true)` when you enter a sensitive screen and clear both on the way out.

It has two requirements, and `isHideOverlayWindowsSupported()` reports on both — it returns `false` rather than claiming a protection you aren't getting:

- Android 12 (API 31) or newer.
- The `android.permission.HIDE_OVERLAY_WINDOWS` manifest permission. Without it the OS throws, so the call is skipped and logged instead. `android.tapjackingGuard=true` declares it for you; if you drive the runtime API without that hint, add `android.hideOverlayWindows=true`. It's a normal install-time permission — no runtime prompt and no special-access screen for the user.

`strict` mode blocks touches where only part of the window is covered, and

ordinary system UI causes that as a matter of course. On some devices this will discard taps the user intended and the app will simply feel broken, with nothing in the logs to explain it. Use it only where a missed tap is clearly preferable to a hijacked one, and test it on real hardware.

This family is Android-only. iOS gives no application a way to draw over another app, so there is nothing to detect: `isScreenObscured()` is always false and the policy has no effect. Screen recording and mirroring are a different threat, covered by `ios.disableScreenshots=true`. In the simulator, **Simulate** > **App Shield** > **Screen Overlay (Tapjacking)** fakes an overlay so you can exercise your listener on the desktop.

91.9. Strong Android certificates

When Android launched RSA1024 with SHA1 was considered strong enough for the foreseeable future, this hasn't changed completely but the recommendation today is to use stronger ciphers for signing & encrypting as those can be compromised.

APKs are signed as part of the build process when you upload an app to the Google Play Store. This process seems redundant as you generate the signature/certificate ourselves (unlike Apple which generates it for you). But, this is a crucial step as it allows the device to verify upgrades and make sure a new update is from the same original author!

This means that if a hacker takes over your account on Google Play, he still won't be able to ship fake updates to your apps without your certificate. That's important since if a hacker would have access to your certificate he could create an app update that would send him all the users private information for example, if you're a bank this could be a disaster.

Android launched with RSA1024/SHA1 as the signing certificates. This was good enough at the time and is still pretty secure. But, these algorithms are eroding and it's conceivable that within the 10-15 year lifetime of an app they might be compromised using powerful hardware. That's why Google introduced support for stronger cryptographic signing in newer versions of Android and you can use that.

91.9.1. The bad news

A downside exists…

Google introduced that capability in Android 4.3 so using these new keys will break compatibility with older devices. If you're building a highly secure app this is probably a tradeoff you should accept. If not this might not be worth it for some theoretical benefit.

Furthermore, if your app is already shipping you're out of luck. Due to the obvious security implications once you shipped an app the certificate is final. Google doesn't provide a way to update the certificate of a shipping app. Thus this feature applies to apps that aren't yet in the play store.

91.9.2. The good

If you're building a new app this is pretty easy to integrate and requires no changes on your part. Just a new certificate. You can generate the new secure key using instructions in articles like this one [https://guardianproject.info/2015/12/29/how-to-migrate-your-android-apps-signing-key/].

If you're using Codename One Setting you can check the box to generate an SHA512 key which will harden the security for the APK.

91.10. Certificate pinning

When you connect to HTTPS servers your networking code checks the certificate on the server. If the certificate was issued by a trusted certificate authority then the connection goes through, otherwise it fails. Imagine you're sitting in a coffee shop connected to the local Wi-Fi, and you try to connect to Gmail to check your email. Since you use HTTPS to Google you trust the connection is secure.

What if the coffee shop was hacked and the router is listening in on everything?

HTTPS is encrypted and the way encryption works is through the certificate. The server sends you a certificate and you can use that to send encrypted data to it.

What if the router grabs the server's certificate and communicates with Google on your behalf?

This won't work since the data you send to the server is encrypted with the certificate from the server.

What if the router sends its own "fake certificate"?

That won't work either. All certificates are signed by a "certificate authority" indicating that a google.com certificate is valid.

What if an attacker could get a fake certificate authorized by a real certificate authority?

That's a problem!

It's obviously hard to do but if someone was able to do this he could execute a "man in the middle" attack as described above. People were able to fool certificate authorities in the past and gain fake certificates using various methods so this is possible and probably doable for any government level attacker.

91.10.1. Certificate pinning

This is the attack certificate pinning (or SSL pinning) aims to prevent. You code into your app the "fingerprint" of the certificate that's "good" and thus prevent the app from working when the certificate is changed. This might break the app if you replace the certificate at some point but that

might be reasonable in such a case.

To do this you have a cn1lib [https://github.com/codenameone/SSLCertificateFingerprint/]. It fetches the certificate fingerprint from the server so you can check the fingerprint against a list of authorized keys. Run `mvn cn1:settings`, open **Extensions**, and install `SSLCertificateFingerprint`. Then use something like this to verify your server:

Fingerprints coded into the app are the part that hurts: the certificate has to be replaced eventually, and a hardcoded pin turns that into an app store release with every un-updated install broken until it lands. Chapter 93, *App Shield* pins the public key rather than the whole certificate, delivers the pin set over the air with the attestation token, and refuses to publish a set that would brick the app — which is the same protection without the release cycle.

Notice that once connection is established you don't need to verify again for the current application run.

91.11. Cryptographic primitives

The `com.codename1.security` package gives you the cryptographic building blocks you need for typical mobile-app concerns — hashing, message authentication, symmetric and asymmetric encryption, digital signatures, JSON Web Tokens, and time/counter-based one-time passwords. The supporting `com.codename1.components.OtpField` component covers the UI side of OTP entry.

The hash and HMAC primitives are implemented in portable Java so they produce identical output on every platform without depending on any external library. Symmetric and asymmetric encryption, signing, and the secure RNG go through each platform's native crypto provider via Codename One's implementation layer:

- The simulator (JavaSE) and Android route through the JRE's `java.security` and `javax.crypto`.
- iOS routes through Apple's CommonCrypto and the Security framework (via `Ports/iOSPort/nativeSources/CN1Crypto.{h,m}` and the corresponding `IOSImplementation` overrides).

Application code never sees these differences — you call the same `com.codename1.security` classes regardless of the platform you are running on.

Cryptographic operations only throw `com.codename1.security.CryptoException`, an unchecked exception. You can let it bubble up or catch it; you don't have to declare it.

91.11.1. Hashing

`com.codename1.security.Hash` implements MD5, SHA-1, SHA-224, SHA-256, SHA-384, and SHA-512. SHA-256 is the recommended default for new code; MD5 and SHA-1 are exposed only for compatibility with older protocols since both are broken for collision resistance:

```
// One-shot
byte[] digest = Hash.sha256("hello".getBytes("UTF-8"));
String hex    = Hash.toHex(digest);          // 64-character lowercase hex
byte[] back   = Hash.fromHex(hex);           // round-trip helper

// Streaming
Hash h = Hash.create(Hash.SHA256);
h.update(part1);
h.update(part2);
byte[] full = h.digest();                    // hash is reset after digest()
```

The algorithm identifier strings (`Hash.MD5`, `Hash.SHA256`, etc.) are also accepted with or without dashes and in any case (`"sha256"` and `"SHA-256"` are equivalent).

91.11.2. Message authentication (HMAC)

`com.codename1.security.Hmac` implements HMAC (RFC 2104) on top of any of the hash algorithms above. Use HMAC whenever a message authentication code is needed — API request signing, session cookie tamper detection, JWT signing with the `HS` family, or TOTP token generation:

```
byte[] tag = Hmac.sha256(secret, message);

// Streaming
Hmac h = Hmac.create(Hash.SHA256, secret);
h.update(part1);
h.update(part2);
byte[] tag2 = h.doFinal();
```

When comparing authentication tags, use `Hmac.constantTimeEquals(a, b)` instead of `Arrays.equals(a, b)` — the latter short-circuits on the first mismatch and is vulnerable to timing attacks.

91.11.3. Secure random numbers

`com.codename1.security.SecureRandom` exposes the platform's cryptographically secure RNG (`SecRandomCopyBytes` on iOS, `/dev/urandom` on Linux/Android, etc.). Use it for keys, nonces, salts, password reset tokens, and any other security-sensitive value. Never use `java.util.Random` or `Math.random()` for these purposes:

```
byte[] iv  = SecureRandom.bytes(12);      // 12-byte AES-GCM nonce
int    pin = SecureRandom.intBelow(1_000_000);   // bias-free 6-digit code
long   id  = SecureRandom.longBelow(1L << 53);
```

91.11.4. Symmetric encryption (AES)

`com.codename1.security.Cipher` exposes AES through the platform's native AES implementation.

AES-GCM is the recommended default because it's authenticated — a single tag-mismatch failure detects any tampering of the ciphertext or the associated data:

```
SecretKey key   = KeyGenerator.aes(256);
byte[]    nonce = SecureRandom.bytes(12);
byte[]    aad   = "v1".getBytes("UTF-8");

byte[] ciphertext = Cipher.aesEncrypt(Cipher.AES_GCM, key, nonce, aad, plaintext);
byte[] decrypted  = Cipher.aesDecrypt(Cipher.AES_GCM, key, nonce, aad, ciphertext);
```

The `Cipher` class exposes the standard JCE-style transformation strings as constants: `Cipher.AES_GCM`, `Cipher.AES_CBC_PKCS5`, `Cipher.AES_CBC`, and `Cipher.AES_ECB_PKCS5`. For GCM, the 16-byte authentication tag is appended to the ciphertext (matching the JCE convention). ECB is exposed only for interop with legacy systems — it leaks structure and should never be used for new designs.

91.11.5. Asymmetric encryption and digital signatures (RSA, ECDSA)

`com.codename1.security.Cipher` also covers RSA encryption, and `com.codename1.security.Signature` covers digital signatures (RSA and ECDSA). Keys are represented by `com.codename1.security.PublicKey` and `com.codename1.security.PrivateKey`, which wrap X.509 SubjectPublicKeyInfo and PKCS#8 DER blobs respectively — the same encodings used by OpenSSL:

```
// Generate a fresh RSA-2048 key pair (run on a background thread; key
// generation can take a noticeable amount of time)
KeyPair kp = KeyGenerator.rsa(2048);

// Encrypt a small payload (e.g. wrap an AES key)
byte[] sealed = Cipher.rsaEncrypt(Cipher.RSA_OAEP_SHA256, kp.getPublicKey(), payload);
byte[] opened = Cipher.rsaDecrypt(Cipher.RSA_OAEP_SHA256, kp.getPrivateKey(), sealed);

// Sign / verify
byte[] sig = Signature.sign(Signature.SHA256_WITH_RSA, kp.getPrivateKey(), data);
boolean ok = Signature.verify(Signature.SHA256_WITH_RSA, kp.getPublicKey(), data, sig);
```

To use a key that was generated outside the app, feed the DER bytes to the static factory methods:

```
PublicKey  pub  = PublicKey.rsa(x509SpkiBytes);          // openssl rsa -pubout -outform DER
PrivateKey priv = PrivateKey.rsa(pkcs8DerBytes);         // openssl pkcs8 -topk8 -nocrypt -outform DER
```

A key that arrives as a file is usually PEM rather than raw DER — base64 between `-----BEGIN-----` lines — so `PublicKey.fromPem` and `PrivateKey.fromPem` take that text, or the bytes of the file straight from `Util.readInputStream`, and work out the algorithm from the key itself.

`fromPem` also reads the containers that aren't the one the platform wants: the older PKCS#1 `RSA PRIVATE KEY` and SEC1 `EC PRIVATE KEY` blocks, and the `-----BEGIN CERTIFICATE-----` file a server or payment gateway is more likely to hand out than a bare key, whose subject public key it uses. It doesn't verify the certificate — neither its signature nor its dates — it only reads the key out of it, so

a certificate you didn't already trust is no more trustworthy for having been parsed here.

The `Signature` class exposes the JCE algorithm strings as constants: `SHA256_WITH_RSA`, `SHA384_WITH_RSA`, `SHA512_WITH_RSA`, `SHA256_WITH_ECDSA`, `SHA384_WITH_ECDSA`, and `SHA512_WITH_ECDSA`.

91.11.6. Key agreement and key derivation (ECDH, HKDF)

Two parties that have never met can agree on a secret over a channel anyone can read. `KeyGenerator.ec(256)` makes a P-256 key pair, each side sends the other its public key, and `KeyAgreement.ecdh` combines one side's private key with the other's public key. Both arrive at the same 32 bytes, and nobody who watched the exchange can compute them:

```
KeyPair alice = KeyGenerator.ec(256);
KeyPair bob = KeyGenerator.ec(256);

// Each side combines its own private key with the other's public key.
byte[] atAlice = KeyAgreement.ecdh(alice.getPrivateKey(), bob.getPublicKey());
byte[] atBob = KeyAgreement.ecdh(bob.getPrivateKey(), alice.getPublicKey());
// atAlice and atBob hold the same 32 bytes
```

The result is a shared secret, not yet a key. `Hkdf` (RFC 5869) turns it into keys of any length, bound to an `info` label so that keys derived for different purposes never coincide. `Hkdf.derive` runs both steps at once:

```
byte[] shared = KeyAgreement.ecdh(mine.getPrivateKey(), theirs.getPublicKey());

// The shared secret is not a key yet. HKDF turns it into one, and the info
// label keeps keys derived for different purposes apart.
byte[] info = "chat message key v1".getBytes();
byte[] key = Hkdf.derive("SHA-256", null, shared, info, 32);

byte[] nonce = SecureRandom.bytes(12);
byte[] sealed = Cipher.aesEncrypt(Cipher.AES_GCM, new SecretKey("AES", key),
        nonce, null, message);
```

Protocols that keep the intermediate key, a ratchet for example, call the two steps one at a time:

```
byte[] prk = Hkdf.extract("SHA-256", salt, shared);
byte[] sendKey = Hkdf.expand("SHA-256", prk, "send".getBytes(), 32);
byte[] receiveKey = Hkdf.expand("SHA-256", prk, "receive".getBytes(), 32);
```

`Hkdf` is portable Java over `Hmac`, so it behaves identically on every port and on a Codename One backend. The key agreement itself runs in the platform's native crypto provider. Use a fresh key pair for each exchange you want to be forward secret, and never use the raw ECDH output as a key.

91.11.7. JSON Web Tokens

`com.codename1.security.Jwt` provides JWT (RFC 7519) signing and verification. The `HS` family (HMAC-SHA-2) is pure Java so it works on every platform; the `RS` family (RSA-PKCS#1 v1.5 with SHA-2) and the `ES` family (ECDSA with SHA-2) route through the platform's native crypto:

```
Map<String, Object> claims = new LinkedHashMap<String, Object>();
claims.put("sub", "user-123");
claims.put("exp", System.currentTimeMillis() / 1000 + 3600);

// Sign with a shared secret (HS256)
String token = Jwt.signHs256(claims, "secret".getBytes("UTF-8"));

// Parse + verify
Jwt parsed = Jwt.parse(token);
if (!parsed.verifyHs256("secret".getBytes("UTF-8"))) {
    throw new SecurityException("bad signature");
}
String subject = (String) parsed.getClaim("sub");
```

For RSA-signed tokens (RS256/384/512) and ECDSA-signed tokens (ES256/384/512), pass the key to the dynamic overloads:

```
KeyPair kp   = KeyGenerator.rsa(2048);
String  rs   = Jwt.sign(claims, kp.getPrivateKey(), Jwt.RS256);
Jwt     read = Jwt.parse(rs);
boolean ok   = read.verify(kp.getPublicKey());
```

`Jwt.parse(token)` doesn't verify the signature — you must call one of the `verify*` methods afterwards. Tokens with an `alg` header of `none` are rejected by `verify` unless you explicitly call `setVerifyAllowNoneAlgorithm(true)` on the parsed JWT. Accepting unsigned tokens is a critical security bug in almost every deployment, so leave it off unless you have decided that the transport is trusted.

91.11.8. HOTP / TOTP one-time passwords

`com.codename1.security.Otp` implements counter-based HOTP (RFC 4226) and time-based TOTP (RFC 6238). The output is identical to standard authenticator apps (Google Authenticator, Microsoft Authenticator, 1Password, Authy, etc.) — you can use this class to generate codes inside your app, to validate codes sent by an authenticator on a sign-in flow, or for SMS-based two-factor flows.

Shared secrets are commonly distributed as Base32 strings (the format embedded in QR codes by authenticator apps). `com.codename1.security.Base32` handles the encoding:

```
byte[] secret = Base32.decode("JBSWY3DPEHPK3PXP");

// Generate the current 6-digit TOTP code (30-second step, SHA-1)
```

```
String code = Otp.totp(secret);

// Verify the code the user typed in, allowing one step of clock skew on
// either side (so the previous, current, and next codes are all accepted)
boolean ok = Otp.verifyTotp(secret, userInput, 1);
```

For HOTP, supply the counter explicitly and increment it after every successful authentication:

```
String code = Otp.hotp(secret, counter, 6);
// advance only once the verifier has accepted it, or a lost code
// desynchronizes this client from a verifier with no look-ahead window
if (serverAccepted(code)) {
    counter++;
}
```

91.11.9. Walkthrough: Adding two-factor authentication to a sign-in flow

The typical TOTP-based two-factor authentication flow has two distinct phases. The first is *enrolment*, where the server provisions a shared secret to the user's authenticator app; the second is *verification*, which happens on every subsequent sign-in.

The TOTP secret should be generated and stored on your **server**, not on the Codename One client. The client only ever sees the secret long enough to display the enrolment QR code, then forgets it. Verification on every subsequent sign-in is also a server-side concern (the client just sends the code the user types in). The code samples below put the cryptography on the client only to keep the example self-contained — in production, the server does the actual generation and verification.

Phase 1 — Enrollment. When the user opts into 2FA, generate a 20-byte random secret and show it to their authenticator app as a QR code that encodes a standard `otpauth://totp/…` URI:

```
// 1. Generate (or fetch from your server) a 20-byte secret -- 160 bits is the
//    de-facto standard for authenticator compatibility.
byte[] secret = SecureRandom.bytes(20);

// 2. Build the otpauth URI. The authenticator app stores the secret against
//    the "Acme Bank: alice@example.com" label and tags it with the issuer
//    so it can show "Acme Bank" next to the rotating code.
String uri = Otp.otpauthUri("Acme Bank", "alice@example.com", secret);

// 3. Render `uri` as a QR code and show it on screen for the user to scan.
//    See "Rendering the QR code" below.
```

The maximum-compatibility settings — 6 digits, 30 second step, SHA-1 — are the defaults of `Otp.otpauthUri(issuer, accountName, secret)`. Pass digits / step /

> algorithm explicitly via the full overload only if you have a specific reason; some authenticator apps don't recognize anything except the defaults.

Rendering the QR code. Codename One core doesn't currently ship a QR-code generator. Pick whichever option fits your deployment:

- **Server-side render** (simplest). Send `uri` to your backend over HTTPS and have it return a PNG. The Google Charts API endpoint `https://chart.googleapis.com/chart?cht=qr&chs=300x300&chl={url-encoded-uri}` and the open-source `https://api.qrserver.com/v1/create-qr-code/?data={url-encoded-uri}` both work; the latter doesn't require Google API setup. Render the resulting PNG with `URLImage` or `EncodedImage.create(bytes)`.
- **Use a QR cn1lib.** Community cn1libs such as `QRMaker` provide native generation. Add as a normal cn1lib dependency.
- **Display the secret as a typed value.** If you can't render a QR code, show the user the Base32-encoded secret (the value after `secret=` in `uri`) and ask them to type it manually into their authenticator's "set up by hand" flow. Less convenient but works on every platform.

Phase 2 — Verification. On every sign-in after enrolment, ask the user for the current six-digit code and verify it against the stored secret. Use [com.codename1.components.OtpField] for the input:

```
OtpField field = new OtpField(6);
field.addCompleteListener(new ActionListener() {
    public void actionPerformed(ActionEvent evt) {
        String userInput = field.getText();
        // tolerance=1 allows the previous, current, and next 30-second
        // windows to compensate for clock skew between the device and the
        // server. tolerance=0 is strict but unforgiving; tolerance=2 or 3
        // is more permissive but increases the brute-force attack surface.
        if (Otp.verifyTotp(secret, userInput, 1)) {
            // Where this check runs on your server, record the time
            // step this code belongs to and reject a second code from
            // the same step: verifyTotp is stateless, so a captured
            // code stays valid for the rest of the tolerance window.
            grantAccess();
        } else {
            field.clear();
            Dialog.show("Invalid code", "Try again", "OK", null);
        }
    }
});
form.add(field);
```

Server-side verification. When your backend does the verification, the corresponding Java looks the same — `Otp.verifyTotp(storedSecret, codeFromClient, 1)`. Make sure you rate-limit verification attempts (for example, lock the account after 5 wrong codes within a minute) and log failures, since the 6-digit search space is small enough to be brute-forced without that. Record the time step that each accepted code belongs to and refuse a second code from the same step for that user. `verifyTotp` is stateless, so a code stays valid for the rest of the tolerance window once it's been used,

and rate limiting doesn't help because a replayed code isn't a wrong one. RFC 6238 requires this single-use check.

91.11.10. OTP input widget

`com.codename1.components.OtpField` is a segmented input — one box per character, that advances to the next box as the user types and steps back on backspace. This is the standard pattern for SMS confirmation and authenticator-app entry screens:

```
OtpField otp = new OtpField(6);                  // 6 digits, numeric
otp.addCompleteListener(new ActionListener() {
    public void actionPerformed(ActionEvent evt) {
        if (Otp.verifyTotp(secret, otp.getText(), 1)) {
            // accepted
        } else {
            otp.clear();
        }
    }
});
form.add(otp);
```

Style the boxes through the UIIDs `OtpField` (the container) and `OtpDigit` (each box). The component supports alphanumeric input via the two-argument constructor (`new OtpField(8, false)`), and pasting a full code into any one box distributes the characters across the remaining boxes automatically.

91.11.11. Algorithm identifier reference

The string constants exposed by these classes are listed below so you can pick them out at a glance.

Class	Constant	Algorithm string
`Hash`	`MD5`, `SHA1`, `SHA224`, `SHA256`, `SHA384`, `SHA512`	`MD5`, `SHA-1`, `SHA-224`, `SHA-256`, `SHA-384`, `SHA-512`
`Cipher`	`AES_GCM`	`AES/GCM/NoPadding`
`Cipher`	`AES_CBC_PKCS5`	`AES/CBC/PKCS5Padding`
`Cipher`	`AES_CBC`	`AES/CBC/NoPadding`
`Cipher`	`AES_ECB_PKCS5`	`AES/ECB/PKCS5Padding` (legacy)
`Cipher`	`RSA_OAEP_SHA256`	`RSA/ECB/OAEPWithSHA-256AndMGF1Padding`
`Cipher`	`RSA_PKCS1`	`RSA/ECB/PKCS1Padding` (legacy)
`Signature`	`SHA256_WITH_RSA`, `SHA384_WITH_RSA`, `SHA512_WITH_RSA`	`SHA256withRSA`, `SHA384withRSA`, `SHA512withRSA`

Class	Constant	Algorithm string
`Signature`	`SHA256_WITH_ECDSA`, `SHA384_WITH_ECDSA`, `SHA512_WITH_ECDSA`	`SHA256withECDSA`, `SHA384withECDSA`, `SHA512withECDSA`
`Jwt`	`HS256`, `HS384`, `HS512`, `RS256`, `RS384`, `RS512`, `ES256`, `ES384`, `ES512`	Same as the JWT `alg` header value

`RSA_OAEP_SHA256` uses SHA-256 for the label hash and for MGF1 alike. The JCE reading of that same transformation name leaves MGF1 on SHA-1, so a JVM backend that names the string and nothing else produces a `BadPaddingException` against ciphertext from a Codename One app, and the other way round. Codename One can't follow the JCE here: Web Crypto and Apple's SecKey both take one hash and apply it to both, so the split pairing can't be expressed on the JavaScript or iOS ports at all. Have the other side name SHA-256 for the mask as well, which on a JVM means passing an `OAEPParameterSpec` of `("SHA-256", "MGF1", MGF1ParameterSpec.SHA256, PSource.PSpecified.DEFAULT)` to `Cipher.init` rather than relying on the provider default. Dropping to `RSA_PKCS1` also makes the two sides agree, and is the wrong fix: PKCS#1 v1.5 encryption padding is what OAEP exists to replace.

91.11.12. Key sizes and recommended defaults

- **AES**: 256 bits (`KeyGenerator.aes(256)`) for new code. 128 bits is also acceptable and faster; pick 192 only if you have a specific reason.
- **RSA**: 2048 bits minimum (`KeyGenerator.rsa(2048)`). Use 3072 or 4096 if you need a longer security margin — key generation gets slow above 2048 so run it on a background thread.
- **Elliptic curve**: `KeyGenerator.ec(256)`, which is P-256, for both signatures and key agreement.
- **HMAC**: a key at least as long as the hash output (32 bytes for HMAC-SHA-256). `KeyGenerator.hmac(256)` returns a key of the requested bit length.
- **TOTP / HOTP**: 160 bits (20 bytes) is the de-facto standard for authenticator-app compatibility.

Chapter 92. Crypto wallets

The `com.codename1.crypto` packages hold everything a wallet, an exchange or a payment backend needs to work with Ethereum and the other EVM chains, Bitcoin, and Solana. That covers recovery phrases and key derivation, addresses, transactions, signing, the node APIs that broadcast transactions and read balances, and price feeds. There are no third-party libraries to add, and the same classes run in the app and in a Codename One backend.

The heavy parts run as native code wherever the platform allows it: secp256k1, Schnorr, Ed25519, the hashes and the PBKDF2 behind a recovery phrase. Elsewhere they fall back to an optimized pure-Java engine. A benchmark in CI compares every kernel against libsecp256k1, libsodium, OpenSSL and BouncyCastle on the same machine, and fails a pull request whose crypto changes fall behind.

The packages, from the bottom up:

Package	What it holds
`crypto.encoding`	Hex, Base58 and Base58Check, Bech32 and Bech32m, RLP, Base64
`crypto.hd`	BIP-39 recovery phrases (`Mnemonic`), BIP-32 and SLIP-10 key derivation, `DerivationPath`
`crypto.evm`	`EvmAddress` (EIP-55), legacy, EIP-2930 and EIP-1559 transactions, EIP-191 and EIP-712 signing, the Solidity ABI
`crypto.bitcoin`	P2PKH, P2SH, P2WPKH, P2WSH and Taproot addresses, scripts, transactions, PSBT, WIF
`crypto.solana`	Addresses and program-derived addresses, legacy and v0 messages, transactions, System, Token and Compute Budget instructions
`crypto.wallet`	The `Signer` interface, `SeedSigner`, `VaultSigner`, and the `Wallet` entry point
`crypto.rpc`	JSON-RPC for EVM nodes, Esplora for Bitcoin, Solana JSON-RPC
`crypto.market`	`PriceFeed`, CoinGecko, any JSON price API, and a caching decorator

92.1. The building blocks

A handful of algorithms do all the work underneath, and the names come up throughout this chapter and in every chain's documentation. You never call most of them directly, but knowing what each one is for makes the rest easier to follow, and it explains why their speed matters.

Elliptic curves and signatures. A private key is a large random number. The public key is a point on an elliptic curve, computed from it in a way that's easy forward and infeasible to reverse. A signature proves that the holder of the private key approved a message, and anyone with the public key can check it.

- **secp256k1** is the curve Bitcoin and Ethereum use. **ECDSA** is the signature scheme they sign transactions with. Ethereum also recovers the sender's public key from a signature, which is why an Ethereum transaction carries no sender address.

- **Schnorr** signatures (BIP-340) are the newer scheme on the same curve, used by Bitcoin's Taproot addresses. They're simpler than ECDSA and can be combined, which is what makes multi-party Taproot spends compact.
- **Ed25519** is a signature scheme on a different curve, Curve25519. Solana uses it, as do many protocols outside cryptocurrency. It was designed to be fast and hard to implement wrongly.

Verifying is the expensive direction. A wallet signs a handful of transactions, but a node, an exchange or an indexer verifies every signature it receives, which is where batches and the GPU come in.

Hash functions. A hash turns any input into a short fixed-size fingerprint. Changing one bit of the input changes the whole fingerprint, and nobody can find two inputs with the same one.

- **SHA-256** is Bitcoin's hash: transaction IDs, block headers and the Merkle trees that commit to a block's transactions. Bitcoin addresses take **RIPEMD-160** of the SHA-256 of the public key, which gives a shorter 20-byte fingerprint.
- **Keccak-256** is Ethereum's hash: addresses, transaction hashes, the selectors of contract functions and the keys of contract storage. It's the algorithm that became SHA-3, but with the original padding, so SHA-3 libraries give different answers.
- **SHA-512** and **HMAC-SHA512** (a keyed hash) are what key derivation is built on.

A **Merkle tree** hashes a list of items in pairs, then hashes the pairs, until one root remains. Changing any item changes the root, so a block header commits to all its transactions in 32 bytes. Building a level of one is a batch of independent hashes, which is what the Merkle rows in the benchmarks measure.

From a recovery phrase to keys. BIP-39 turns random bytes into a phrase of 12 or 24 words and back. It stretches the phrase into a 64-byte seed with **PBKDF2**, which runs HMAC-SHA512 2,048 times on purpose, so that guessing phrases is slow for an attacker. It's also the one step a user waits for when they restore a wallet. **BIP-32** derives a tree of keys from that seed, so one phrase yields every account on every chain, and **SLIP-10** does the same for Ed25519. A **derivation path** such as `m/44'/60'/0'/0/0` names one key in the tree.

Engines, kernels, and batches. The public classes are plain Java and the same everywhere. Underneath, a **crypto engine** supplies the compute-heavy **kernels**, which are the signature and hash operations above. On iOS, macOS, Android, Windows, Linux and a production backend the engine is native C, which uses the processor's vector and hash instructions where it has them. On the JVM and in the browser it's an optimized pure-Java engine. A **batch** hands many independent operations to the engine at once, so it can spread them across every CPU core and, for large batches, the GPU.

92.2. From a recovery phrase to a wallet

A wallet starts as a recovery phrase. Every key on every chain is derived from it, so the phrase is the only thing a user ever needs to back up.

```
// 24 words; 128 gives 12.
```

```
String words = Mnemonic.generate(256);

// Words typed back in by the user are checked before anything is derived from them.
if (!Mnemonic.isValid(words)) {
    throw new IllegalArgumentException("not a valid recovery phrase");
}
// The passphrase is the optional "25th word"; "" when the user set none.
Wallet wallet = Wallet.fromMnemonic(words, "");
```

`Mnemonic.isValid` checks the words against the English list and verifies the checksum the last word carries, so a typo is caught before it turns into an empty wallet with a different address.

`Wallet` answers addresses on the paths other wallets use. A phrase restored here shows the same accounts it shows in MetaMask, Electrum, Sparrow or Phantom:

```
Wallet wallet = Wallet.fromMnemonic(Mnemonic.generate(128), "");
EvmAddress eth = wallet.getEvmAddress(0, 0);            // m/44'/60'/0'/0/0
BitcoinAddress btc = wallet.getBitcoinAddress(BitcoinNetwork.MAINNET,
        Wallet.BIP84, 0, 0, 0);                         // m/84'/0'/0'/0/0, bc1q...
SolanaAddress sol = wallet.getSolanaAddress(0);         // m/44'/501'/0'/0'

String shown = eth.toChecksumString();                  // EIP-55 mixed case
```

For Bitcoin, the purpose picks the address type: `Wallet.BIP44` for legacy 1⋯ addresses, `BIP49` for P2SH-wrapped SegWit, `BIP84` for native SegWit `bc1q`⋯ and `BIP86` for Taproot `bc1p`⋯. The same network object also selects testnet, signet, or regtest.

92.3. Sending a transaction

The pattern is the same on every chain. You read what the transaction needs from a node, build it, sign it on the device, and hand the signed bytes back to the node. Private keys never leave the `Signer`.

The node clients are blocking calls over an `RpcTransport`. In the app that's `NetworkTransport`, which goes through the `NetworkManager` queue and keeps the UI responsive when called from the EDT. In a backend, `com.codename1.backend.WebRpcTransport` does the same over the backend's HTTP client. A provider's API key goes in a header: `new NetworkTransport().header("Authorization", "Bearer ⋯")`.

92.3.1. Ethereum and EVM chains

```
Wallet wallet = Wallet.fromMnemonic(Mnemonic.generate(128), "");
String recipient = "0x5aAeb6053F3E94C9b9A09f33669435E7Ef1BeAed";
EvmRpc rpc = new EvmRpc(new NetworkTransport(), "https://ethereum-sepolia-rpc.publicnode.com");
DerivationPath path = Wallet.evmPath(0, 0);
EvmAddress from = wallet.getEvmAddress(path);
EvmAddress to = EvmAddress.parse(recipient);
UInt256 value = UInt256.parseUnits("0.01", 18);
```

```
long nonce = rpc.getTransactionCount(from, "pending");
UInt256[] fees = rpc.suggestFees();                    // {tip, fee cap}
long gas = rpc.estimateGas(from, to, value, null);

EvmTransaction tx = EvmTransaction.eip1559(rpc.chainId(), nonce, fees[0], fees[1],
        gas, to, value, null);
String hash = rpc.sendRawTransaction(wallet.signEvmTransaction(tx, path));
```

Amounts are `UInt256`, an exact unsigned 256-bit integer, so wei never passes through a `double`. `parseUnits("0.01", 18)` and `formatUnits(18)` convert to and from the decimal amount a person reads. `suggestFees` sets the fee cap at twice the next base fee plus the tip, which stays valid through several full blocks. The chain ID comes from the node and goes into the signature, so a transaction signed for one chain can't be replayed on another.

Token transfers, contract calls and EIP-712 typed data use the same flow. Look at `Erc20`, `Abi` and `TypedData` in `crypto.evm`, and at `Wallet.signTypedData` and `Wallet.personalSign` for sign-in messages.

92.3.2. Bitcoin

A Bitcoin transaction spends earlier outputs ("coins") rather than debiting a balance, and a signer has to know the value of each coin it signs for. A PSBT (BIP-174) carries that information, and it's also the format hardware wallets and multisig co-signers exchange:

```
Wallet wallet = Wallet.fromMnemonic(Mnemonic.generate(128), "");
String recipient = "tb1qw508d6qejxtdg4y5r3zarvary0c5xw7kxpjzsx";
long feeSats = 1500;
BitcoinNetwork net = BitcoinNetwork.TESTNET;
EsploraClient esplora = new EsploraClient(new NetworkTransport(), EsploraClient.MEMPOOL_TESTNET);
DerivationPath path = Wallet.bitcoinPath(net, Wallet.BIP84, 0, 0, 0);
BitcoinAddress from = wallet.getBitcoinAddress(net, Wallet.BIP84, 0, 0, 0);

EsploraClient.Utxo coin = esplora.getUtxos(from).get(0);
BitcoinTransaction tx = new BitcoinTransaction();
tx.addInput(coin.getTxid(), coin.getVout());
tx.addOutput(coin.getValue() - feeSats, BitcoinAddress.parse(recipient, net));

// The PSBT carries what a signer needs to know about the coin being spent.
Psbt psbt = Psbt.fromTransaction(tx);
psbt.setWitnessUtxo(0, coin.toOutput());
psbt.signAll(wallet.getBitcoinKey(path));
psbt.finalizeAll();
String txid = esplora.broadcast(psbt.extract());
```

`EsploraClient` speaks the REST API of `mempool.space` and `blockstream.info`, or of your own Esplora server. `getFeeEstimates` returns sats per virtual byte by confirmation target. Multiply that by the size of the transaction to get `feeSats`. Every output the snippet doesn't spend is paid as a fee, so a real wallet adds a change output back to one of its own addresses.

`Wallet.signPsbt(psbt)` signs any input whose BIP-32 origin matches the wallet's own fingerprint. That lets a PSBT built elsewhere, by a coordinator or a watch-only wallet, be signed without being

told which keys to use. Taproot inputs are signed with BIP-340 Schnorr signatures automatically.

92.3.3. Solana

```
Wallet wallet = Wallet.fromMnemonic(Mnemonic.generate(128), "");
String recipient = "9WzDXwBbmkg8ZTbNMqUxvQRAyrZzDsGYdLVL9zYtAWWM";
SolanaRpc rpc = new SolanaRpc(new NetworkTransport(), SolanaRpc.DEVNET);
SolanaAddress from = wallet.getSolanaAddress(0);

List<Instruction> instructions = new ArrayList<Instruction>();
instructions.add(SystemProgram.transfer(from, SolanaAddress.parse(recipient), 10000000L));
SolanaMessage message = SolanaMessage.compile(from, instructions, rpc.getLatestBlockhash());

SolanaTransaction tx = new SolanaTransaction(message);
wallet.signSolanaTransaction(tx, 0);
String signature = rpc.sendTransaction(tx);
```

Amounts are in lamports (a billionth of a SOL). A blockhash expires after about a minute, so fetch it right before signing. `TokenProgram` builds SPL token transfers, and `SolanaAddress.associatedTokenAddress` finds the account a token is held in. `ComputeBudget.setComputeUnitPrice` adds a priority fee when the network is busy.

92.4. Prices

`PriceFeed` answers one question: the price of one asset in another. `CoinGeckoFeed` works without a key at the public rate limit, and takes a demo or pro key for more. `JsonPriceFeed` turns any JSON price API into a feed from a URL template and the path to the price. Wrap either in `CachingPriceFeed`, so a screen that prices twenty balances makes one request:

```
UInt256 weiBalance = UInt256.parseUnits("1.5", 18);
PriceFeed prices = new CachingPriceFeed(new CoinGeckoFeed(new NetworkTransport()),
        60000, 600000);                                  // fresh 1 min, usable 10 min
Quote q = prices.getQuote("ETH", "USD");
double usd = q.valueOf(weiBalance, 18);
```

A cached quote stays fresh for the first window. After that it's still returned when a refresh fails, until the second window ends. That keeps a balance screen useful through a brief outage without showing a price that's hours old.

92.5. Verifying many signatures at once

A backend that scans a block for deposits, or an indexer that checks every transaction it stores, verifies thousands of signatures at a time. `CryptoBatch` takes them as arrays and answers one `boolean` per entry:

```
// A block's deposits; filled from the transactions being scanned.
```

```
byte[][] hashes = new byte[0][];
Secp256k1.EcdsaSignature[] signatures = new Secp256k1.EcdsaSignature[0];
byte[][] publicKeys = new byte[0][];
boolean[] valid = CryptoBatch.verifySecp256k1(hashes, signatures, publicKeys);
int good = 0;
for (boolean v : valid) {
    if (v) {
        good++;
    }
}
```

With native kernels the whole batch crosses into native code once and runs on every CPU core, which makes it several times faster than the same calls in a loop. `verifySchnorr`, `verifyEd25519`, `sha256` and `keccak256` work the same way. Every entry gets exactly the answer a single call would give, and a malformed entry, such as a key that doesn't parse, is invalid rather than an exception, so one bad entry never stops the rest.

For the largest batches, every method also has a packed form that takes flat arrays at a fixed stride: 32-byte hashes one after another, 64-byte signatures one after another, and the public keys likewise, with one result byte per entry. On a native target the kernels read those arrays in place, so nothing is copied and no object is created per entry. Allocate them with `Simd.get().allocByte(int)` and they're also aligned for the vector units:

```
int count = 1024;
Simd simd = Simd.get();
byte[] hashes = simd.allocByte(32 * count);
byte[] signatures = simd.allocByte(64 * count);
byte[] publicKeys = simd.allocByte(33 * count);
byte[] results = simd.allocByte(count);
// ... fill entry i at 32 * i, 64 * i and 33 * i ...
CryptoBatch.verifySecp256k1(hashes, signatures, publicKeys, 33, results, count);
// results[i] is 1 for a valid entry and 0 for any other
```

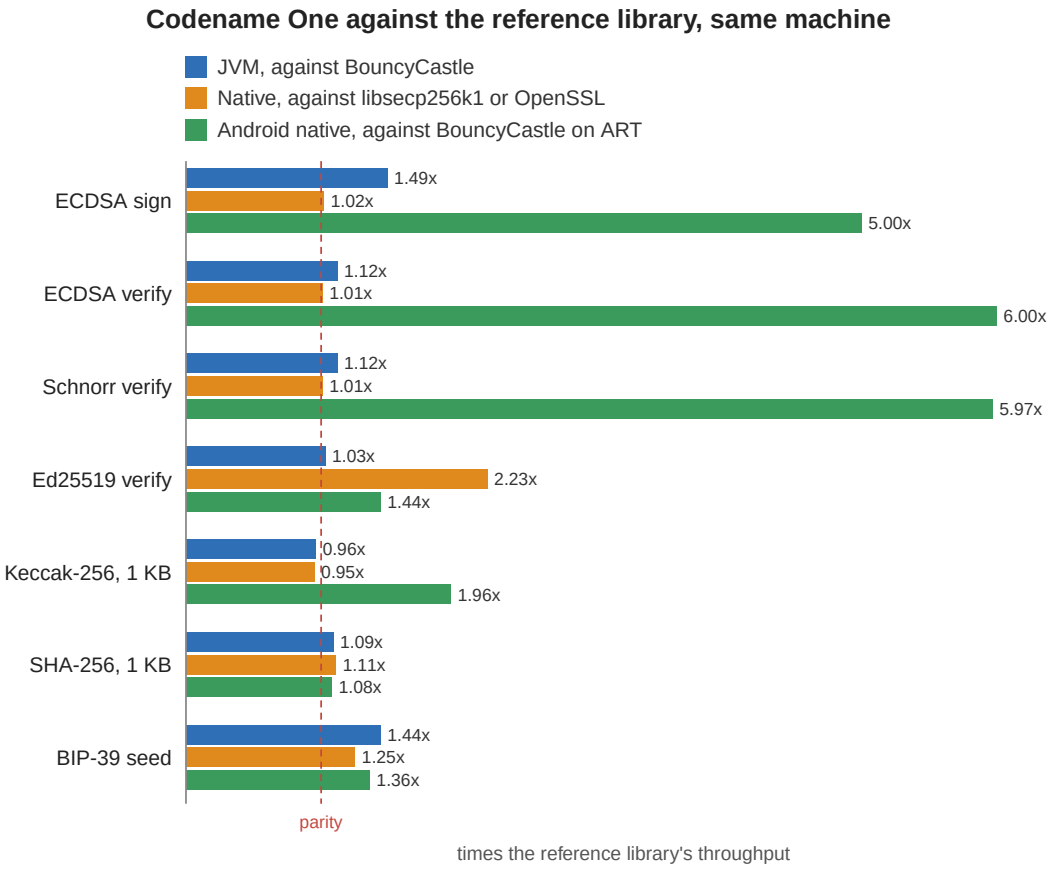
On iOS, macOS, Android, Windows and Linux, a large enough batch is shared between the CPU cores and the GPU, through Metal on Apple platforms and Vulkan elsewhere. The split follows the measured speed of each: the CPU and the GPU work on their parts at the same time, and a device whose GPU is slower than its CPU keeps the whole batch on the CPU. In a browser the GPU is reached through WebGPU, with the same kernels. The GPU only ever sees public data, meaning signatures, public keys and messages, and never a private key. Your code doesn't change, and the results are the same either way.

92.5.1. Asynchronous batches

Every `CryptoBatch` method has an asynchronous form with `Async` added to its name. It takes the same arguments plus a `CryptoBatch.Callback`, returns at once, and runs the batch on a background thread:

```
byte[][] hashes = new byte[0][];
```

```
Secp256k1.EcdsaSignature[] signatures = new Secp256k1.EcdsaSignature[0];
byte[][] publicKeys = new byte[0][];
final Label status = new Label("Scanning...");
CryptoBatch.verifySecp256k1Async(hashes, signatures, publicKeys, new CryptoBatch.Callback<boolean[]>() {
    public void done(boolean[] valid, Throwable error) {
        // on the EDT: safe to update the UI
        if (error != null) {
            status.setText("Scan failed: " + error.getMessage());
            return;
        }
        int good = 0;
        for (boolean v : valid) {
            if (v) {
                good++;
            }
        }
        status.setText(good + " of " + valid.length + " deposits verified");
    }
});
```



In the app the callback runs on the EDT and can update the UI directly. In a backend it runs on the thread that did the work. The arguments are checked before the call returns, so a malformed batch, such as arrays of different lengths, throws right away instead of reaching the callback. The callback gets exactly what the synchronous form would have returned, or the exception it would have thrown. A packed form hands back the results array you passed in. The batch reads your arrays directly rather than copying them, so until the callback runs they belong to the batch: change one before then and you change what's being verified.

In a browser, use the asynchronous forms. A large batch there goes to the GPU through WebGPU, which answers only asynchronously. The synchronous form still works, but it holds the calling thread until the GPU is done, and on the EDT that means the UI waits too. When the browser has no WebGPU adapter, both forms run on the CPU. The GPU kernels are about 460 KB of JavaScript, and they're included only in apps that call `CryptoBatch`, loaded the first time a batch is large enough to use them.

92.6. Performance

Every operation is benchmarked against the library a project would otherwise use for it, in the same process run, on the same machine. The figures below are ratios: 2.00x means Codename One did twice the work of the reference library in the same time, and anything above 1.00x is faster. Ratios stay steady from one machine to the next where absolute speeds don't, so they're also what CI checks. A run fails when any ratio drops below the floor recorded for it in `scripts/crypto-bench/floors.json`.

These numbers come from an Apple M4 Max (12 performance cores, 40-core GPU), and the Android ones from an arm64 API 36 emulator on the same machine.

92.6.1. On the JVM

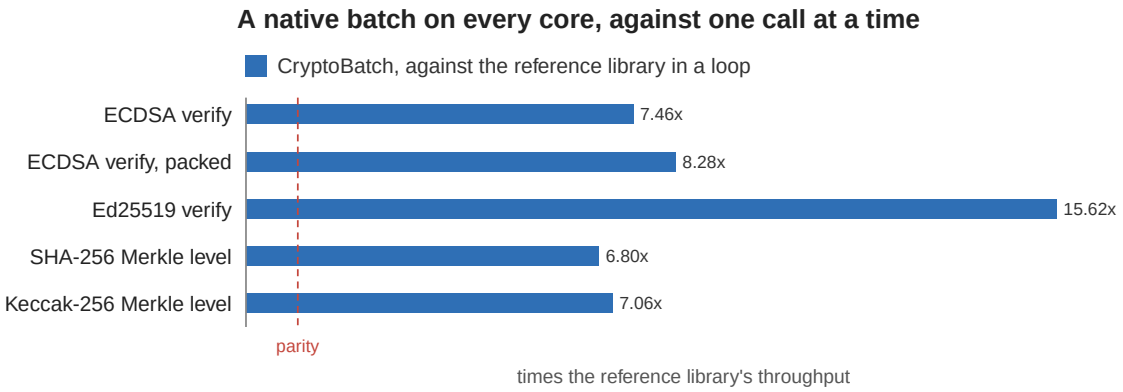
The simulator, JavaSE desktop apps and the backend in development run the portable Java implementation. It's compared with BouncyCastle 1.84 and, for Ed25519, with the JDK's own provider, on JDK 25. CI runs the same benchmark on JDK 17.

Operation	Codename One (ops/s)	Reference (ops/s)	Ratio
secp256k1 public key	30,583	17,391	1.76x
ECDSA sign	24,109	16,220	1.49x
ECDSA verify	14,252	12,748	1.12x
Schnorr sign, with a `KeyPair`	15,297	16,051	0.95x
Schnorr verify	14,299	12,816	1.12x
Ed25519 sign	49,360	45,707	1.08x
Ed25519 verify	17,293	16,865	1.03x
Ed25519 sign, against the JDK	49,946	2,484	20.10x
Ed25519 verify, against the JDK	7,599	2,469	3.08x
Keccak-256, 1 KB	484,694	503,524	0.96x
SHA-256, 1 KB	238,253	218,499	1.09x
SHA-512, 1 KB	339,664	297,983	1.14x
RIPEMD-160, 1 KB	139,370	96,919	1.44x

Operation	Codename One (ops/s)	Reference (ops/s)	Ratio
HMAC-SHA512 (a BIP-32 step)	679,117	473,458	1.43x
BIP-39 seed (PBKDF2, 2048 rounds)	802	558	1.44x

Ed25519 verification rewrites its check with two scalars of half the length, found by a lattice reduction, so the multiplication needs half the doublings. The rewrite gives exactly the answer of the direct check for every input, including keys with a small-order component. On x86-64 the field multiplication also takes a Karatsuba split, which needs 75 products instead of 100. arm64 has the registers to keep the direct form faster, so each architecture gets the form that's faster on it. The CI runners are x86-64, and they're held to the same floors.

92.6.2. Native targets



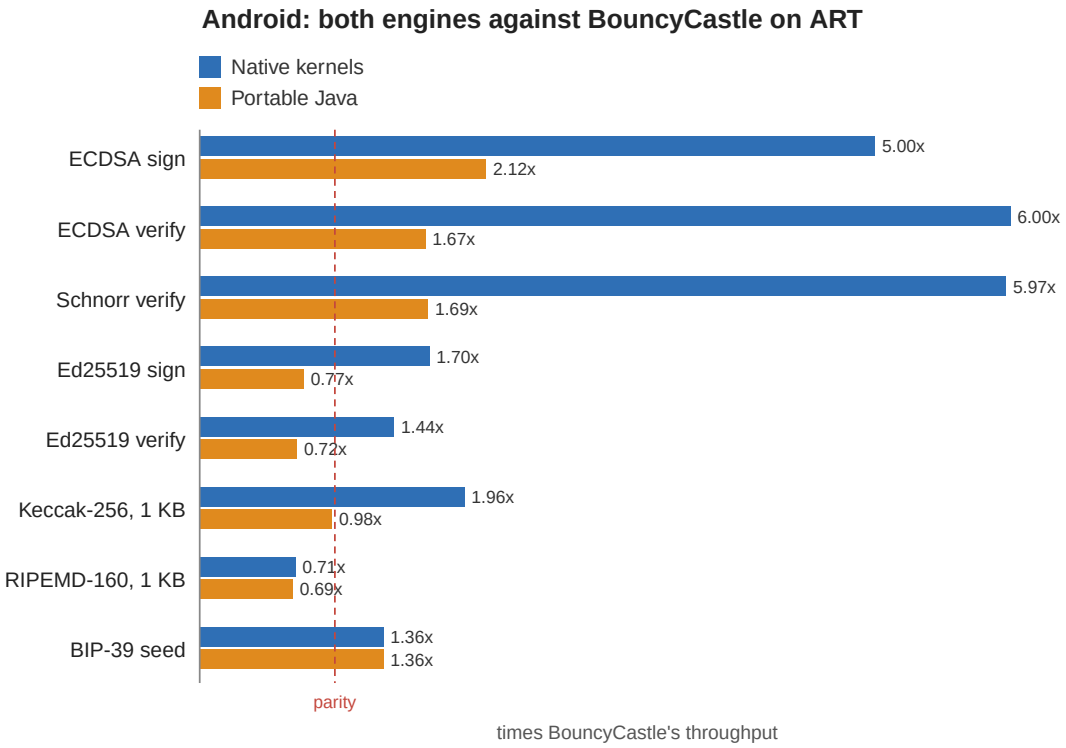
On iOS, macOS, Windows, Linux and the production backend the same operations run as C, compared with Bitcoin Core's libsecp256k1 for the secp256k1 curve and OpenSSL 3.6 for everything else, both built with the same compiler and flags.

Operation	Codename One (ops/s)	Reference (ops/s)	Ratio
secp256k1 public key	95,819	93,050	1.03x
ECDSA sign	60,770	59,453	1.02x
ECDSA verify	50,857	50,302	1.01x
Schnorr sign, one call against `keypair_create` and sign	46,180	44,659	1.03x
Schnorr verify	48,394	47,835	1.01x
Ed25519 sign	105,161	43,155	2.44x
Ed25519 verify	39,129	17,521	2.23x
Keccak-256, 1 KB	614,062	647,427	0.95x
SHA-256, 1 KB	1,675,236	1,507,576	1.11x
SHA-512, 1 KB	1,055,920	834,025	1.27x
RIPEMD-160, 1 KB	429,239	318,439	1.35x
HMAC-SHA512 (a BIP-32 step)	2,174,970	889,725	2.44x
BIP-39 seed (PBKDF2, 2048 rounds)	2,105	1,679	1.25x

A batch runs on every core, so it's measured against the reference library verifying the same entries one at a time, which is what an application without `CryptoBatch` would do. The figures are batches of 1,024 signatures, or Merkle levels of 4,096 nodes, per second:

Batch	Codename One	Reference, one at a time	Ratio
ECDSA verify	333	45	7.46x
ECDSA verify, packed	374	45	8.28x

Batch	Codename One	Reference, one at a time	Ratio
Ed25519 verify	261	17	15.62x
SHA-256 Merkle level	7,164	1,053	6.80x
Keccak-256 Merkle level	5,613	796	7.06x



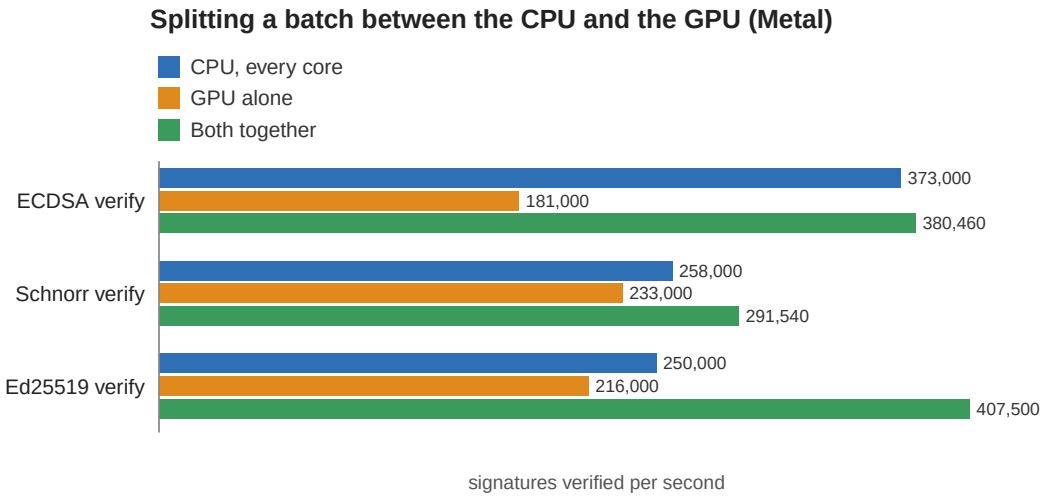
92.6.3. Android

Android has no curve secp256k1 in its platform, so apps there would otherwise ship BouncyCastle. The table shows both the native kernels and the portable Java implementation, each against BouncyCastle on the same device. The two engines ran in turn, each beside its own BouncyCastle run, so each ratio is against the BouncyCastle figure from its own run; the column shows the one from the native run, and the two agree to within 4%.

Operation	Native kernels	Portable Java	BouncyCastle on ART
secp256k1 public key	116,210 (8.44x)	45,203 (3.40x)	13,770
ECDSA sign	71,125 (5.00x)	31,338 (2.12x)	14,232
ECDSA verify	59,615 (6.00x)	16,757 (1.67x)	9,940
Schnorr verify	60,243 (5.97x)	17,163 (1.69x)	10,094
Ed25519 sign	117,185 (1.70x)	53,194 (0.77x)	69,038
Ed25519 verify	39,721 (1.44x)	19,633 (0.72x)	27,571
Keccak-256, 1 KB	762,149 (1.96x)	384,908 (0.98x)	388,709
SHA-256, 1 KB	292,535 (1.08x)	287,546 (1.08x)	270,445
RIPEMD-160, 1 KB	214,766 (0.71x)	205,703 (0.69x)	304,410
BIP-39 seed	1,037 (1.36x)	1,033 (1.36x)	761

SHA-256 and the BIP-39 seed go through the platform's own native implementation in both columns, which is why they match. With the native kernels, RIPEMD-160 is the one row where BouncyCastle stays ahead; it's hashed once per Bitcoin address, so it's never the bottleneck. The portable Java column trails BouncyCastle on Ed25519 and RIPEMD-160 and matches it on Keccak-

256.



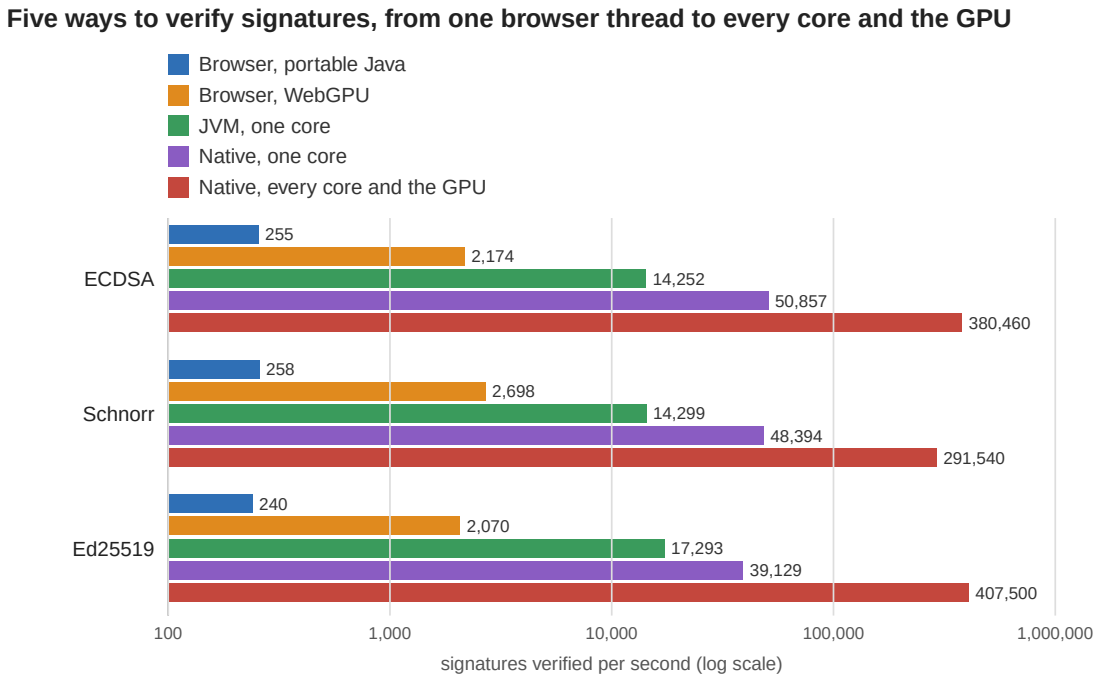
92.6.4. The GPU

A GPU verifies signatures in parallel by the thousand, but each entry first needs some preparation on the CPU, and the GPU's work has to be dispatched and collected. A batch is therefore split, with the CPU cores and the GPU each taking a share in proportion to their measured speed, and a batch smaller than the crossover stays on the CPU. With Metal on the M4 Max:

Kernel	CPU, every core	GPU alone	Both together	Crossover
ECDSA verify	373,000/s	181,000/s	1.02x the CPU alone	784 entries
Schnorr verify	258,000/s	233,000/s	1.13x	539 entries
Ed25519 verify	250,000/s	216,000/s	1.63x	552 entries
Keccak-256	7.1 GB/s	3.6 GB/s	1.01x	3 MB

The chart shows the signature rows; Keccak-256 is measured in bytes rather than signatures, so it appears only in the table.

On this machine the gain is modest, because sixteen CPU cores with vector units are already fast. The split is worked out from the speeds measured on each device, so a GPU that's strong relative to its CPU takes a larger share, and one that's slower takes none. SHA-256 has no GPU row: in this run no SHA-256 batch reached the GPU's minimum size, so they all ran on the CPU.



92.6.5. In the browser

The JavaScript port runs the portable Java implementation, translated to JavaScript. Large batches go to the GPU through WebGPU and arrive through the asynchronous forms. In headless Chromium on the same machine, with batches of 4,096 signatures:

Batch	WebGPU	Portable Java	Ratio
ECDSA verify	2,174/s	255/s	8.5x
Schnorr verify	2,698/s	258/s	10.5x
Ed25519 verify	2,070/s	240/s	8.6x
SHA-256	28.3 MB/s	8.1 MB/s	3.5x
Keccak-256	174.8 MB/s	1.9 MB/s	92x

In the browser most of the time a WebGPU batch takes is the preparation in JavaScript, not the GPU work, and the browser's figures move more from run to run than the native ones: across three runs SHA-256 on WebGPU ranged from 4 to 34 MB/s, and in the slowest it trailed the CPU. The answers never differed: the first run compared a sample of the signatures, and the runs after it compared every entry and every hash. Given records prepared in advance, the kernels alone verified about 164,000 ECDSA, 119,000 Schnorr and 146,000 Ed25519 signatures a second there.

The chart puts the ways a signature can be verified side by side, on a logarithmic scale. They don't measure the same thing: the browser bars are batches on one JavaScript thread, the JVM and native bars are one signature at a time on one core, and the last bar is a native batch across every core and the GPU. Read it as what each setup delivers, not as one benchmark run across platforms.

92.6.6. Running the benchmarks

The harnesses are in `scripts/crypto-bench` and `scripts/crypto-gpu` of the Codename One repository:

```
scripts/crypto-bench/jvm-run.sh            # JVM, against BouncyCastle and the JDK
scripts/crypto-bench/native/run.sh         # C, against libsecp256k1 and OpenSSL
scripts/crypto-bench/android-run.sh        # an attached device or emulator
scripts/crypto-gpu/batch-check.sh          # the GPU split, with its crossover
scripts/crypto-gpu/js-batch-check.sh       # WebGPU in headless Chromium
python3 scripts/crypto-bench/gate.py jvm <output>   # hold a run to its floors
```

Each prints the compiler, JDK and reference library versions above its numbers. `scripts/crypto-bench/charts.py` draws the two charts above from the saved results.

92.7. Where the keys live

Whoever holds the recovery phrase holds the funds. Decide where it lives before you write the first screen.

On the device, in a vault. `VaultSigner` keeps the phrase sealed in a vault (see "Vaults: One password, every device" in the security chapter) and opens it only while the vault is unlocked, by biometrics or the vault password. It works anywhere `Wallet` expects a signer:

```
Vault vault = Vault.named("wallet");
String words = Mnemonic.generate(256);
// Once, when the wallet is created or restored:
VaultSigner.store(vault, "main", words, "");

// Every later launch: the phrase is opened only while the vault is unlocked.
```

```
Wallet wallet = new Wallet(new VaultSigner(vault, "main"));
```

This is the model for a self-custody wallet. A lost device loses nothing as long as the user kept the phrase, and `revealMnemonic` shows it again for a backup. A signer whose vault is locked throws rather than signing, so a stolen, locked phone can't move funds.

On a server, behind your own controls. An exchange or a custodial app derives its deposit addresses and signs its withdrawals in the backend, where the same classes run. Keep the phrase out of the database and the source tree: load it from a secret store or an HSM at startup, and keep withdrawals behind an approval step. The Bastion sample does exactly this. Its implementor's guide walks through hot and deposit wallets, confirmation depth and reorg handling.

`SeedSigner` holds the derived master key in memory. Call `destroy()` when you're done with it, and the key bytes are overwritten. Strings can't be wiped, which is why `VaultSigner.revealMnemonic` answers a `char[]`.

Chapter 93. App Shield

The security chapter covers a lot of ground that ends at the same place: every check runs on the device, and a device the attacker fully controls is a device where every check can be patched out. Root detection returns false. The pinning code is skipped. The jailbreak probe is stubbed. None of it reaches your server, which is where the money is.

App Shield closes that loop. The app obtains a short-lived, Codename One-signed **attestation token** backed by a server-side verification of Apple's App Attest and Google's Play Integrity statements, and your own API refuses to serve a request that doesn't carry a valid one. The statement that matters is made by a party the attacker doesn't control, and your backend can check it in about twenty lines of middleware.

App Shield doesn't make an app unhackable, and no product does. What it changes is the cost: scripted abuse of your API goes from "curl in an afternoon" to "reverse-engineer a native binary, and start again after every rotation," and your backend gets a cryptographically verifiable statement it can act on. Be careful not to promise more than that, internally or in marketing.

This is an **Enterprise** feature. The public API in `com.codename1.security.shield` ships in the open-source core and is safe to call in any build — in a build without the attestation engine it degrades to a documented no-op rather than failing — but tokens are only ever minted for entitled accounts.

93.1. How it fits together

Three parties are involved: the app, the Codename One attestation service, and your own API. A protected request goes through five steps.

1. The app asks the attestation service for a challenge, and the service answers with a nonce it generated. The nonce is what stops a token captured once from being replayed later.
2. The app asks the platform to attest itself against that nonce. Apple's App Attest or Google's Play Integrity produces a statement signed by hardware the app can't forge.
3. The app sends that statement to the attestation service, together with any runtime signals it has collected.
4. The service verifies the statement with Apple or Google, applies the policy you configured, and answers with a short-lived ES256 JWT and the current certificate pin set.
5. The app sends that token to **your** API in the `X-CN1-Attest` header, and your middleware verifies its signature against the public keys the service publishes.

Steps 1 to 4 are the framework's job and happen on the network thread. Step 5 is automatic for every `ConnectionRequest` to a host you registered. The decision — what to do about a device the service declined — is yours, and it belongs in step 5, on your server.

93.2. Turning it on

Two things have to be true: the account has to be entitled, and the build has to ask for it.

Build hint	Default	Description
`shield.enabled`	`false`	Master switch. The build server injects the hardening engine and wires it into the app's startup. A build that asks for it without an Enterprise subscription, or on a server where the engine is unavailable, **fails with an explanation** rather than producing an unprotected app and saying nothing.
`shield.policyVersion`	*(service default)*	The policy generation this build was compiled against.
`shield.pins`	*(none)*	The initial pin set, so the first launch on a new install is pinned before it has ever reached the service. Comma-separated base64 SHA-256 SPKI digests.
`shield.jwksPin`	*(none)*	Pins the key that signs the tokens, so a compromised DNS answer can't introduce a signing key the app will trust.
`shield.attestationVerifyUrl`	*(Codename One cloud)*	Override for a private deployment of the verification service.
`shield.hardFail`	`false`	The hardening engine's own failure policy: `false` reports a problem inside the engine as a signal and lets the app run, `true` makes it fatal. Leave the default unless support advises otherwise.
`ios.appAttest.environment`	`development` for debug builds, `production` for release	The App Attest environment written into the entitlement.

The engine is injected at build time and isn't present in a source checkout, in the simulator, or in an unentitled build. That's deliberate: the detection logic is the part an attacker most wants to read. Everything in this chapter that's **API** is open source; only the engine behind it isn't.

93.3. Protecting hosts

Registration is the whole configuration. A host you don't register is never touched — no header, no certificate check, no behaviour change of any kind.

```
AppShield.init(new ShieldConfig()
        // Money moves here, so refuse the request when no token can be obtained.
        .protect("api.mybank.example", HostPolicy.ENFORCED)
```

```
        // Everything else under the domain gets a token when one is available.
        .protect("*.mybank.example", HostPolicy.PROTECTED));

// From here on nothing changes at the call sites. A request to a protected
// host is given its token and its certificate check on the network thread.
ConnectionRequest r = new ConnectionRequest("https://api.mybank.example/transfer", true);
NetworkManager.getInstance().addToQueueAndWait(r);
```

`HostPolicy` is two independent decisions plus what to do when the shield can't deliver:

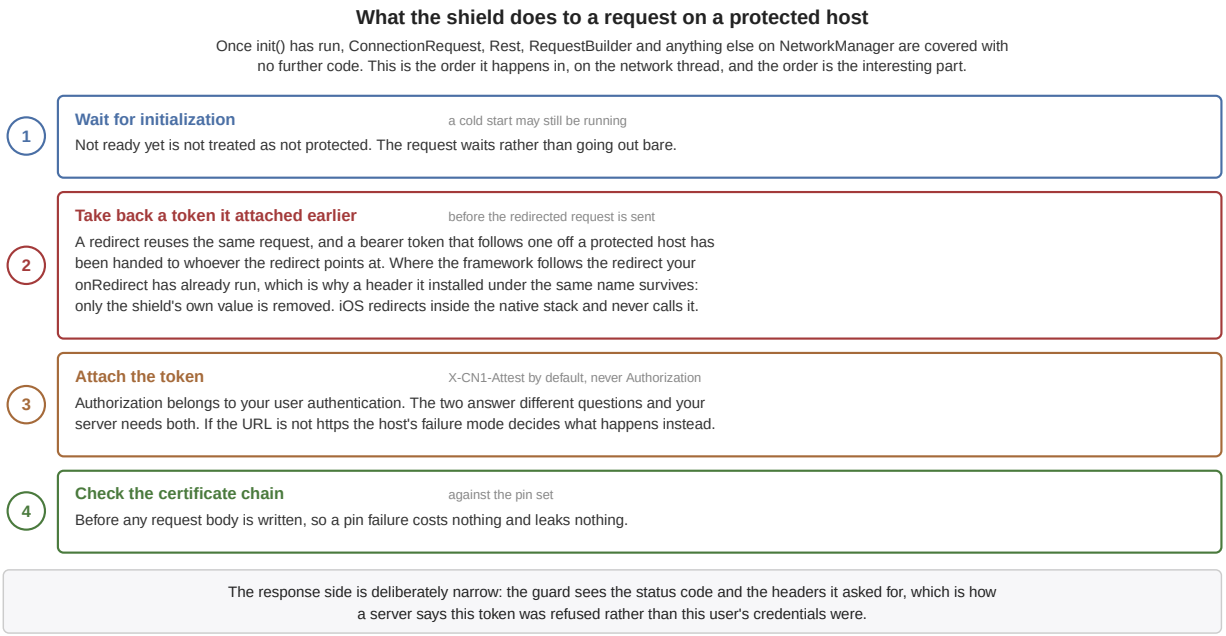
Policy	Token	Pins	When no token can be obtained
`HostPolicy.UNPROTECTED`	no	no	Not applicable. This is what an unregistered host gets.
`HostPolicy.PROTECTED`	yes	yes	**Fail open.** The request goes out without a token and your backend decides. Right for most hosts.
`HostPolicy.ENFORCED`	yes	yes	**Fail closed.** `ShieldException` is thrown and nothing is sent. Right for the handful of endpoints that move money or read personal data.

Fail-closed is a promise that a request without a valid token never leaves the device, so it applies to the awkward cases too: a protected host reached over plain `http` is refused rather than handed the bearer token in clear text, and a shield that was interrupted before it finished starting refuses rather than guessing.

If most of your hosts want the same failure mode, set it once and register them the short way:

```
AppShield.init(new ShieldConfig()
        .defaultFailureMode(FailureMode.CLOSED)
        // Registered the short way, so it picks up the default above.
        .protect("api.mybank.example")
        // And this one opts back out, because an outage here should degrade
        // rather than block the app.
        .protect("images.mybank.example", HostPolicy.PROTECTED));
```

The default failure mode is read when a host's policy is **resolved**, not when it's registered, so `.protect(h).defaultFailureMode(CLOSED)` and the same two calls in the other order mean the same thing.



93.3.1. Wildcards and hosts discovered at runtime

A pattern may be an exact host or a leading `.` wildcard covering its subdomains — `.example.com` matches `api.example.com` and `a.b.example.com`, but not the apex `example.com` and not `example.com.somewhere-else.test`. The most specific rule wins, so an exact registration is never relaxed by a wildcard.

Backends the app only learns about after it starts — a regional endpoint chosen at login, a tenant-specific host — are registered the same way, with the same matching:

```
// Exact host or a "*." wildcard, resolved the way the configured ones are:
// the most specific rule wins, and a runtime registration beats a configured
// one for the same pattern.
AppShield.addProtectedHost(region + ".api.mybank.example", HostPolicy.ENFORCED);
AppShield.addProtectedHost("*.cdn.mybank.example", HostPolicy.PROTECTED);
```

93.4. What happens to a request

Once `init()` has run, `ConnectionRequest`, `Rest`, `RequestBuilder` and anything else built on `NetworkManager` are covered without further code. For a request to a protected host, on the network thread:

- It waits for initialization to finish if a cold start is still in progress, rather than treating "not ready yet" as "not protected."
- Any token the shield attached earlier is taken back off before the redirected request is sent — a redirect reuses the same request object, and a bearer token that follows a redirect off a protected host has been handed to whoever the redirect points at. A header your own `onRedirect()` installed under the same name is left alone: the shield removes its token only while the value is still the token it attached. Note `onRedirect()` runs only where the framework follows the redirect — iOS redirects inside the native stack and never calls it, so there is no opportunity to substitute a header there.
- The token is added under the token header, unless the URL isn't `https`, in which case the host's failure mode decides.
- The certificate chain is collected and checked against the pin set, before any request body is written.

The response side is just as narrow: the guard sees the status code and the headers it asked for, which is how a backend tells the app its **token** was refused as opposed to the user's credentials.

93.4.1. The token header

The default is `X-CN1-Attest`. It isn't `Authorization`, by design: that slot belongs to your own user authentication, and the two answer different questions — who the user is, versus whether this is a genuine unmodified app on an uncompromised device. Your backend needs both, so they have to compose.

`ShieldConfig.tokenHeader(String)` changes it, and refuses names that can't carry a token rather than accepting them and failing out of sight later:

- Anything that isn't a legal HTTP field name. A name with a space or a separator in it isn't the header you asked for by the time it reaches the server — and it also slips past every check below, because `Cookie ` isn't `Cookie`.
- `Content-Type`, which `ConnectionRequest` routes to the request's media type rather than the header map, so the token would replace the content type and survive the redirect cleanup.
- Your app's cookie header, whatever it has been renamed to, because the cookie string is written after the request's own headers and would overwrite the token after `attach()` reported success.
- Headers the transport owns — framing, routing, and the hop-by-hop names a correctly behaving proxy consumes and doesn't forward.

93.5. Status, and what to do about it

The most important distinction in the API is between "the shield couldn't be reached" and "the shield looked at this device and said no." Reacting to the first the way you react to the second is how an app locks a paying customer out on a train.

Status	Transient	Meaning
`OK`	-	A valid token is in hand.
`UNPROTECTED`	no	This build has no attestation engine. Nothing is enforced.
`NOT_INITIALIZED`	no	`init()` hasn't run, or was interrupted.
`NO_NETWORK`, `POOR_NETWORK`	yes	The service couldn't be reached.
`SERVICE_DOWN`	yes	The service answered with an error.
`RATE_LIMITED`	yes	This device is being throttled. Retry after a backoff.
`REJECTED`	no	The service evaluated this device and declined to mint a token.
`PIN_MISMATCH`	no	A pinned host presented a chain matching none of its pins. Nothing was sent.

`ShieldStatus` is a constant **object** rather than an enum on purpose: the vocabulary is visible on the wire and the service must be able to add a status without breaking apps built against an older

release. Compare with `equals`, branch on `isSuccess()` and `isTransient()`, and treat an id you don't recognize as a non-success.

Listeners are delivered on the EDT, so they may touch the UI directly. The framework never shows a dialog and never terminates the app over a shield event — what the user sees is entirely your decision:

```
AppShield.addListener(new ShieldListener() {
    public void statusChanged(ShieldStatus status) {
        if (status.isSuccess()) {
            return;
        }
        if (status.isTransient()) {
            // The service could not be reached. This is a bad connection, not a
            // bad device -- treating it like a rejection is how an app locks out
            // users on a train.
            Log.p("AppShield: attestation unavailable (" + status.getId() + ")");
            return;
        }
        // REJECTED or PIN_MISMATCH: the service evaluated this device and
        // declined, so degrade rather than retry.
        disableTransfers();
    }

    public void signalRaised(ShieldSignal signal) {
        // Informational. The server decides what a signal means -- an emulator
        // signal is normal on a developer's machine.
        Log.p("AppShield signal " + signal.getId() + " severity "
                + signal.getSeverity());
    }

    public void tokenRefreshed(ShieldToken token) {
    }
});
```

93.6. Getting a token yourself

For anything the guard doesn't cover — a third-party HTTP client, a payload you sign yourself, a handshake — ask for the token directly. `fetchToken()` is asynchronous and returns immediately, including during a cold start:

```
AsyncResource<ShieldToken> pending = AppShield.fetchToken();
pending.ready(new SuccessCallback<ShieldToken>() {
    public void onSucess(ShieldToken token) {
        sendToMyBackend(token.getValue());
    }
});
pending.except(new SuccessCallback<Throwable>() {
```

```
    public void onSucess(Throwable error) {
        ShieldStatus status = ((ShieldException) error).getStatus();
        Log.p("AppShield: no token (" + status.getId() + ")");
    }
});
```

Pass a binding value to tie the token to one specific request, so a token lifted from it can't be replayed onto another:

```
// The digest travels in the token, so a token lifted off this request and
// replayed on another one does not verify against the other one's body.
AppShield.fetchToken(sha256(payload)).ready(new SuccessCallback<ShieldToken>() {
    public void onSucess(ShieldToken token) {
        sendToMyBackend(token.getValue());
    }
});
```

`AppShield.attach(ConnectionRequest)` does the same work synchronously for a request you are about to send. It blocks on a network round trip, so it must not be called on the EDT:

```
ConnectionRequest r = new ConnectionRequest("https://api.mybank.example/transfer", true);
try {
    // Blocks on the attestation round trip, so never on the EDT. In normal use
    // the guard does this for you on the network thread.
    AppShield.attach(r);
} catch (ShieldException err) {
    if (ShieldStatus.PIN_MISMATCH.equals(err.getStatus())) {
        // The chain presented for a pinned host matched no pin. Nothing was
        // sent, and this is the one status worth surfacing to the user: it
        // usually means the connection is being intercepted.
        warnAboutInterception();
        return;
    }
    // A fail-closed host with no token. Retry later if the status is transient.
    Log.e(err);
    return;
}
NetworkManager.getInstance().addToQueueAndWait(r);
```

Token lifetime is measured from a monotonic clock, never from `exp` against the device clock, because on a rooted device the wall clock is whatever the attacker wants it to be. `getCachedToken()` returns the current token without any network access, and `invalidateToken()` discards it so the next request re-attests — which is what to call when your backend tells you the token itself was refused:

```
ConnectionRequest r = new ConnectionRequest("https://api.mybank.example/transfer", true) {
    @Override
    protected void readHeaders(Object connection) throws IOException {
        // Your middleware sets this header when the ATTESTATION was the problem,
```

```
        // as opposed to the user's own credentials. Without it a 401 or 403 is
        // ambiguous, and an app re-attests its way through a wrong password.
        if (getHeader(connection, AppShield.REJECT_HEADER) != null) {
            AppShield.invalidateToken();
        }
    }
};
NetworkManager.getInstance().addToQueueAndWait(r);
```

`AppShield.REJECT_HEADER` is `X-CN1-Attest-Reject`. Have your middleware set it only when the **token** was the problem: a protected API normally carries your own user authentication too, and an app that reads every 401 as an attestation failure re-attests its way through a wrong password.

93.7. Certificate pinning

Pins are published by the service and refreshed with the token, so rotating a certificate is a console action rather than an app store release. They're pinned over the **subject public key info**, so renewing a certificate on the same key pair doesn't invalidate the pin, and a chain matches if any certificate in it matches any pin for the host — which is what makes it safe to pin an issuing CA as the backup.

Pinning is the one part of the shield that can take an app offline for a reason the developer can't fix remotely, so the failure behaviour is asymmetric by design:

Condition	Behaviour
Host has no pins	Never enforced. Covers first run, a cold start with no network, and any host the service hasn't published pins for.
Pin fetch failed	Never fails a request. The last known set is kept.
Set past its soft expiry	Still enforced; a refresh is attempted.
Set past its hard expiry	Dropped, and enforcement stops. A device offline for weeks loses pinning, not the app.
Chain matches a pin	Request proceeds.
Host has pins, chain matches none	**Fail closed.** `ShieldException` with `PIN_MISMATCH`, before any body is written.

```
PinSet pins = AppShield.getPinSet();
if (!pins.isEnforcedFor("api.mybank.example")) {
    // No published pins for this host yet, or the set has hard-expired on a
    // long-offline device. Pinning is not enforced, and the app still works.
    Log.p("AppShield: no pins in force (version " + pins.getVersion() + ")");
}
```

A pin mismatch surfaces as an exception on the request, not as a silent empty response. If you swallow `IOException` at your call sites you won't see it, and an intercepted connection is the one failure worth telling the user about.

93.8. Runtime signals

The framework's own detections — root, jailbreak, hooking frameworks, emulators, debuggers, repackaging, untrusted accessibility services — are reported to `ShieldSignals` rather than acted on locally, and ride along with the next token fetch. There is no separate beacon to block and no extra battery cost.

This is a deliberate inversion of the older `exit(0)` style checks. Terminating the app is trivially patched out, destroys the telemetry that makes the feature useful, and turns a detection into a crash report. **The client reports; the service decides.** An emulator signal is normal on a developer's machine; ten high-severity signals from one device in an hour is a device the service can keep flagging on its next clean-looking attestation.

Your own code can report what only it can notice — a server-side consistency check that failed, a sequence of actions no human performs:

```
// Severity is 0-100. The service applies the policy; the client only reports.
ShieldSignals.add("serverStateMismatch", 60,
        "balance disagreed with the ledger after a retry");

// The framework's own detections arrive the same way.
for (ShieldSignal s : AppShield.getSignals()) {
    if (ShieldSignal.HOOK.equals(s.getId())) {
        requireStepUpAuth();
    }
}
```

The bus is bounded and repeat reports of an id collapse onto the existing entry, so a detector that trips on every frame can't exhaust memory. An identical repeat refreshes the entry without notifying listeners again; a changed severity or detail is a new observation and is announced.

93.9. Transports the guard doesn't cover

Coverage matters more here than anywhere else in this chapter, because a gap is invisible at the call site: the code compiles, the request succeeds, and no token was ever attached.

Transport	Coverage
`ConnectionRequest`, `Rest`, `RequestBuilder`, `NetworkManager`	Token and pinning, automatically.

Transport	Coverage
`WebSocket`	Token via `header()` on the opening handshake — and only on Android, desktop, Windows and Linux. iOS and the browser hand the handshake to a platform socket that exposes no way to add a header, which drops it without reporting anything. Pinning isn't reachable through the WebSocket implementations at all.
`BrowserComponent`	The initial navigation only, through `setURL(url, headers)`. Requests the loaded page makes for itself are invisible to the framework: no token, no pinning.
A native or third-party HTTP client	Nothing automatic. Use `fetchToken()` and set the header yourself.

```
// BrowserComponent: the INITIAL navigation only. Requests the loaded page makes
// itself are invisible to the framework and cannot be given a token or pinned.
Hashtable headers = AppShield.headersFor("https://api.mybank.example/statement");
browser.setURL("https://api.mybank.example/statement", headers);

// WebSocket: the handshake carries the token. Emitted on Android, desktop,
// Windows and Linux; silently dropped on iOS and in the browser, whose platform
// sockets expose no way to add a header.
WebSocket.build("wss://api.mybank.example/stream")
        .header("X-CN1-Attest", token)
        .connect();
```

93.10. Composing with your own network guard

`NetworkManager` holds exactly one guard and seals the slot after the first one is installed, so an app that needs its own interception has to delegate to the shield's rather than displace it:

```
// NetworkManager holds exactly one guard and seals the slot, so an app with its
// own has to delegate rather than replace -- calling attach() by hand instead
// would restore the token and silently drop the certificate callbacks that
// enforce pinning.
final NetworkGuard shield = AppShield.getNetworkGuard();
NetworkManager.setNetworkGuard(new NetworkGuard() {
    public void beforeRequest(ConnectionRequest r) throws IOException {
        r.addRequestHeader("X-My-Trace", newTraceId());
        shield.beforeRequest(r);
    }

    public boolean isCertificateCheckRequired(String url) {
        return shield.isCertificateCheckRequired(url);
    }

    public void checkCertificates(ConnectionRequest r, SSLCertificate[] chain)
```

```
            throws IOException {
        shield.checkCertificates(r, chain);
    }

    public String[] interestingResponseHeaders() {
        return shield.interestingResponseHeaders();
    }

    public void afterResponse(ConnectionRequest r, int code, String[] headers) {
        shield.afterResponse(r, code, headers);
    }
});
```

Don’t "work around" the single slot by dropping the shield’s guard and calling `attach()` by hand. That restores the token and drops the certificate callbacks with no error, so pinning stops being enforced while everything still looks like it’s working — the half of the shield whose absence looks exactly like success.

93.11. Verifying the token in your backend

The token is a compact ES256 JWT with `typ` of `cn1-attest+jwt`, signed by a key published at `/.well-known/cn1-attest-jwks.json` and named by the header’s `kid`. Verification is ordinary JWT verification against a JWKS URL — `NimbusJwtDecoder.withJwkSetUri` in Spring, `jose` in Node, `PyJWT[crypto]` in Python — and the console renders a copy-paste quickstart for each, including a Cloudflare Worker for the zero-code-change case.

Beyond the standard `iss`, `aud`, `sub`, `iat`, `exp` and `jti`, the claims your middleware acts on are:

- `pkg` and `plat` — the package name and platform the token was minted for. Check them against the app you expect.
- `vrd` — the verdict: `attested`, `monitored` or `unverified`.
- `dec` — the decision under the current policy: `allow`, or `would_deny` while the app is still in monitor mode.
- `sig` — the signals the device reported.
- `pol` — the policy version the decision was made under.
- `ph` — the payload binding, when the request asked for one.

Roll it out in two stages, and keep the two sides independent. While the service is in **monitor** mode it mints a token for everyone and marks the ones it would have refused, so you can watch the would-deny rate against real traffic before anything breaks. Your middleware has its own switch: log and pass through, or reject. Move one at a time.

Reject with an opaque `403`, not a `401`. A `401` invites the client to retry with fresh credentials, which is exactly the loop you don’t want, and a detailed reason is an oracle for whoever is probing you.

93.12. iOS App Attest specifics

Apple's model is **one attestation, then many assertions**: the first token carries a hardware-backed public key and its attestation, and every later token is a small assertion naming the key. The framework manages the key, the state and the retry policy in the keychain, including recovery when iOS invalidates the key — a restore to a new device, or a reinstall — and Apple's rate limits, which are strict enough that attesting per request gets an app throttled.

The one thing your code has to do is close the loop when the backend has stored the key, because a registration call that was lost leaves the device asserting against a key the server has never seen:

```
// iOS App Attest is attest-once, assert-many: the FIRST token carries the public
// key, every later one is an assertion naming it. Call this once your backend
// has stored that key, or a device whose registration call was lost keeps
// sending assertions for a key the server never saw.
DeviceIntegrity.confirmAttestation(keyId);
```

`DeviceIntegrity.resetAttestation()` throws the key away and starts again, which is the recovery path for a backend that no longer knows the key.

App Attest doesn't work in Apple's iOS simulator — it needs the Secure Enclave. Test the iOS path on a real device, and use the simulator menu below for everything else.

93.13. Testing it in the simulator

None of this is testable against a real service on a developer's desktop, so the simulator ships a simulation engine behind **Simulate** > **App Shield**. Switching on any item installs it; leaving the menu alone leaves the shield inert.

Menu item	What it makes reachable
Attestation Supported	Unchecking it simulates a platform with no attestation at all.
Attestation Result	`PASS`, or each failure in turn: `FAIL_REJECTED`, `FAIL_NO_NETWORK`, `FAIL_SERVICE_DOWN`, `FAIL_RATE_LIMITED`, `UNSUPPORTED`. This is how you exercise the transient-versus-final branch in your listener.
Device signal toggles	Rooted / jailbroken, hooking framework, emulator, debugger, repackaged, untrusted accessibility service — each raising the signal your code reacts to.

Menu item	What it makes reachable
Screen Overlay (Tapjacking)	Fakes another app drawing over yours. It drives the real reporting path rather than setting a flag, so your tapjacking listener fires and the `tapjack` signal is raised exactly as it would be on a device. The desktop has no overlay windows, so this is the only way to reach that branch outside Android.
Serve Expired Token	The refresh path, without waiting out a real token's lifetime.
Force Pin Mismatch On Next Request	The most valuable item here: a fail-closed pinning branch is otherwise only reachable by mis-pinning a live host on purpose. It's a one-shot that disarms itself once spent.
Fail Pin Fetch	Confirms that a failed pin refresh doesn't fail requests.
Show Shield Status…	What the simulation is currently set to, and whether the simulated engine is registered.

The simulated token is stamped so it can't be mistaken for a real one, and the simulator's engine never contacts the service. A backend that accepts a simulated token is a backend that isn't verifying signatures.

93.14. When there is no engine

Every method in this chapter is safe to call in a build without the engine — an open-source build, an unentitled account, the simulator with the menu untouched. The degradation contract is explicit, and it's the reason you don't need to guard your call sites:

- `init()` succeeds and logs one line. `isProtected()` returns `false`.
- `fetchToken()` always completes, with `UNPROTECTED`, and never hangs.
- `attach()` does nothing. No header, no exception.
- **No request is ever blocked**, including one to a host registered as `ENFORCED`. Fail-closed enforcement requires an engine to fail; with no engine there is nothing to enforce and the app must keep working.
- `getSignals()` still returns real `DeviceIntegrity` data, so the free-tier detections described in the security chapter keep working.

Chapter 94. App Hardening

Every Codename One app is already obfuscated by default. On Android the release build runs through R8, which renames the Java names. On iOS and the other native ports your code is compiled to native machine code through ParparVM, which is hard to reverse engineer on its own — but the class names, method names and string literals still travel into the binary as readable text, so a reader who can't follow the machine code can still read the labels and the constants.

App Hardening is the Enterprise layer that closes that remaining gap across **all** the ports from one place. It renames classes, methods and fields; encrypts string constants so they're not present as plaintext in the binary; and obfuscates control flow — and it does this to the merged application before each platform build, so Android, iOS, JavaScript and the native desktop targets are all covered by one transform and one mapping.

This is a tool for apps that face serious security scrutiny — banking, payments, government and other high-risk targets. It raises the cost of static analysis and tampering; it's one layer, so pair it with Chapter 93, *App Shield* so the statement your backend trusts is made by hardware the attacker doesn't control.

App Hardening is an **Enterprise** feature. A build that asks for it without an Enterprise subscription **fails with an explanation** rather than producing an unhardened binary that would look protected without being so.

94.1. What it changes, per port

The transform runs on the merged application jar, at the bytecode level, before any platform-specific build step. That's why one implementation reaches every port: iOS/ParparVM translates the already-hardened bytecode to C (so the C constant pool never sees the plaintext), R8 consumes already-hardened classes on Android, and the JavaScript backend minifies already-hardened classes.

Transform	Ports	Notes
Class / method / field renaming	iOS, JavaScript, Windows, Linux, desktop	Android keeps R8 as its sole renamer — renaming twice would only force a pointless mapping composition. The renamer uses a distinctive name dictionary on purpose: short names such as `a`/`b` are substrings of the ParparVM native identifiers and would defeat the translator's dead-code elimination, so a six-character prefixed name is used instead.

Transform	Ports	Notes
String constant encryption	iOS, Android, Windows, Linux, desktop	Both channels are handled: the `LDC` string literals in method bodies **and** the `ConstantValue` attribute of `static final String` fields, which would otherwise leak into the ParparVM C constant pool even after the readers were encrypted. Each distinct literal is decoded once (per class) and interned, so equal encrypted literals stay reference-equal to each other. The decoder is synthesized into each class with a per-class key, so there is no single framework method to hook. Not applied on the JavaScript port, where a string literal can be a live reference into the native bridge. One caveat: an encrypted app literal is a different object from an equal **un-encrypted** literal elsewhere — for example a literal of the same value returned by the framework, which isn't hardened. Reference (`==`) comparison of string literals across that boundary can therefore change. Compare strings with `.equals()`, which is unaffected; `==` on distinct string values was never a guarantee to rely on. One exclusion: a string used as an **annotation value** (or an annotation-method default) is stored by javac in the annotation metadata, not as an `LDC` or a field constant, so it's not encrypted and remains readable in the binary. Codename One has no runtime reflection, so your app can't read that value back anyway — but don't place a secret in an annotation and expect it hidden. Another exclusion: string concatenation such as `"prefix=" + value`, compiled by a JDK 9 or newer javac, becomes an `invokedynamic` whose literal fragments live in the concatenation recipe rather than an `LDC` or a field constant, so the encryption can't reach them and they stay readable. The engine counts these sites and the build report lists them, so a build that ships such literals says so rather than claiming complete string encryption. Compiling with `-XDstringConcat=inline` (or an older `-target`) makes javac emit `StringBuilder` calls whose literals the engine does encrypt.
Control-flow obfuscation	Android, desktop	An opaque predicate guarded by a value the decompiler can't fold. Left off the ParparVM native ports, where it fights the translator's optimizer and the arithmetic reducer, and off JavaScript, where it inflates the bundle. Never applied to constructors.

94.2. Turning it on

Add the level to your `codenameone_settings.properties`:

```
codename1.arg.harden.level=standard
```

Build hint	Default	Description
`harden.level`	`off`	Master switch: `off`, `standard`, `aggressive` or `paranoid`. An unrecognized value **fails the build** rather than being treated as `off`.
`harden.rename`	*(level)*	Override renaming on/off independently of the level.
`harden.strings`	*(level)*	`off`, `constants`, or `all`.
`harden.controlFlow`	*(level)*	Override control-flow obfuscation on/off.
`harden.keep`	*(none)*	Keep rules in ProGuard syntax, one rule per line, for classes resolved by name at runtime that the automatic analysis can't see. Same syntax as `android.proguardKeep`, so existing rules port directly. (Rules are separated by newlines only, since a `;` is legal inside a rule body such as `{ *; }`.)
`harden.<platform>.enabled`	`true`	Per-port opt-out (`and`, `ios`, `mac`, `linux`, `win`, `javascript`, `javase`), mirroring the Crash Protection opt-outs. Only an explicit `false` disables a platform.
`harden.requireSymbolUpload`	`true`	Fail the build if the symbol/mapping upload fails. Losing a hardened build's mapping makes its crash reports permanently unreadable, so this defaults to strict.
`harden.allowUnhardenedLocalBuild`	`false`	Escape hatch: allow a local or source-project target to build unhardened instead of failing the pre-flight.
`harden.seed`	*(build id)*	Fixes the renaming seed for a reproducible mapping across rebuilds; leave unset for a fresh mapping per build.

94.3. Levels

The level is the one decision most projects need to make. The individual switches are overrides on top of it.

	`off`	`standard`	`aggressive`	`paranoid`
Class/method/field renaming	—	yes	yes	yes
String encryption	—	constants	all	all

	`off`	`standard`	`aggressive`	`paranoid`
Control-flow obfuscation	—	—	yes	yes + opaque predicates
Local-variable debug stripping	—	yes	yes	yes
Symbol/mapping upload	—	required	required	required

On a renamed build the source file name (`SourceFile`) is stripped, matching DexGuard: the engine-renamed ports drop it, and on a minified Android release R8 drops it too. `LineNumberTable` is kept so a hardened crash still retraces to a line number against the mapping; the retrace reconstructs the file name from the (retraced) class name. Renaming also removes the local-variable and parameter names.

An explicitly **unminified** Android build (`android.enableProguard=false`, which `android.onDeviceDebug` also forces) doesn't rename at all — only string encryption and control-flow obfuscation apply — so its class names, and `SourceFile` along with them, remain. That's a debug configuration, not the release artifact hardening targets.

94.4. Keeping what must not be renamed

Renaming is safe for code the compiler and runtime resolve by symbol. Codename One has no runtime reflection — `Class.forName` never resolved an obfuscated application class — so there is no reflective seam to protect, and there is no serialization to keep members for. What must survive is the small set the build resolves by **name**: the main class and its generated stub, the generated router and annotation bootstraps, and each native interface with its generated `Impl`/`Stub` peer. The engine finds the native interfaces in the input and keeps exactly those peers, and keeps the rest of that set automatically.

`PropertyBusinessObject` properties are safe without any special handling: a property's JSON key and database column come from the **string** passed to its `Property`, not from the field name, so renaming the field doesn't change the on-disk schema or the wire format. String encryption decodes those strings back to the same value at runtime.

If you have a class the build resolves by a name the automatic analysis can't see, add a `harden.keep` rule for it.

Package names are obfuscated along with class names. Codename One's own resource loading uses absolute paths (`Display.getResourceAsStream("/name")`, the theme `.res`), which are unaffected. The one thing renaming can break is a **package-relative** resource lookup — `getClass().getResourceAsStream("config.properties")`, without a leading slash — because the runtime resolves it under the class's now-obfuscated package while the resource stays at its original path. This is uncommon in application code, but a bundled third-party dependency might do it; if one loads a resource relative to its own package, add a `harden.keep` rule for that class (or its package) so its package path stays put.

94.5. Crash reports from a hardened build

Hardening and Crash Protection are designed together. The build server retains the obfuscation

mapping and symbolicates incoming reports against it, so a crash from a hardened build still lands as a readable, correctly lined GitHub issue — see Chapter 104, *Crash Protection*. Two consequences follow: a report whose mapping has aged out of retention can no longer be retraced, and a locally hardened build (whose mapping never reached the server) can't be symbolicated at all, which is why the pre-flight refuses to harden a local target by default.

94.6. Local and source builds aren't hardened

Hardening runs on the Codename One build server, and only there. The engine itself is open source — it lives in this repository and ships inside the Maven plugin — so its protection isn't the secrecy of the algorithm. What the server boundary provides is enforcement and custody: the Enterprise entitlement is checked where the account lives (a client can't grant itself the feature), the renaming dictionary and decoder keys are seeded per build so the exact obfuscation differs each time and can't be predicted without the build key, and the obfuscation mapping is retained server-side for symbolication rather than handed to the client.

A local or source-project target (`-source, local-`) never reaches the server, so its output isn't hardened; the build fails the pre-flight rather than mislead you, unless you set `harden.allowUnhardenedLocalBuild=true`. The simulator is never obfuscated either — it runs your `target/classes` directly. App code can read `com.codename1.security.hardening.Hardening.isHardened()` to tell a hardened build apart from one of these.

94.7. Hardening and App Shield

These are two different Enterprise features and you can use either or both. App Hardening protects the **binary** — it raises the cost of reading and modifying the app on the device. App Shield protects the **app-to-server relationship** — it gives your backend a cryptographically verifiable statement that a request came from a genuine, unmodified app on an uncompromised device. Hardening makes an attacker work harder to patch out App Shield's checks; App Shield makes patching them out insufficient, because the statement your backend trusts is made by a party the attacker doesn't control.

94.8. What this doesn't protect against

Hardening raises the cost of static analysis and casual tampering. It doesn't stop a determined attacker with time, it doesn't protect a secret you embed in the client (put it on your server — see the security chapter), and it's not a substitute for server-side authorization. Treat it as one layer of defense in depth, not a guarantee.

Chapter 95. Biometric Authentication

Codename One ships first-class biometric authentication (Touch ID, Face ID, Android `BiometricPrompt`) under the `com.codename1.security` package. A single entry point exposes the platform prompt, a typed enum reports the modalities currently enrolled, and a typed error enum lets callers react to failures without string matching.

A sibling `SecureStorage` API stores secret strings (auth tokens, refresh tokens, encryption keys) behind biometric authentication using the iOS keychain or the Android Keystore.

95.1. Quick start: Authenticate

```
Biometrics b = Biometrics.getInstance();
if (!b.canAuthenticate()) {
    // Fall back to password
    return;
}
b.authenticate("Unlock your account").onResult((success, err) -> {
    if (err != null) {
        BiometricError code = ((BiometricException) err).getError();
        switch (code) {
            case USER_CANCELED: /* user dismissed the prompt */ break;
            case LOCKED_OUT:    /* too many bad attempts */ break;
            case NOT_ENROLLED:  /* prompt the user to enrol in Settings */ break;
            default:            /* generic failure */ break;
        }
    } else {
        // Authenticated. Continue with the gated action.
    }
});
```

Always gate the call on `canAuthenticate()` and never on `isSupported()` alone. `isSupported()` only checks for hardware, while `canAuthenticate()` also requires at least one enrolled credential and that the device isn't in a locked-out state.

95.2. Quick start: Secure storage

Entries are bound to the current set of enrolled biometrics. If the user enrols a new fingerprint or face after writing, the next `get` fails with `BiometricError.KEY_REVOKED` and the application must re-prompt for the original value and write it again.

95.3. Platform behaviour

Platform	Implementation	Notes
iOS	`LocalAuthentication.framework` (`LAContext`) + `Security.framework` keychain	Add the `ios.NSFaceIDUsageDescription` build hint when targeting Face ID hardware.
Android API 29+	`BiometricPrompt`	Face / iris / fingerprint per `PackageManager` features.
Android API 23-28	`FingerprintManagerCompat`	Fingerprint only. Goes through the support library rather than `android.hardware.fingerprint` directly, which Android removed in API 37, so an app compiled against any platform still authenticates on these devices.
JavaSE simulator	`Simulate → Biometric Simulation` submenu	Toggle hardware availability, per-modality enrolment, and the next-call outcome.
All other ports	Non-supporting fallback	`canAuthenticate()` returns `false`; `authenticate()` completes with `BiometricError.NOT_AVAILABLE`.

Application code never needs a platform `if`. The API itself returns the right thing on each port. On platforms without biometric hardware, the fallback reports `NOT_AVAILABLE` immediately.

95.4. Build hints

The Codename One Maven plugin and the build daemon both **automatically inject** the platform configuration when the app's bytecode references `com.codename1.security`:

- **iOS:** `LocalAuthentication.framework` is linked into the generated Xcode project.
- **Android:** `<uses-permission android:name="android.permission.USE_BIOMETRIC" />` (and `USE_FINGERPRINT` with `maxSdkVersion=28` for the legacy path) is injected into `AndroidManifest.xml`.

Apps that never touch the API pay nothing: no extra framework, no extra permission.

One thing the plugin won't inject: the iOS Face ID usage description. Apple rejects placeholder text, so you must supply the build hint yourself:

```
ios.NSFaceIDUsageDescription=Authenticate to securely access your account
```

The JavaSE simulator automatically sets this hint to a default the first time biometrics is invoked, so projects developed in the simulator have a working default; you should overwrite the text before shipping.

To share keychain entries with iOS App Extensions, set both the build hint and the runtime access group:

```
ios.keychainAccessGroup=TEAMID123.group.com.example.app
```

```
SecureStorage.getInstance().setKeychainAccessGroup("TEAMID123.group.com.example.app");
```

The Team ID prefix is required; omitting it produces `errSecMissingEntitlement`.

95.5. Configuring the prompt

Use `AuthenticationOptions` to control prompt copy and security policy:

```
Biometrics.getInstance().authenticate(new AuthenticationOptions()
    .setReason("Authorize transfer")                // iOS localizedReason; Android title fallback
    .setTitle("Confirm payment")                    // Android only
    .setSubtitle("Stripe charge $25.00")            // Android only
    .setNegativeButtonText("Cancel")                // Android only
    .setBiometricOnly(true)                         // reject PIN / passcode fallback
    .setSensitiveTransaction(true)                  // request class-3 ("strong") biometric (Android 30+)
);
```

Unrecognized options are ignored, so callers can set the union without platform-checking.

95.6. Typed error handling

`BiometricException.getError()` returns a `BiometricError`:

Code	Meaning
`NOT_AVAILABLE`	No biometric hardware or the platform doesn't support it
`NOT_ENROLLED`	Hardware present but the user hasn't enrolled
`LOCKED_OUT`	Too many failed attempts; temporary
`PERMANENTLY_LOCKED_OUT`	User must unlock with passcode before biometrics can be used again
`PASSCODE_NOT_SET`	Device has no PIN / pattern configured (can't use biometrics)
`USER_CANCELED`	User dismissed the prompt
`SYSTEM_CANCELED`	OS dismissed the prompt (app backgrounded, system pre-empted)
`AUTHENTICATION_FAILED`	Prompt completed but the user wasn't recognized

Code	Meaning
KEY_REVOKED	SecureStorage entry can no longer be decrypted (re-enrolment occurred)
UNKNOWN	Anything not covered above

95.7. Cancelling an in-flight prompt

Call Biometrics.getInstance().stopAuthentication() to dismiss an active prompt; the pending AsyncResource then completes with BiometricError.USER_CANCELED. The method returns true if a prompt was cancelled, false if nothing was pending.

95.8. Listing enrolled biometrics

getAvailableBiometrics() returns a List<BiometricType> to drive UI affordances (icon, prompt copy):

- FINGERPRINT: iOS Touch ID; Android fingerprint sensor.
- FACE: iOS Face ID; Android face recognition (API 29+).
- IRIS: a handful of Samsung devices; never on iOS.
- STRONG: Android class-3 authenticator tier (false-acceptance < 1/100,000); only Android API 30+.
- WEAK: Android class-2 authenticator tier; only Android API 30+. Can't unlock Keystore-bound keys, so weak-only devices can't use SecureStorage.

Never use this list to decide whether to call authenticate(); always use canAuthenticate() for that decision.

95.9. Simulator workflow

The JavaSE simulator's Simulate → Biometric Simulation submenu lets you exercise every code path without a device:

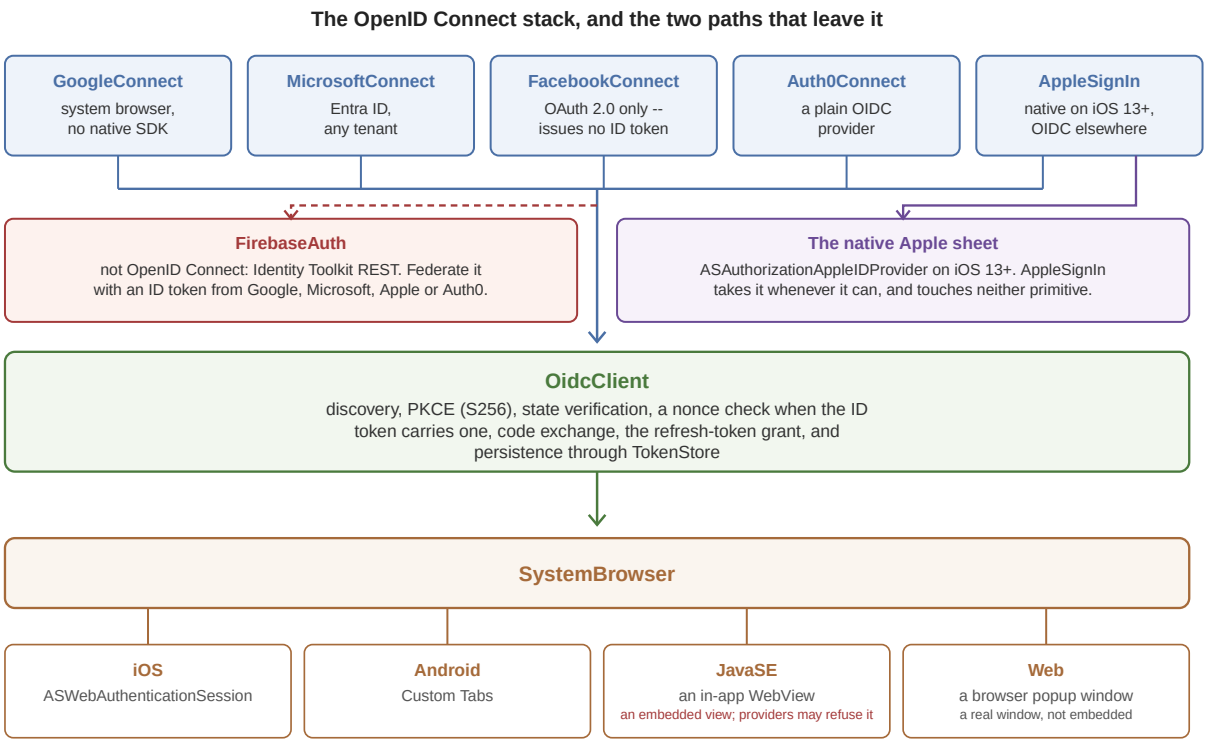
- **Hardware Available**: toggles isSupported() and canAuthenticate().
- **Face ID Enrolled / Touch ID Enrolled / Iris Enrolled**: populate getAvailableBiometrics().
- **Next authenticate() Outcome**: radio button that picks the outcome of the next prompt: SUCCEED, FAIL, CANCEL, LOCKED_OUT, PERMANENTLY_LOCKED_OUT, NOT_ENROLLED, PASSCODE_NOT_SET. The selection is sticky; change it any time.

When authenticate() is invoked, a small modal Swing dialog mirrors the platform prompt so the developer can see the trigger fire and click through. State persists across simulator restarts via java.util.prefs.

SecureStorage round-trips against java.util.prefs in the simulator, so you can test the full set → get → KEY_REVOKED flow end-to-end.

95.10. Security notes

The Android backing for `authenticate()` doesn't simply forward the OS success callback; it binds the prompt to a single-use AES probe cipher in the Android Keystore (with `setUserAuthenticationRequired(true)` and, on API 24+, `setInvalidatedByBiometricEnrollment(true)`). On success the cipher performs a real `doFinal` operation. A hooked or spoofed success callback fails because the Keystore refuses the operation. This guards against the bypass class documented by CodeQL's `java/android/insecure-local-authentication` rule.



Chapter 96. Authentication and Identity

This chapter covers Codename One's modern sign-in stack: OpenID Connect, Sign in with Apple, Google, Facebook, Microsoft Entra ID, Auth0 and Firebase Authentication.

The stack is rebuilt around two new primitives:

- `com.codename1.io.oidc.OidcClient` — a full OpenID Connect / OAuth 2.0 client with PKCE, discovery, refresh and token persistence.
- `com.codename1.io.oidc.SystemBrowser` — routes the sign-in step through the platform's hardened sign-in surface where one exists: `ASWebAuthenticationSession` on iOS and Android Custom Tabs. Elsewhere it falls back to `BrowserWindow`, and what that means differs: the Web port opens a real top-level browser window, while JavaSE renders a JavaFX `WebView` inside the app. The desktop one is an embedded view, so a provider that blocks those can refuse a simulator sign-in that works on a device. The Web one has a constraint of its own — it's a `window.open()` call, and it happens after the discovery request comes back rather than inside the click that started the sign-in, so a browser that has already expired the transient activation blocks it. Tell your users to allow popups for the site, or start the flow from an `OidcClient` you configured ahead of time instead of `discover()`. And point the redirect URI at a page on the app's own origin: the port watches the popup by reading its location, the same-origin policy blocks that read once the popup navigates elsewhere, and the fallback reports the authorization URL again — so a callback hosted anywhere else never gets recognized and `authorize()` simply never completes. That applies to Apple's `form_post` bridge too, which has to live on that origin rather than beside the Services ID.

Every provider-specific class is a thin layer on top of these primitives, so once you learn the underlying client you understand the whole stack.

Two places step outside it, and both are deliberate. `AppleSignIn` calls the native Apple sheet whenever the platform offers one, which on iOS 13+ means neither primitive is involved; the OpenID Connect path is what it falls back to everywhere else. And `FirebaseAuth` isn't an OpenID Connect provider at all — you reach it by handing it an ID token you already obtained, which `FacebookConnect` can't give you because Facebook's flow issues an access token and nothing else.

The legacy `com.codename1.io.Oauth2` class is **deprecated**. It opens an in-app `WebBrowser`, which modern identity providers (Google, Apple, Microsoft, Facebook) now refuse to render — they detect the embedded view and block the page. The new `OidcClient` works the same on every supported platform without that limitation. See Section 96.11, "Migrating from `Oauth2`" for a migration recipe.

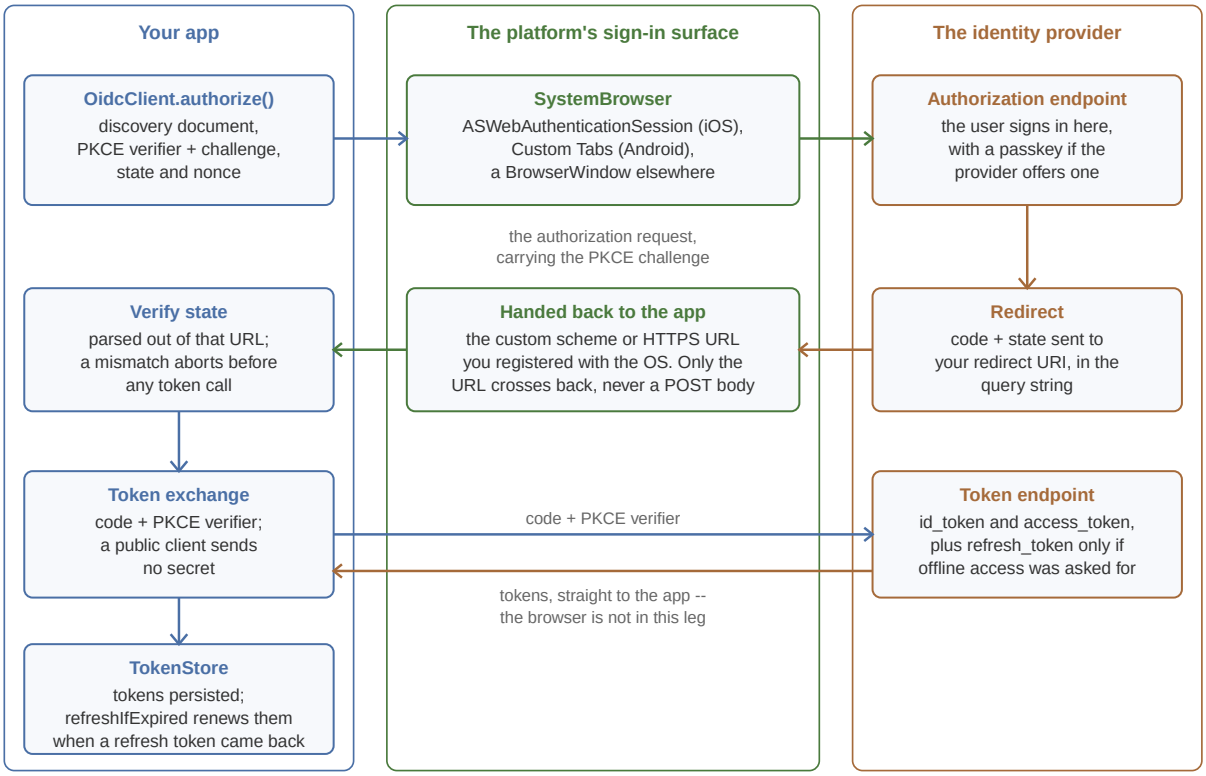
96.1. Why the change

Identity providers tightened their rules in 2023 and 2024:

- **Google** — the legacy `GoogleSignIn` SDK has been replaced by Google Identity Services (GIS). GIS expects PKCE and discourages embedded WebViews.
- **Apple** — Sign in with Apple, mandatory for App Store apps that offer any other social login, requires a native ASAuthorizationAppleIDProvider call on iOS 13+ or a web flow with `form_post response_mode`.
- **Microsoft** — Entra ID (formerly Azure AD) requires PKCE for public clients and forwards all browser flows through Microsoft Authenticator when installed.
- **Facebook** — Facebook Login still supports OAuth 2.0 but its embedded-WebView detection now blocks unknown user agents.

The old `Oauth2` class drove the entire flow through `com.codename1.components.WebBrowser`, which is an embedded view. That model no longer works on a Codename One device build for these providers.

96.2. Quick start — any OpenID Connect provider



If your identity provider publishes a standard `.well-known/openid-configuration` document (Google, Microsoft, Apple, Auth0, Okta, Keycloak, AWS Cognito, Authentik, and most others do) you can sign users in with about ten lines of code.

```
OidcClient.discover("https://accounts.google.com").ready(new SuccessCallback<OidcClient>() {
    public void onSucess(OidcClient client) {
        client.setClientId("YOUR_CLIENT_ID")
              .setRedirectUri("com.example.app:/oauth2redirect")
              .setScopes("openid", "email", "profile");
        client.authorize().ready(new SuccessCallback<OidcTokens>() {
            public void onSucess(OidcTokens tokens) {
                // tokens.getAccessToken() -- bearer for API calls
                // tokens.getIdToken()     -- JWT with user identity claims
                // tokens.getEmail()       -- convenience accessor
            }
        }).except(new SuccessCallback<Throwable>() {
```

```
            public void onSucess(Throwable err) {
                System.out.println("Sign-in failed: " + err.getMessage());
            }
        });
    }
});
```

That call:

1. Fetches `accounts.google.com/.well-known/openid-configuration`.
2. Generates a PKCE pair (S256), a `state`, and a `nonce`.
3. Opens the OS system-browser sheet at the discovered authorization endpoint.
4. Exchanges the code for tokens on the discovered token endpoint.
5. Verifies `state`, the issuer the response names, and the ID token, and persists the tokens via the default `TokenStore`.

The token exchange is the leg worth noticing: it goes straight from your app to the provider's token endpoint, carrying the PKCE verifier, and the browser has already done its job by then. A provider that treats your app as a public client wants no secret on that request, which is the arrangement PKCE exists to make safe. Apple is the exception on its non-native path and wants a `client_secret` JWT your server mints, which is what Section 96.3.3, "One-time Apple setup" is about.

Only the redirect URL crosses back from the browser, which is why Apple's non-iOS path needs a server in front of it: `AppleSignIn` asks for `response_mode=form_post`, so Apple POSTs `code` and `state` to your redirect URI rather than putting them in the query string, and `OidcClient` parses the URL alone. The page at that URI has to turn the POST into a redirect carrying the same parameters, or

the sign-in fails with `STATE_MISMATCH`.

Whether the token endpoint hands back a refresh token is up to the request: the quick start above asks for `openid`, `email` and `profile` and nothing more, so Google returns none and there is nothing for `refreshIfExpired` to renew. `GoogleConnect.signIn` adds `access_type=offline` and `prompt=consent` for exactly that reason.

96.2.1. What's verified before you get the tokens

`OidcClient` doesn't hand over tokens it hasn't checked. A sign-in that fails one of these checks fails with an `OidcException`, and nothing is stored.

- **The authorization response.** Its `state` has to be the one the request carried. If the response names an issuer with the `iss` parameter, that issuer has to be the provider you configured. A provider whose discovery document sets `authorization_response_iss_parameter_supported` always names itself, so a response without `iss` is refused for that provider. The error is `issuer_mismatch`. This stops an answer from one provider being taken for another's when an app signs in with several.
- **The ID token's claims.** `iss` is the provider, `aud` is your client ID, `exp` hasn't passed, and `nonce` is the one the request carried. When the token has an `at_hash`, it has to match the access token that came with it. The device's clock may be five minutes off, and `setIdTokenClockSkew` changes that.
- **The ID token's signature.** The provider's keys are fetched from its `jwks_uri` once and kept. They're fetched again when a token names a key that isn't among them, but not more than once in 60 seconds. A token that names an unknown key within 60 seconds of the last fetch is refused without another request to the provider. `RS256`, `RS384`, `RS512`, `ES256` and `ES384` are accepted. An unsigned token is refused. A token signed with `HS256` or another shared-secret algorithm is refused too, because an app can't keep the secret that would verify it.

A configuration you build by hand needs a `jwksUri` for the last check. `discover` fills it in.

The signature check has no silent fallback. If the platform the app runs on can't verify a signature of the token's algorithm, the token is refused and the error says so. For a provider whose ID tokens can't be verified on a platform you ship to, or one that signs them with `HS256`, turn the check off explicitly. There is no other way to have such a token accepted:

```
// Only for a provider whose ID tokens this platform can't verify.
client.setVerifyIdTokenSignature(false);
```

The claims are still checked then, but they're only as trustworthy as the TLS connection to the token endpoint. Don't make a decision on your server from an ID token the app forwards. Verify it there.

96.2.2. Picking a redirect URI

For mobile apps, use a **custom scheme** unique to your app, for example `com.example.app:/oauth2redirect`. Register the scheme with the OS via the build hints below so the system browser can hand the redirect back to your app.

For web / simulator runs, use a normal HTTPS URL pointing at a page you control. The Codename One fallback `BrowserWindow` closes as soon as the URL matches.

iOS

Add the URL scheme to your Info.plist via the standard build hint:

```
ios.urlScheme=<key>CFBundleURLTypes</key>\n<array>\n  <dict>\n    <key>CFBundleURLSchemes</key>\n    <array>\n
<string>com.example.app</string>\n    </array>\n  </dict>\n</array>
```

`AuthenticationServices.framework` is added to the linker automatically whenever your app references anything in `com.codename1.io.oidc` or `com.codename1.social.AppleSignIn` — you don't need to add `ios.add_libs=AuthenticationServices.framework` manually.

Android

Add an intent filter for the redirect scheme to the application manifest via the `android.xintent_filter` build hint:

```
android.xintent_filter=<intent-filter>\n  <action android:name="android.intent.action.VIEW"/>\n  <category
android:name="android.intent.category.DEFAULT"/>\n  <category android:name="android.intent.category.BROWSABLE"/>\n  <data
android:scheme="com.example.app"/>\n</intent-filter>
```

The `androidx.browser:browser:1.8.0` Gradle dependency (for Custom Tabs) is added to your app's Gradle build automatically whenever it references anything in `com.codename1.io.oidc`. Override the version with build hint `android.customTabsVersion=1.x.y` if needed.

96.2.3. Saving and restoring tokens

`OidcClient` saves the response under a per-issuer + per-client-ID key using `com.codename1.io.oidc.TokenStore.DefaultStorageTokenStore` (which serializes to `com.codename1.io.Storage`). To restore on next launch:

```
client.refreshIfExpired(60).ready(new SuccessCallback<OidcTokens>() {
    public void onSucess(OidcTokens tokens) {
        if (tokens == null) {
            // No saved tokens, or they expired and we have no refresh token.
            client.authorize();
        } else {
            // Reuse `tokens.getAccessToken()` -- still valid (refreshed if needed).
        }
    }
});
```

If the saved access token is within 60 seconds of expiring and a refresh token is available, `refreshIfExpired` performs a refresh-token grant in the background and persists the new tokens.

96.2.4. Encrypting tokens at rest

The default token store uses `com.codename1.io.Storage`, which is sandboxed but not encrypted. `SecureStorageTokenStore` keeps the tokens in the platform keychain or keystore instead, through `com.codename1.security.SecureStorage`:

```
// Encrypted by the platform, read without a prompt.
client.setTokenStore(new SecureStorageTokenStore());

// Behind Face ID or a fingerprint. Reading the tokens prompts the user.
client.setTokenStore(new SecureStorageTokenStore()
        .requireBiometrics("Unlock your notes"));

// Ordinary storage on a platform that has no secure storage.
client.setTokenStore(new SecureStorageTokenStore()
        .allowPlainStorageFallback(true));
```

The first form encrypts the tokens and reads them without asking the user. That's the one to use when a token goes out with every request. The second form puts them behind a biometric prompt. Load the tokens once when the app starts if you choose it, because every read prompts.

A platform without secure storage isn't given a weaker store behind your back. Every operation fails there with an `OidcException` whose code is `storage_unavailable`. The third form is the opt-in: on such a platform, and only there, the tokens go to ordinary storage.

96.3. Sign in with Apple

`com.codename1.social.AppleSignIn` consolidates the previous `cn1-applesignin` cn1lib into core. On iOS 13+ it uses native ASAuthorizationAppleIDProvider; on Android, JavaSE and the Web port it uses the public Apple OIDC issuer through `OidcClient`.

96.3.1. iOS

The iOS port implements the `com.codename1.social.AppleSignInNative` interface. No build hints are required beyond enabling the `Sign in with Apple` capability:

```
ios.signinwithapple=true
```

```
AppleSignIn.getInstance().signIn("name email", new AppleSignInCallback() {
    public void onSuccess(AppleSignInResult result) {
        // result.getIdentityToken()  -- JWT to verify on your server
        // result.getUserId()         -- stable opaque user id, use as PK
        // result.getEmail()          -- may be a real or relay address
    }
    public void onError(String err) { }
    public void onCancel()          { }
```

```
});
```

Apple only returns the user's name and email on the **first** authorization. AppleSignIn persists those values in `Preferences` so the result is consistent on subsequent sign-ins.

96.3.2. Android, JavaSE, Web

Apple requires a separate **Services ID** (a "web client") for non-iOS environments and a `client_secret` JWT generated by your server. The recipe lives at Section 96.3.3, "One-time Apple setup".

On Android there is a second thing to arrange. The Services ID callback is an HTTPS URL, and the Android sign-in surface hands control back by matching the scheme of the redirect it's waiting for, so the `com.example.app` custom scheme registered earlier in this chapter does nothing for it. The callback host and path need their own verified App Link: an `android.xintent_filter` carrying an `android:autoVerify="true"` filter for `android:scheme="https"` on that host, and an `assetlinks.json` served from it. Deep-Link Routing Section has both, and says how to put that filter and the custom-scheme one in a single hint value — the hint holds one string, so an app doing both needs them together.

96.3.3. One-time Apple setup

1. In the Apple Developer portal, create a **Services ID** alongside your App ID. Enable "Sign in with Apple" for both.
2. Configure the Services ID's **Web Authentication Configuration** with the primary App ID and your redirect URI.
3. Generate an **AuthKey** private key in the Apple developer portal (`.p8` file). Apple doesn't allow public mobile clients to mint the `client_secret` JWT themselves; your backend must do it. See Apple's docs [https://developer.apple.com/documentation/sign_in_with_apple/generate_and_validate_tokens] for the JWT recipe.

96.4. Google Sign-In

`com.codename1.social.GoogleConnect` now offers a modern `signIn(…)` method that runs entirely through `OidcClient`:

```
GoogleConnect.getInstance().signIn(
    // the iOS or Android client for a native build; the Web client
    // belongs with an https redirect, in the simulator or web port
    "YOUR_IOS_OR_ANDROID_CLIENT_ID.apps.googleusercontent.com",
    "com.example.app:/oauth2redirect",
    "openid", "email", "profile"
).ready(new SuccessCallback<OidcTokens>() {
    public void onSucess(OidcTokens t) {
        String email = t.getEmail();
```

```
        String idToken = t.getIdToken();
    }
});
```

`signIn` works on iOS, Android, JavaSE and Web with the same code, against the **Web Application** OAuth 2.0 client ID from Google Cloud Console. The redirect URI you supply must match one of the **Authorized redirect URIs** configured for that client.

The legacy `doLogin()` / `setClientSecret(…)` path is still available for source compatibility but is no longer recommended.

96.4.1. Migrating from the legacy Google integration

If you currently rely on `GoogleConnect.doLogin()` with the Google Sign-In SDK on Android or `GIDSignIn` on iOS, you can switch to the modern flow without touching your build:

- On Android, the legacy code uses `com.google.android.gms.auth.api.Auth.GoogleSignInApi` — this is the part Google deprecated. New code via `signIn(…)` doesn't require the native SDK at all.
- On iOS, the legacy code uses `GIDSignIn` (Google Sign-In SDK). The new code uses `ASWebAuthenticationSession` via `SystemBrowser`, which is what Google now recommends for non-broker apps.

96.5. Facebook Login

`com.codename1.social.FacebookConnect` exposes both the old SDK-based `doLogin()` and a new SDK-free `signIn(…)` that uses the system browser via `OidcClient`. Use the new method for the simulator, the web port, and for apps that don't want to bundle the Facebook SDK at all:

```
FacebookConnect.getInstance().signIn(
    "FB_APP_ID",
    // This flow is for the simulator and the web port, where the
    // response comes back through the browser, so the redirect is an
    // https URL registered with Facebook. A native Android or iOS build
    // registers a custom scheme instead, as the OidcClient samples above
    // do -- match the redirect to the target you are building.
    "https://example.com/oauth2redirect",
    "public_profile", "email"
).ready(new SuccessCallback<OidcTokens>() {
    public void onSucess(OidcTokens t) {
        String accessToken = t.getAccessToken(); // ID token will be null
        // call https://graph.facebook.com/me with the access token for user data
    }
});
```

Facebook doesn't issue OpenID-Connect ID tokens for classic OAuth flows, so `getIdToken()` returns `null`. Read user profile fields via the Graph API.

96.6. Microsoft / Entra ID

`com.codename1.social.MicrosoftConnect` wraps the same OIDC client against `https://login.microsoftonline.com/{tenant}/v2.0`. The default tenant `common` accepts personal and work / school accounts; pass a tenant GUID, `organizations`, or `consumers` to restrict.

Apps that need broker (Microsoft Authenticator) support for Conditional Access can bundle the MSAL SDK manually and bypass `MicrosoftConnect`. For the vast majority of apps the system-browser flow is sufficient and lets the simulator and web port share the same code path.

96.7. Auth0

`Auth0Connect` is the simplest of the providers because Auth0 is a clean OIDC provider; everything beyond `withDomain` is optional.

96.8. Firebase Authentication

Firebase Auth isn't an OIDC provider — it issues Google-Identity-Toolkit-style tokens via REST endpoints. `com.codename1.social.FirebaseAuth` wraps those endpoints:

```
void firebaseEmailSignIn(String email, String password) {
    // withApiKey is not optional: without it every call completes its
    // AsyncResource with IllegalStateException instead of reaching
    // Firebase. Do it once, wherever your app initializes.
    FirebaseAuth auth = FirebaseAuth.getInstance().withApiKey("YOUR_WEB_API_KEY");
    auth.signInWithEmailAndPassword(email, password)
        .ready(user -> {
            // user.getIdToken() is a Firebase token rather than an OIDC
            // one, and it is a bearer credential: send it to your service,
            // never to the log. Anything written with Log or println ends
            // up in logcat and in device diagnostics.
            callMyBackend(user.getIdToken());
        })
        .except(err -> ToastBar.showErrorMessage(err.getMessage()));
}
```

For federated sign-in (Google / Apple / Microsoft as Firebase providers), first obtain an ID token via the matching `*Connect` class, then swap it for a Firebase session:

```
String clientId = "YOUR_IOS_OR_ANDROID_CLIENT_ID.apps.googleusercontent.com";
String redirectUri = "com.example.app:/oauth2redirect";
// without the api key every FirebaseAuth call fails before it is sent
FirebaseAuth.getInstance().withApiKey("YOUR_FIREBASE_WEB_API_KEY");
GoogleConnect.getInstance().signIn(clientId, redirectUri, "openid", "email")
    .ready(new SuccessCallback<OidcTokens>() {
        public void onSucess(OidcTokens g) {
```

```
            FirebaseAuth.getInstance().signInWithIdpIdToken(g.getIdToken(), "google.com")
                .ready(new SuccessCallback<FirebaseAuth.FirebaseUser>() {
                    public void onSucess(FirebaseAuth.FirebaseUser u) {
                        // Firebase user is now signed in.
                    }
                });
        }
    });
```

Refresh the Firebase session at app launch:

```
FirebaseAuth fa = FirebaseAuth.getInstance().withApiKey(KEY);
if (!fa.isSignedIn()) {
    fa.refresh().ready(new SuccessCallback<FirebaseAuth.FirebaseUser>() {
        public void onSucess(FirebaseAuth.FirebaseUser u) {
            // u is null if no refresh token was stored
        }
    });
}
```

96.9. Passkeys / WebAuthn

Codename One ships a portable WebAuthn client at `com.codename1.io.webauthn.WebAuthnClient`. It wraps the OS public-key credential APIs (`ASAuthorizationPlatformPublicKeyCredentialProvider` on iOS 16+, `androidx.credentials.CredentialManager` on Android API 28+) behind a JSON-friendly Java surface so you can talk to any relying-party server with the same code on every supported platform.

96.9.1. When you actually need this class

If you sign users in via `OidcClient` against Google, Apple, Microsoft Entra ID, Auth0 or Firebase, the **identity provider already supports passkeys**. The user's web browser at the IdP shows the passkey sheet, and OIDC just hands you the resulting ID / access tokens. You don't have to call `WebAuthnClient` at all — everything in the rest of this chapter that signs users in via `OidcClient` already gets passkey-backed sign-in transparently, with no additional code on your side.

Reach for `WebAuthnClient` when:

- Your app talks to **your own** relying-party server and you want passwordless sign-in / step-up auth backed by a passkey.
- You wire up a direct Auth0 or Firebase passkey ceremony (see Section 96.9.5, "Auth0 passkeys" and Section 96.9.6, "Firebase passkeys").
- You drive a third-party SDK that emits a WebAuthn challenge.

96.9.2. Quick start — own backend

Pseudo-code (the actual HTTP calls depend on your server library):

```
// Registration -- enroll a new passkey
String challengeJson = myServer.startPasskeyRegistration(currentUserId); // PublicKeyCredentialCreationOptionsJSON
PublicKeyCredentialCreationOptions opts =
        PublicKeyCredentialCreationOptions.fromJson(challengeJson);

WebAuthnClient.getInstance().create(opts)
        .ready(new SuccessCallback<PublicKeyCredential>() {
            public void onSucess(PublicKeyCredential cred) {
                myServer.finishPasskeyRegistration(cred.toJson()); // server verifies + persists
            }
        })
        .except(new SuccessCallback<Throwable>() {
            public void onSucess(Throwable err) {
                if (err instanceof WebAuthnException) {
                    String code = ((WebAuthnException) err).getError();
                    // "NotAllowedError" -- user dismissed the sheet
                    // "not_supported"   -- platform lacks a passkey impl
                    // ... etc.
                }
            }
        });

// Sign-in -- assert with an existing passkey
String requestJson = myServer.startPasskeySignIn(); // PublicKeyCredentialRequestOptionsJSON
WebAuthnClient.getInstance()
        .get(PublicKeyCredentialRequestOptions.fromJson(requestJson))
        .ready(new SuccessCallback<PublicKeyCredential>() {
            public void onSucess(PublicKeyCredential cred) {
                myServer.finishPasskeySignIn(cred.toJson()); // server verifies signature
            }
        });
```

`PublicKeyCredential#toJson()` is in the W3C `RegistrationResponseJSON` / `AuthenticationResponseJSON` format, which every WebAuthn server library accepts as-is. On the server, verify the response with one of:

- Java — webauthn4j [https://webauthn4j.github.io/webauthn4j/en/]
- Node — @simplewebauthn/server [https://simplewebauthn.dev/]
- Rust — webauthn-rs [https://github.com/kanidm/webauthn-rs]
- Python — py_webauthn [https://github.com/duo-labs/py_webauthn]

Do **not** try to verify the attestation or assertion on the device. The relying-party server holds the credential record and the signature counter; only it can detect cloned authenticators.

96.9.3. Platform requirements

Platform	Notes
iOS	iOS 16+. The `AuthenticationServices.framework` library is linked automatically when your app references `com.codename1.io.webauthn.*`. Add an `Associated Domains` entitlement with `webcredentials:<rp.id>` and host an `apple-app-site-association` file at `https://<rp.id>/.well-known/apple-app-site-association` describing your bundle's `webcredentials` app IDs.

Platform	Notes
Android	API 28+ via `androidx.credentials:credentials` (added to your Gradle build automatically; override the version with build hint `android.credentialsVersion=1.x.y`). Publish a Digital Asset Links file at `https://<rp.id>/.well-known/assetlinks.json` declaring your app's SHA-256 certificate fingerprint.
JavaSE / desktop, Web port	`WebAuthnClient.isSupported()` returns `false`. Calls fail with `WebAuthnException.NOT_IMPLEMENTED`. Use this to gate the UI — present a fallback (password sign-in, email magic link) when passkeys are unavailable.

96.9.4. Build hints

iOS:

```
ios.entitlements.com.apple.developer.associated-domains=<array>\n  <string>webcredentials:example.com</string>\n</array>
```

Android: nothing beyond the dependency that gets injected automatically. The asset-links file lives on your server; the build doesn't touch it.

96.9.5. Auth0 passkeys

`Auth0Connect` exposes two passkey helpers driven by Auth0's WebAuthn grant (`urn:okta:params:oauth:grant-type:webauthn`). They drive `WebAuthnClient` under the hood, so the same iOS / Android platform requirements apply.

Enable **Passkeys** in the Auth0 dashboard (Authentication → Database → your connection → Authentication Methods → Passkey), and add **WebAuthn** to the application's **Grant Types**.

96.9.6. Firebase passkeys

`FirebaseAuth` exposes `registerPasskey` (enroll a passkey for the signed-in user) and `signInWithPasskey` (sign in with an existing passkey). Both use Firebase Identity Platform's v2 passkey REST endpoints (`accounts/passkeyEnrollment:start|finalize`, `accounts/passkeySignIn:start|finalize`).

Passkey support requires the **Identity Platform** tier of Firebase Auth (the upgraded plan). The free Firebase Auth tier doesn't expose the passkey endpoints; the calls will fail with an HTTP 403. Check your project plan in the Firebase console under Build → Authentication → Settings → User account linking.

96.9.7. Mapping WebAuthn errors

`WebAuthnException.getError()` returns one of the W3C-defined error names:

Code	Meaning
`NotAllowedError`	User dismissed the OS sheet, no matching credential, or the authenticator denied the request.
`InvalidStateError`	The credential being created already exists on the authenticator.
`NotSupportedError`	Platform doesn't support the requested algorithm / transport combo.
`SecurityError`	Origin / RP-ID validation failed. Most often an Associated Domain (iOS) or asset-links (Android) misconfiguration.
`AbortError`	Caller cancelled the ceremony.
`ConstraintError`	A constraint (resident key, user verification) couldn't be satisfied.
`not_supported`	The platform has no native WebAuthn implementation at all. Caller should fall back to password sign-in.
`transport_error`	Network failure while POSTing to your relying-party server.
`invalid_options`	The options JSON received from the relying party couldn't be parsed.
`invalid_response`	The response returned by the authenticator couldn't be parsed.

96.10. Signing in against a Codename One backend

A Codename One backend can be its own identity provider. Its authorization server speaks OpenID Connect, so the app signs in with the same `OidcClient` it would use for any other provider. Section 42.12, "The authorization server" covers the server side. This section is the app's half.

96.10.1. Signing in

Register the app on the server as a public client: no secret, the authorization code and refresh token grants, and the exact redirect URI the app uses. Then discover the server and authorize:

```
OidcClient.discover("https://api.example.com").ready(discovered -> {
    client = discovered
            .setClientId("notes-app")
            .setRedirectUri("com.example.notes:/oauth2redirect")
            .setScopes("openid", "profile", "notes.read")
            .setTokenStore(new SecureStorageTokenStore());
    client.authorize()
            .ready(tokens -> showNotes())
            .except(err -> showSignInFailed(err));
});
```

The issuer you pass to `discover` is the server's `cn1.security.authorizationserver.issuer`, without a trailing slash. The redirect URI has to match the registered one exactly. The server doesn't accept wildcards.

The answer holds an access token, a refresh token and an ID token. The access token is a signed JWT that the server's resource chain verifies. Its `scope` claim becomes the caller's `SCOPE_` authorities

there.

96.10.2. Sending the token with every request

`OidcRequestAuthorizer` adds the access token to the app's requests and renews it when it expires. Create one for the client, give it the base URL of your API, and load the session a previous run saved:

```
authorizer = new OidcRequestAuthorizer(client).install("https://api.example.com");
authorizer.addSignInRequiredListener((source, reason) -> showSignIn());
authorizer.load().ready(saved -> {
    if (saved == null) {
        showSignIn();
    } else {
        showNotes();
    }
});
```

From then on every request under that base URL carries `Authorization: Bearer …`. That includes requests made with `Rest`, with `ConnectionRequest`, and by a generated `@RestClient` client created for that base URL. Tokens the client obtains later reach the authorizer by themselves.

```
// No header to add: the authorizer covers every request under its base URL.
Rest.get(SERVER + "/api/notes").acceptJson().fetchAsJsonMap(response -> {
    if (response.getResponseCode() == 200) {
        show(response.getResponseData());
    }
});

// A blocking call waits through the renewal too.
Response<String> profile = Rest.get(SERVER + "/api/me").getAsString();
```

The base URL is matched by origin and by whole path segments. The origin is the scheme, the host and the port. Scheme and host are compared without regard to case, and a port that's left out is the scheme's own, so `https://api.example.com` and `https://API.example.com:443` are the same base URL. The path is compared exactly and ends where a segment ends, so `/v1` covers `/v1/pets` and doesn't cover `/v10`. When two registrations cover a request, the one with the longer path wins.

A token is never sent to another origin. That holds for a redirect too: a request the server redirects to another host, another port or plain `http` is sent there without the header. A request redirected to a path outside the base URL goes without it too. This is the behavior where Codename One follows the redirect itself. On iOS the system follows redirects before the app sees them, so don't have a token-protected API redirect to a host you don't control.

The authorizer works on the event dispatch thread only. It puts the header on a request when you queue it, and the network thread sends what the request carries. A request you queue from another thread is passed to the event dispatch thread first and queued from there, without making your thread wait. Call the authorizer's own methods, such as `setTokens` and `signOut`, on the event

dispatch thread. Called from another thread they wait for it, so don't call them from a thread the event dispatch thread is itself waiting for.

96.10.3. Renewing before the token expires

The authorizer renews a token before the server has a chance to refuse it. When you queue a request and the access token is within a minute of its expiry, the refresh token is exchanged first. The request is kept out of the queue until the exchange is done, and is then sent once with the new token. Requests queued in the meantime wait for the same exchange.

Nothing blocks while this happens, because the request hasn't reached a network thread yet. Code that waits for the request gets the one final answer.

Change the minute with `setRefreshLeeway`. A larger value suits a server whose clock runs ahead of the device's. A negative value turns renewing ahead of time off:

```
// Renew a token that has less than two minutes left.
authorizer.setRefreshLeeway(120);
```

If the server refuses that exchange, the session is over, as the next section describes, and the request is sent without a token so that it's answered `401`. If the exchange can't reach the server, the request is sent with the token it has, which might still be good.

A token whose response carried no `expires_in` has no known expiry. It's renewed only when the server refuses it.

96.10.4. What happens on a 401

A token can still be refused: the server revoked it, restarted with new keys, or the device's clock is wrong. When the server answers `401` to a request that carried the authorizer's token, the app doesn't see that answer. The request is held, and the refresh token is exchanged for a new set of tokens. The request is then sent again with the new access token, and its answer is delivered as usual.

A few rules keep this predictable:

- A request is renewed once. If the second attempt is also refused, that `401` is delivered.
- Requests refused at the same moment share one exchange. The server replaces the refresh token every time it's used, so a second exchange with the old one would fail.
- Code that waits for a request waits until the end. `getAsString()` and the other blocking methods return the final answer, and so does `addToQueueAndWait`.
- If the server refuses the refresh token, the session is over. The tokens are removed from memory and from the token store, the held requests deliver their `401`, and your sign-in listener runs so you can show the sign-in screen.
- If the exchange fails because the server can't be reached, the tokens are kept. The held request delivers its `401`, and the next request tries again.

When a renewal fails, the refused request is sent one more time as it was first sent. The `401` you receive is that second answer, handled by your error handlers like any other response.

You can also choose the authorizer for one request:

```
// Another authorizer for one request.
Rest.get("https://partner.example.org/feed").authorizer(other).fetchAsString(r -> show(r));

// No authorizer for one request, not even the default.
Rest.get(SERVER + "/api/public/status")
        .authorizer(RequestAuthorizer.NONE)
        .fetchAsString(r -> show(r));

// A header you set yourself always wins.
Rest.get(SERVER + "/api/notes").bearer("a-token-from-elsewhere").fetchAsString(r -> show(r));
```

An `Authorization` header that's already on a request always wins. That's true for a header you set on the request and for a default header set with `NetworkManager.addDefaultHeader`. The authorizer isn't asked about such a request, and a `401` to it isn't renewed.

To sign out, revoke the refresh token and clear the stored session:

```
OidcTokens current = authorizer.getTokens();
if (current != null && current.getRefreshToken() != null) {
    client.revoke(current.getRefreshToken());
}
authorizer.signOut();
```

96.10.5. The device grant

A television, a watch or a kiosk has no browser to sign in with and no comfortable keyboard. The device grant lets the user approve such a device from a phone or a computer. The app asks for a code, shows it, and waits:

```
client.requestDeviceAuthorization().ready(device -> {
    showCode(device.getUserCode(), device.getVerificationUri());
    AsyncResource<OidcTokens> waiting = client.pollDeviceToken(device);
    waiting.ready(tokens -> showNotes());
    waiting.except(err -> {
        if (err instanceof OidcException
                && OidcException.EXPIRED_TOKEN.equals(((OidcException) err).getError())) {
            showCodeExpired();
        } else {
            showSignInFailed(err);
        }
    });
});
```

The user opens the verification address on another device, signs in and types the code. `getVerificationUriComplete()` returns the same address with the code in it, which suits a QR code.

`pollDeviceToken` asks the server at the interval the server chose. It waits five seconds longer each time the server answers `slow_down`. It stops with an `OidcException` when the user refuses (`access_denied`) or the code runs out (`expired_token`), and it stops when you cancel the resource it returned. The tokens are stored the same way `authorize()` stores them, so the authorizer picks them up.

The client needs the `urn:ietf:params:oauth:grant-type:device_code` grant on the server. It needs no redirect URI for this flow.

96.10.6. Passkeys

A backend that declares `http.webAuthn(…)` serves the two WebAuthn ceremonies, and `WebAuthnClient` runs the device's side of each. Section 42.14, "Passkeys" lists the endpoints.

A signed-in user adds a passkey like this:

```
// The user is signed in, so the authorizer's token goes with both requests.
String options = Rest.post(SERVER + "/webauthn/register/options").getAsString().getResponseData();
WebAuthnClient.getInstance()
        .create(PublicKeyCredentialCreationOptions.fromJson(options))
        .ready(credential -> Rest.post(SERVER + "/webauthn/register")
                .queryParam("label", "My phone")
                .jsonContent()
                .body(credential.toJson())
                .fetchAsString(r -> show(r)));
```

A user who has one signs in with it:

```
String options = Rest.post(SERVER + "/webauthn/authenticate/options").getAsString().getResponseData();
WebAuthnClient.getInstance()
        .get(PublicKeyCredentialRequestOptions.fromJson(options))
        .ready(credential -> Rest.post(SERVER + "/login/webauthn")
                .jsonContent()
                .useBoolean(true)
                .body(credential.toJson())
                .fetchAsJsonMap(r -> {
                    if (Boolean.TRUE.equals(r.getResponseData().get("authenticated"))) {
                        // The answer set the session cookie, and later requests send it.
                        showNotes();
                    }
                }));
```

Both requests of a ceremony have to reach the server with the same cookies, because the server keeps the challenge in the session. `ConnectionRequest` keeps cookies for you unless you turned them off.

Two server settings matter to an app. The chain has to leave the passkey endpoints out of CSRF protection with `csrf.ignoringRequestMatchers("/webauthn/**", "/login/webauthn")`, because an app

has no page to read a CSRF token from. An Android app's origin isn't a web address but `android:apk-key-hash:` followed by a hash of its signing certificate, and it has to be in the server's allowed origins.

96.10.7. One-time codes

A backend with a second factor expects a six-digit code after the password. The server uses the same `com.codename1.security.Otp` class your app has, so an authenticator screen in your app produces codes the server accepts:

```
String code = Otp.totp(Base32.decode(base32Secret));
```

A code is good once. The server refuses a code it has already accepted, even inside the same 30 seconds.

96.11. Migrating from `Oauth2`

A typical legacy snippet:

```
Oauth2 oauth = new Oauth2(
    "https://provider.example.com/oauth2/authorize",
    "CLIENT_ID",
    "https://example.com/callback",
    "openid email",
    "https://provider.example.com/oauth2/token",
    "CLIENT_SECRET");
oauth.showAuthentication(new ActionListener() {
    public void actionPerformed(ActionEvent e) {
        if (e.getSource() instanceof AccessToken) {
            AccessToken t = (AccessToken) e.getSource();
            // null
        }
    }
});
```

becomes:

```
OidcConfiguration cfg = OidcConfiguration.newBuilder()
    .authorizationEndpoint("https://provider.example.com/oauth2/authorize")
    .tokenEndpoint("https://provider.example.com/oauth2/token")
    .build();
// An installed app cannot keep a secret, so it is a public client: no
// client secret, and PKCE -- which OidcClient applies to every flow --
// is what protects the code exchange. The redirect has to come back to
// the app, so it is a custom scheme rather than an https URL.
OidcClient client = OidcClient.create(cfg)
    .setClientId("CLIENT_ID")
```

```
    .setRedirectUri("com.example.app:/oauth2redirect")
    .setScopes("openid", "email");
client.authorize().ready(new SuccessCallback<OidcTokens>() {
    public void onSucess(OidcTokens t) {
        AccessToken legacy = t.toAccessToken();  // for code that still expects AccessToken
    }
});
```

Or, if the provider exposes a discovery document:

```
OidcClient.discover("https://provider.example.com").ready(new SuccessCallback<OidcClient>() {
    public void onSucess(OidcClient client) {
        client.setClientId("CLIENT_ID")
              // Same public-client rules as the sample above: the
              // redirect has to be the custom scheme the app
              // registers, or the browser never hands control back.
              .setRedirectUri("com.example.app:/oauth2redirect")
              .setScopes("openid", "email");
        client.authorize().ready(tokens -> Log.p("signed in"));
    }
});
```

`OidcTokens#toAccessToken()` returns a `com.codename1.io.AccessToken`, so callers that already deal in `AccessToken` (most subclasses of `com.codename1.social.Login`) can adopt `OidcClient` without changing their token type.

96.12. Verifying a phone number

Signing a user in by phone number is a flow of its own rather than an OpenID Connect one: your server sends a code to the number and checks the code the user types back, and the device's part is entering the number, entering the code, and letting the platform offer the code out of the arriving message so the user never types it.

`com.codename1.components.PhoneVerification` is that screen, and `com.codename1.ui.TextArea#ONE_TIME_CODE` is the hint that makes the platform offer the code without any messaging permission. See Chapter 97, *Phone Number Verification*.

96.13. A universal sign-in demo

A complete sample is included under `samples/UniversalSignInDemo` in the repository. It renders one button per provider (Apple, Google, Microsoft, Facebook, Auth0, Firebase, generic OIDC) and dumps the resulting tokens to a `TextArea` so you can inspect them. See its `README.md` for the credentials wiring.

Chapter 97. Phone Number Verification

Signing a user in by phone number, or proving that a number they typed is theirs, is the same two steps everywhere: send a code to the number, then check the code they type back. This chapter covers the device half of that — entering the number, entering the code, and letting the platform hand the code over so the user never types it.

97.1. Who does what

Codename One doesn't send the message. The service that does is yours, and which one you use (Twilio, Vonage, AWS SNS, Firebase Phone Auth, your own SMPP gateway) is a decision the framework has no part in. It also doesn't judge a code: the code exists on your server, and a client that could check it could also be persuaded to lie.

Your server	Codename One
Generates the code, sends the message, expires it, rate limits it	Collects the number in E.164 form
Decides whether a submitted code is correct	Collects the code, and accepts the one the platform offers
Issues whatever session or token follows	Owns the screen: the two stages, the resend wait, the way back to a mistyped number, and the errors your server reports

97.2. Quick start

`com.codename1.components.PhoneVerification` is the whole screen. You supply the two server calls:

```
PhoneVerification verify = new PhoneVerification();
verify.setCodeSender((number, response) -> myServerSendsCode(number, response));
verify.setCodeVerifier((number, code, response) -> myServerChecksCode(number, code, response));
verify.addVerifiedListener(e -> onVerified(verify.getPhoneNumber()));
form.add(verify);
```

That's a working verification screen. It starts on the number, moves to the code once your server accepts the number, submits the code as soon as the last box is filled, and reports the result.

97.3. The code arrives by itself

The field the code goes into carries `com.codename1.ui.TextArea#ONE_TIME_CODE`. The constraint has no behaviour of its own — it's a statement about what the field holds, and it's what makes the platform offer the arriving code:

Platform	What the hint buys
iOS	The keyboard's suggestion bar offers the code from Messages, above the number pad.
Android	The autofill service offers the code from the SMS on the field.
Web	The input is marked `one-time-code`, which is what a password manager matches on, and what puts the code in iOS Safari's suggestion bar.
Desktop and everywhere else	Nothing changes. The user types the code.

None of these routes reads messages, and none asks for a messaging permission. Your application says what the field is for; the platform decides what to offer, and the user decides whether to accept it.

A field without the hint is offered nothing, on every platform. The only alternative left is reading the SMS yourself, which on Android means holding `READ_SMS` — a permission Google Play restricts to applications whose core function is messaging, and one that has sunk more than one app review.

The constraint is worth setting on any field of your own that holds a code, even outside this flow:

```
TextField code = new TextField("", "Code", 6, TextArea.NUMERIC | TextArea.ONE_TIME_CODE);
```

97.4. The code field

`com.codename1.components.OtpField` draws the code one box per digit and tells you when it's complete:

```
OtpField otp = new OtpField(6);
otp.addCompleteListener(e -> checkCode(otp.getText()));
form.add(otp);
otp.startEditing();
```

`getText()` returns what has been entered so far, `isComplete()` says whether every box is filled, `clear()` empties the field and puts the caret back at the start, and `startEditing()` opens the keyboard, which saves the user a tap on a screen that exists for one purpose.

The boxes are drawn, and one field behind them holds the whole code. That's what lets an offered code land in a single step, and it's not an implementation detail you can ignore if you build your own: a code is one value, both mobile ports enforce a field's maximum length as a hard native filter, and a six-character code offered to a row of one-character fields is truncated to its first digit. `getBox(int)` returns the box that displays a character, for theming; the value is read and written through the field.

97.5. Entering the number

`com.codename1.components.PhoneNumberField` pairs a country selector with a number field and produces one E.164 string — a leading `+`, the calling code, then the national number, digits only:

```
PhoneNumberField phone = new PhoneNumberField();
form.add(phone);
// the user picks Israel and types 50-123-4567; separators are dropped
String number = phone.getE164();   // "+972501234567"
boolean plausible = phone.isValid();
// typing the trunk prefix they say out loud, 050-123-4567, keeps it:
// "+9720501234567". Your sending service normalizes that -- see below.
```

It starts on the country the device reports and offers every calling code in a searchable list. An application that serves three countries has no reason to show two hundred, and one that already knows the number can set it:

```
PhoneNumberField phone = new PhoneNumberField();
phone.setCountries(new PhoneNumberField.Country[]{
    PhoneNumberField.findCountry("IL"),
    PhoneNumberField.findCountry("US"),
    PhoneNumberField.findCountry("GB")
});
phone.setE164(lastNumberWeSawForThisUser());
```

Country names are English, and each is looked up in the theme's resource bundle first under `Country.` plus the ISO 3166 code, so an application that ships translations gets them without replacing the list.

Two things the field doesn't do, by design:

- **It doesn't strip a national trunk prefix.** A leading `0` is a trunk prefix in Israel and part of the number in Italy, and telling them apart is a per-country rule this field doesn't carry. Users type their number the way they know it; your sending service normalizes.
- **It doesn't decide a number exists.** `isValid()` checks the shape — a national part that's present and short enough to keep the whole number inside E.164's fifteen digits — and that's all a client can check. The service that sends the message is the authority, and its refusal reaches the user like any other failure.

Several countries share a calling code: `+1` covers the United States, Canada and much of the Caribbean, which the North American area code tells apart and this field doesn't. `setE164` keeps the country already selected when its code matches, and otherwise takes the first country listed for that code.

97.6. The flow in detail

Each server call is handed a `PhoneVerification.Response` and calls exactly one of `succeeded()` or `failed(String)` when the server answers. Either may be called from any thread, so a callback on a networking thread needs no hop of its own.

Three behaviours are worth knowing, because they're the ones that get rewritten by hand on every verification screen:

- **A request in flight disables the button that started it,** so a second tap can't send a second message. It's re-enabled when the response arrives.
- **A second answer to the same request is ignored** rather than rejected. A server wrapper that answers twice on a retry is a nuisance, not a reason to leave a screen stuck.
- **An answer to a request the user has moved past is dropped.** If they gave up waiting, went back, corrected the number and sent again, the first server's answer no longer describes the screen they're looking at, and applying it would move them somewhere they didn't ask to go.

A failure message you pass to `failed(String)` is shown to the user as-is, so it should be something a user can act on; passing null shows a generic message instead. `addFailedListener` reports the same failures to your code, for counting attempts or logging them.

Resend is held back for `setResendDelay(int)` seconds — 60 by default — with the remaining time shown on the button. Zero offers it at once.

You don't have to use the built-in buttons. `requestCode(String)`, `submitCode()`, `showCodeStage(String)` and `showNumberStage()` are public, so a screen with its own layout can drive the same flow, and an application that sent the message itself can start at the second stage:

```
PhoneVerification verify = new PhoneVerification();
verify.setCodeVerifier((number, code, response) -> myServerChecksCode(number, code, response));

// we sent the message ourselves, so start at the code
verify.showCodeStage("+972501234567");

// ... and drive the rest from our own controls
myOwnVerifyButton.addActionListener(e -> verify.submitCode());
myOwnEditNumberButton.addActionListener(e -> verify.showNumberStage());
```

97.7. Talking to your server

The two callbacks are where your API lives. A typical pair over REST:

```
PhoneVerification verify = new PhoneVerification();

verify.setCodeSender((number, response) ->
    Rest.post(myApi + "/verify/start")
        .jsonContent()
```

```
        .body("{\"phone\":\"" + number + "\"}")
        .fetchAsJsonMap(result -> {
            if (result.getResponseCode() == 200) {
                response.succeeded();
            } else {
                response.failed(null);
            }
        }));

verify.setCodeVerifier((number, code, response) ->
    Rest.post(myApi + "/verify/check")
        .jsonContent()
        .body("{\"phone\":\"" + number + "\",\"code\":\"" + code + "\"}")
        .fetchAsJsonMap(result -> {
            if (result.getResponseCode() == 200) {
                // the session the server issued lives in the response body
                storeSession(result.getResponseData());
                response.succeeded();
            } else {
                response.failed(null);
            }
        }));
```

A few things belong on the server side of that boundary rather than in the app:

- Rate limit by number and by device. An unthrottled send endpoint is a way to bill you for somebody else's messages.
- Expire codes, and cap attempts per code. A six-digit code is a million guesses, which isn't many.
- Never return the code to the client, in any field, for any reason.
- Treat the number as unverified until your own check passes. The client says what the user typed, and a client can be modified.

97.8. Trying it without a device

In the simulator and on the desktop ports the hint changes nothing — no message is arriving, so nothing is offered and the code is typed. Everything else works there: the stages, the countdown, the errors, and the field itself.

`Samples/samples/PhoneVerificationSample` runs the whole flow against a fake server that accepts any number and one code, so the screen can be driven without a backend. On a device it's also how to exercise the platform's offer: send yourself a message with a code in it while the second stage is showing.

97.9. Styling

UIID	Applies to
`OtpField`	The code field as a whole.
`OtpDigit`	One box of the code.
`PhoneNumberField`, `PhoneNumberCountry`, `PhoneNumberText`	The number entry, its country selector and its number field.
`PhoneVerification`, `PhoneVerificationText`, `PhoneVerificationError`	The flow, its explanatory line and its error line.
`PhoneVerificationButton`, `PhoneVerificationLink`	The send and verify buttons, and the resend and change-number buttons.

The shipped native themes style these. A theme of your own that doesn't define `OtpDigit` gets the theme's default component style for the boxes, which is seldom what you want — derive it from `TextField`.

Monetization and analytics

Chapter 98. Commerce

Commerce is an optional service that validates in-app purchases and subscriptions server-side and gives your app a single, store-agnostic question to ask: *does this user have this entitlement right now?* It answers that question for a customer on every platform at once, so a subscription bought on an iPhone unlocks the same account on Android, on the desktop and on the web. On top of entitlements it adds offerings you configure remotely, paywalls and a customer center you design in the console, targeting and experiments, lifecycle webhooks, integrations and revenue reports.

Commerce wraps the `Purchase` API (see the monetization chapter) and doesn't replace it. Purchases still go through the platform store, and code that talks to `Purchase` directly keeps working unchanged. When the service can't answer — commerce is switched off in the build, the device is offline, or the account is over its plan — the app falls back to the store's own receipts, so a paying user keeps access.

Codename One doesn't process payments and never touches your money. The stores, or your own Stripe or Paddle account for web purchases, do. Commerce is infrastructure that sits beside the money flow.

98.1. Quick start

Every cloud build is ready to use the service: there is nothing to add to the build. Three steps take you from nothing to a working paywall.

1. In the console, open **Commerce**. On the **Products** page, create an entitlement such as `pro` and attach your store products to it. Then, on the **Offerings** page, create an offering with a package for each product you want to sell.
2. Install a receipt store in your `init` method, as the next section shows.
3. Check the entitlement, and show the paywall when the customer doesn't have it:

```
CommerceManager cm = CommerceManager.getInstance();
if (cm.isEntitled("pro")) {
    // unlock the paid features here
} else {
    // getOfferings() blocks on the network, so it runs on a thread of
    // its own and the paywall is shown back on the EDT.
    new Thread(() -> {
        Offering current = cm.getOfferings().getCurrent();
        if (current != null) {
            CN.callSerially(() -> Paywall.show(current, null));
        }
    }).start();
}
```

The paywall sells the packages of the offering and the service validates the purchase. From then on `isEntitled("pro")` returns `true`, on this device and on every other one the customer signs in to. Pass a `PaywallListener` instead of `null` to react the moment the purchase is confirmed, as the paywall

section shows.

98.2. Entitlements and products

The core idea is the **entitlement**: an abstract access right such as `pro` or `remove_ads`. Your code checks the entitlement and never a store product:

```
if (CommerceManager.getInstance().isEntitled("pro")) {
    // unlock pro features
}
```

98.2.1. Mapping products to entitlements

The **Products** page of the console holds the mapping. Each row names a store, a product id in that store and the entitlement the product grants. One entitlement usually has several products: a monthly and an annual subscription in each store, and perhaps a lifetime purchase. Changing the entitlement of a product moves the product's existing grants with it, so customers who already bought it follow the new mapping.

An entitlement is active when **any** of its granting products is active. A promotional grant and a paid subscription, or a sandbox and a production purchase, can both map to `pro` without one hiding the other. Access is decided by a single rule — the latest expiry over the active grants, evaluated against the service's clock — so a device clock set back can't extend it. Everything else (will-renew, billing stage, period type, family sharing) is advisory and never removes access by itself.

98.2.2. Setting up the client

Installing a receipt store is part of the setup. `Purchase` submits pending purchases and reloads its receipt list only when one is installed, so without it the service is never handed a receipt from this device. On iOS `isSubscriptionSupported()` returns false until one is installed, so subscriptions don't start at all. The monetization chapter builds a store you can use here.

```
CommerceManager cm = CommerceManager.getInstance();
cm.setAppUserId(myAccountId);   // optional; a stable id for the signed-in user

// A receipt store is a prerequisite rather than an extra. Purchase only
// submits pending purchases and reloads its receipt list when one is
// installed, so without it refresh() finds nothing and no entitlement is
// ever granted. On iOS isSubscriptionSupported() is false outright,
// because it is defined as "a receipt store is installed". The
// Monetization chapter builds one.
Purchase.getInAppPurchase().setReceiptStore(myReceiptStore);
```

You can still drive purchases by product id through the manager. These calls delegate to the `Purchase` API:

```
cm.subscribe("pro_monthly");
// or cm.purchase("remove_ads");
```

98.2.3. Refreshing

`refresh()` validates the device's receipts with the service and then asks the service what the customer is entitled to. The customer is asked even when the device holds no receipt at all, which is what unlocks a purchase made on another platform or an entitlement granted from the console. It's a blocking network call, so keep it off the EDT. Call it when the app starts and when it returns to the foreground:

```
CommerceManager cm = CommerceManager.getInstance();
// refresh() blocks on the network, so it runs off the EDT.
new Thread(() -> {
    cm.refresh();
    CN.callSerially(() -> {
        if (cm.isDegraded()) {
            // The service gave no answer. isEntitled() is answering
            // from the stored answer and the store's own receipts.
        }
        boolean pro = cm.isEntitled("pro");
    });
}).start();
```

You don't need to call `refresh()` after a purchase. When `Purchase` finishes synchronizing receipts, the manager refreshes by itself in the background and the customer-info listeners hear the result. If you synchronize receipts yourself and want to act as soon as the answer is in, chain the refresh off the synchronization:

```
// Purchase submits a new receipt to the receipt store asynchronously,
// and refresh() only validates the receipts already stored. Called
// straight after a purchase it would not see the new one, and nothing
// retries it later, so chain it off the synchronization instead.
Purchase.getInAppPurchase().synchronizeReceipts(0, synced -> {
    if (!Boolean.TRUE.equals(synced)) {
        // The receipt was not submitted or fetched, so it is still
        // pending and the stored list is the old one. Refreshing from
        // it would read a stale entitlement and leave a paying user
        // locked out with no sign anything went wrong.
        showPurchasePendingRetry();
        return;
    }
    // This callback arrives on the EDT and refresh() blocks on the
    // network, so it needs a thread of its own.
    new Thread(() -> {
        cm.refresh();
        // Back to the EDT to read the entitlement and touch the UI:
```

```
        // Codename One UI calls are only legal there.
        CN.callSerially(() -> {
            // Same rule as the entitlement sample earlier in the chapter:
            // the store-direct check is for when the cloud had no answer,
            // not an override of one it gave.
            boolean pro = cm.isEntitled("pro");
            if (!pro && (!cm.isCloudEnabled() || cm.isDegraded())) {
                pro = Purchase.getInAppPurchase().isSubscribed("pro_monthly");
            }
            if (pro) {
                // unlock the paid features here
            }
        });
    }).start();
});
```

98.2.4. Customer information

`getCustomerInfo()` returns everything the service last said about the customer. It never returns null and never touches the network:

```
CustomerInfo info = CommerceManager.getInstance().getCustomerInfo();
EntitlementInfo pro = info.getEntitlement("pro");
if (pro != null && pro.isActive()) {
    String product = pro.getProductId();    // the product that granted it
    String store = pro.getStore();          // where it was bought
    long expires = pro.getExpiresDate();    // 0 for a lifetime purchase
    boolean renews = pro.isWillRenew();
    String period = pro.getPeriodType();    // trial, introductory or normal
}
for (String sku : info.getActiveSubscriptions()) {
    // one line per subscription on an account screen
}
```

Each `EntitlementInfo` carries these fields:

Method	What it tells you
`getId()`	The entitlement id, the name your code checks.
`isActive()`	Whether the service considers the entitlement held. This is the service's decision, made with its own clock.
`getExpiresDate()`	When the entitlement ends, in milliseconds since the epoch. `0` for a lifetime purchase.
`getProductId()`	The store product that granted it.
`getStore()`	The store the grant came from.

Method	What it tells you
`getPeriodType()`	Whether the customer is in a trial, an introductory period or the normal one.
`getOwnershipType()`	Whether the customer bought the product or received it through family sharing.
`getBillingStage()`	Where the subscription is in its billing life, such as a grace period or billing retry.
`isWillRenew()`	Whether the subscription is set to renew.
`getProvenance()`	How the grant came to be: a purchase, a promotional grant or a transfer.

`CustomerInfo` also lists the active subscriptions by product id, the customer's attributes, the virtual currency balances and a management address for the subscription.

To follow changes, add a listener. It's called on the EDT whenever the customer information changes: after a refresh, a purchase, a restore, a sign-in or a sign-out.

```
CommerceManager.getInstance().addCustomerInfoListener(evt -> {
    // Called on the EDT. The source is the new customer information.
    CustomerInfo info = (CustomerInfo) evt.getSource();
    boolean pro = info.isEntitled("pro");
    // show or hide the paid features to match
});
```

98.2.5. The stored answer and degraded mode

The last answer the service gave is stored on the device, per customer. After a cold start `isEntitled` and `getCustomerInfo` answer from it at once, before any network call and with no network at all. A stored entitlement is reported exactly as it was stored, even when its expiry date has passed by the device's clock. The device clock is the user's to set, so only the service decides when an entitlement ends, and it does so on the next `refresh()`.

`isDegraded()` is true after a call that couldn't get an answer the app can trust: the service was unreachable, the response failed its signature check, or the account is over the validated volume of its plan. While it's true, the stored answer stays in place, and `isEntitled` also accepts the store's own receipt, treating the entitlement id as a subscription product id. A paying user is therefore not locked out while the network is down.

When commerce isn't enabled in the build, or the manager is degraded, you can check the granting product yourself, as the receipt synchronization example does. Don't do it when the service answered no: a refunded or revoked receipt still looks active on the device, and treating that as a grant unlocks the app after the service denied it.

98.3. Identity

The service keys everything on an *app user id*. Until you set one, the manager generates an anonymous id and persists it, so entitlements survive restarts on the device.

When the user signs in to your own account system, call `logIn` with your stable id for that user:

```
CommerceManager cm = CommerceManager.getInstance();
String accountId = "account-1234";   // your own id for the signed-in user
// logIn() blocks on the network, so it runs off the EDT.
new Thread(() -> {
    if (cm.logIn(accountId)) {
        // Purchases made before signing in now belong to the account,
        // and the account's purchases from other platforms unlock here.
        cm.refresh();
    } else {
        // The service did not accept the change. The previous id is
        // still current and the call can be repeated.
    }
}).start();
```

Signing in moves purchases from the device's own anonymous id to the signed-in id, and only from there. It never moves purchases from one signed-in account to another, so logging in with someone else's id doesn't take their purchases. Pick app user ids that can't be guessed, such as a random identifier your account system issues, rather than an email address or a counter. The original anonymous id stays available through `CustomerInfo.getOriginalAppUserId()`. `logIn` returns `false` and leaves the previous id in place when the service didn't accept the change, and you can call it again.

`setAppUserId` sets the id without telling the service anything. Use it when the id is known before the first purchase, for example when your app requires an account before it shows anything. Use `logIn` whenever an anonymous customer might already own something.

98.3.1. Transfer policies

A store purchase is tied to the store account on the device, not to your app user id. When a purchase is restored or validated under a different id than the one that owns it, for example after another user signs in on the same device and restores, the transfer policy of the app decides who keeps it. Set it on the **App settings** page of the console:

Policy	Behavior
`TRANSFER`	The purchase moves to the id that restored or validated it. This is the default, and it matches what the stores do when a device changes hands.
`KEEP_WITH_ORIGINAL`	The purchase stays with the id that owns it. The other id gets nothing from it.

Policy	Behavior
`TRANSFER_IF_NO_ACTIVE`	The purchase moves only when the id that owns it has no active entitlement from it.

Every move is reported to your backend as a `TRANSFER` webhook event.

98.3.2. Signing out and restoring

`logOut()` forgets the current customer. A new anonymous id is generated and the customer information becomes empty, so the next user of the device doesn't inherit the previous user's entitlements. Nothing is sent to the service. Refresh afterward to pick up what the store account on the device still owns:

```
CommerceManager cm = CommerceManager.getInstance();
cm.logOut();
// The device may still hold purchases of its store account. Refreshing
// attaches them to the new anonymous customer.
new Thread(() -> cm.refresh()).start();
```

`restore()` asks the store to restore the purchases of the store account on the device, on platforms that support it. The restored receipts reach the service through the receipt synchronization that follows, and the manager refreshes by itself. The customer-info listeners hear the result. The built-in paywall and the customer center both have a restore button that calls it.

98.4. Offerings and packages

An **offering** is the set of things you're selling at one moment: "the standard plans," "the holiday sale." A **package** is one entry of an offering — a store product together with the role it plays, such as the monthly plan. Because offerings live in the console, you change what the app sells, and at what price points, without shipping an update.

98.4.1. Console setup

On the **Offerings** page, create an offering and add packages to it. Each package has:

- An id that's unique inside the offering.
- A type: `LIFETIME`, `ANNUAL`, `SIX_MONTH`, `THREE_MONTH`, `TWO_MONTH`, `MONTHLY`, `WEEKLY` or `CUSTOM`.
- A product id for each store the app ships to. The service hands each device the product of its own store.
- The billing period, and the free trial and introductory price if the product has them. Enter these as you configured them in the store. Periods are ISO-8601 durations such as `P1M` or `P7D`.

Mark one offering as the current one. That's the offering `getCurrent()` returns unless a targeting rule or an experiment selects another.

98.4.2. Reading offerings

```
CommerceManager cm = CommerceManager.getInstance();
new Thread(() -> {
    // Pass null, or call getOfferings(), for the default offerings.
    Offerings offerings = cm.getOfferings("onboarding");
    Offering current = offerings.getCurrent();
    if (current == null) {
        return;
    }
    CommercePackage monthly = current.getMonthly();
    CommercePackage annual = current.getAnnual();
    for (CommercePackage pkg : current.getPackages()) {
        String period = pkg.getPeriod();            // "P1M", "P1Y"
        if (pkg.isEligibleForIntro() && pkg.getTrialPeriod() != null) {
            // this customer can still take the free trial
        }
        if (pkg.getProduct() != null) {
            // the store's localized price
            String price = pkg.getProduct().getLocalizedPrice();
        }
    }
}).start();
```

`getOfferings` is a blocking network call. The last answer is stored on the device and is what the call returns when the service can't be reached, so a paywall still opens offline. It never returns null. The result is empty, and `getCurrent()` is null, when commerce isn't enabled in the build or there has never been an answer.

After a fresh answer the manager asks the store for the products of the packages, where the platform lists products, and attaches each to its package. `getProduct()` then carries the store's localized price and name. On a platform whose store doesn't list products it stays null.

`Offering` has shortcuts for the standard types — `getMonthly()`, `getAnnual()`, `getWeekly()` and `getLifetime()` — and `getPackage(id)` for any other. `getMetadata()` returns the free-form values you attached to the offering in the console, which is a convenient place for a headline or a feature flag that should change with the offering.

98.4.3. Placements

A *placement* is a named place in your app that sells something: `"onboarding"`, `"settings"`, `"export_limit"`. Pass it to `getOfferings(String)`. A targeting rule in the console can give a placement an offering of its own, so the upsell after onboarding and the one behind a locked feature can differ without a code change. A placement with no rule gets the current offering.

98.4.4. Trial and introductory eligibility

`isEligibleForIntro()` tells you whether this customer may still take the free trial or introductory price of a package. The service computes it from the customer's purchase history across platforms,

so a customer who used a trial on one device isn't promised another one elsewhere. Use it to decide whether a paywall says "Start your free week" or "Subscribe." The built-in paywall variables described below follow the same rule.

98.4.5. Buying a package

`purchase(CommercePackage)` starts a subscription for every package that's one and a one-time purchase otherwise. The outcome arrives through the customer-info listeners once the service has validated the purchase:

```
CommerceManager cm = CommerceManager.getInstance();
cm.addCustomerInfoListener(evt -> {
    if (((CustomerInfo) evt.getSource()).isEntitled("pro")) {
        // the purchase was validated: unlock the paid features
    }
});
new Thread(() -> {
    Offering current = cm.getOfferings().getCurrent();
    if (current != null && current.getAnnual() != null) {
        CN.callSerially(() -> cm.purchase(current.getAnnual()));
    }
}).start();
```

98.5. Targeting and experiments

Targeting and experiments decide which offering `getCurrent()` returns for a given customer. Both are evaluated by the service on every `getOfferings` call, so they take effect without an app update.

98.5.1. Targeting rules

A targeting rule on the **Targeting** page names an offering and the conditions under which a customer gets it. A rule can match on:

- **Country** — one or more store countries.
- **Platform** — the platform the app is running on.
- **App version** — a minimum version, a maximum version, or both.
- **Attribute** — a subscriber attribute with a given value.
- **Placement** — the placement the app asked for.

A condition you leave empty matches everyone. Rules are tried in priority order, lowest number first, and the first rule whose conditions all match wins. When no rule matches, the customer gets the current offering.

98.5.2. Experiments

An experiment splits customers between two or more offerings so that you can compare them. On

the **Experiments** page, give the experiment an id, optionally limit it to a placement, and add variants. Each variant names an offering and a weight. Start the experiment when it's ready and stop it when you have an answer.

Assignment is deterministic. The service hashes the experiment id together with the app user id and maps the result onto the variant weights, so a customer always sees the same variant, on every device and after every restart, and nothing about the assignment needs to be stored. A customer who logs in moves from the anonymous id to the account id and is assigned by the account id from then on.

The app can read which variant it was given, for example to tag its own analytics:

```
new Thread(() -> {
    Offerings offerings = CommerceManager.getInstance().getOfferings();
    String experiment = offerings.getExperimentId();    // null when not in one
    String variant = offerings.getExperimentVariant();
}).start();
```

The **Experiments** page reports, for each variant, the number of customers who saw a paywall of its offering, the number who went on to buy, and the conversion rate between the two. The counts come from the paywall events described in the next section, so an experiment needs the built-in paywall or your own `logEvent` calls to produce results.

98.6. Paywalls

A paywall is the screen that sells an offering. You design it in the console as a document attached to the offering, and the app draws it with native components. Changing the paywall doesn't require an app update.

98.6.1. Showing a paywall

`Paywall.show` opens the paywall of an offering in a form of its own, over the current form. Closing the paywall or going back returns to the form that was showing. When a purchase or a restore completes, the paywall also returns to that form by itself and then tells the listener, so `purchaseCompleted` is the place to unlock the feature or show a form of your own. Call `Paywall.show` on the EDT:

```
new Thread(() -> {
    Offering offering = CommerceManager.getInstance().getOfferings().getCurrent();
    if (offering == null) {
        return;
    }
    CN.callSerially(() -> Paywall.show(offering, new PaywallListener() {
        @Override
        public void purchaseStarted(CommercePackage pkg) {
            // the store's purchase sheet is up
        }
```

```
        @Override
        public void purchaseCompleted(CustomerInfo info) {
            // the service confirmed the purchase: unlock the features
        }

        @Override
        public void purchaseCancelled() {
            // closed before the purchase was confirmed
        }

        @Override
        public void restoreCompleted(CustomerInfo info) {
            // check info.isEntitled("pro") after a restore
        }

        @Override
        public void closed() {
            // the previous form is showing again
        }
    }));
}).start();
```

Every listener method is called on the EDT:

Method	When it's called
`purchaseStarted(CommercePackage)`	The customer pressed the purchase button and the store was asked to sell the package.
`purchaseCompleted(CustomerInfo)`	The service confirmed the purchase. The customer now owns the product of the package. A paywall opened with `Paywall.show` has already returned to the previous form.
`purchaseCancelled()`	The paywall was closed after a purchase was started and before the service confirmed it.
`restoreCompleted(CustomerInfo)`	The customer information changed after the customer asked to restore purchases. A paywall opened with `Paywall.show` has already returned to the previous form.
`closed()`	The paywall was closed: by the customer, or by itself after a completed purchase or restore.

98.6.2. The built-in paywall

An offering with no paywall document is shown with the built-in one: a close button, a title, the packages of the offering as a list, a purchase button, a restore button and a footer. It names no colors, so your theme decides them all. `Paywall.createDefault(offering)` returns that document as a map you can change before you hand it to a `PaywallView`.

`PaywallView` is the component behind `Paywall.show`. Use it directly to embed a paywall in a form of your own, and tell it what closing means there. An embedded view never navigates by itself: after a

completed purchase or restore it stays where it's and the listener decides what your form shows next.

```
new Thread(() -> {
    Offering offering = CommerceManager.getInstance().getOfferings().getCurrent();
    CN.callSerially(() -> {
        Form previous = Display.getInstance().getCurrent();
        // Start from the built-in document and change it, or pass a
        // document of your own as a parsed JSON map.
        Map<String, Object> document = Paywall.createDefault(offering);
        PaywallView view = new PaywallView(offering, document);
        Form upgrade = new Form("Upgrade", new BorderLayout());
        upgrade.add(BorderLayout.CENTER, view);
        view.setCloseHandler(() -> previous.showBack());
        upgrade.show();
    });
}).start();
```

The view reports `IMPRESSION` when it's first shown, then `PURCHASE_START`, `PURCHASE` and `CLOSE`, through `CommerceManager.logEvent`. The console charts these as a funnel for each offering and paywall, and experiments count them. If you build a purchase screen of your own instead, call `logEvent` with the same event names to get the same reports. Events are queued and sent from a background thread, and reporting never delays or fails a purchase.

98.6.3. Theming

Every element of a paywall has a UIID, so your theme can restyle it. The colors a document names are applied on top of the theme.

UIID	Element
`PaywallForm`	The form `Paywall.show` creates.
`Paywall`	The view itself.
`PaywallStack`	A `stack` node.
`PaywallTitle`, `PaywallHeadline`, `PaywallBody`, `PaywallCaption`	The text of a `text` node, by its style.
`PaywallImage`, `PaywallIcon`	An `image` node and an `icon` node.
`PaywallFeatures`, `PaywallFeature`, `PaywallFeatureIcon`, `PaywallFeatureText`	A `features` node, one of its rows, and the two parts of a row.
`PaywallPackages`	A `packages` node.
`PaywallPackage`, `PaywallPackageTitle`, `PaywallPackagePrice`	A package and its two lines.
`PaywallPackageSelected`, `PaywallPackageTitleSelected`, `PaywallPackagePriceSelected`	The same three for the selected package.

UIID	Element
`PaywallPurchaseButton`, `PaywallRestoreButton`, `PaywallCloseButton`	The three buttons.
`PaywallCloseBar`	The row that holds the close button.
`PaywallCarousel`	A `carousel` node.
`PaywallFooter`, `PaywallFooterLink`	A `footer` node and its links.
`PaywallSpacer`	A `spacer` node, and the gap between the children of a stack.

98.6.4. The paywall document

A paywall document is a JSON object. The **Paywalls** page of the console edits it with a live preview that uses the same `PaywallView` class the device does.

Field	Meaning
`version`	The format version, `1`.
`id`	The id of the paywall, reported with every paywall event.
`defaultLocale`	The locale of `strings` to use when the device's locale has no entry.
`strings`	Translations: an object per locale, each mapping a key to its text.
`colors`	A `light` and a `dark` set, each with `background`, `text`, `muted`, `accent` and `accentText` as `#rrggbb`. The `dark` set is used when the device is in dark mode.
`root`	The node the paywall starts from, normally a `stack`.

A node is an object with a `type`. A node of a type the app doesn't know is skipped, so a document that uses a newer node type still shows on an older build. Sizes are millimeters.

Node type	Fields	What it draws
`stack`	`axis` (`y` or `x`), `gap`, `padding`, `align`, `children`	Its children, one after another along the axis.
`text`	`text`, `style` (`title`, `headline`, `body` or `caption`), `align`	A block of text.
`image`	`url`, `height`	An image loaded from an address.
`icon`	`name`	A material icon, by name.
`features`	`items`, each with `icon` and `text`	A list of selling points.
`packages`	`style` (`list` or `tiles`), `selected`	The packages of the offering. `selected` is the id of the package that starts selected.
`purchaseButton`	`text`	The button that buys the selected package.
`restoreButton`	`text`	The button that restores purchases.
`closeButton`		The button that closes the paywall.

Node type	Fields	What it draws
`carousel`	`children`	Its children as swipeable pages.
`footer`	`termsUrl`, `privacyUrl`	Links to your terms and privacy policy.
`spacer`	`size`	Empty space.

A text is first looked up in `strings`, by the device's locale and then by the default locale. When it isn't a key there, it's used as written. Then the variables in it are replaced from the selected package, and replaced again whenever the customer selects another one:

Variable	Replaced with
`{{price}}`	The price. This is the store's localized price when the store listed the product.
`{{period}}`	The billing period, in words.
`{{trialPeriod}}`	The length of the free trial.
`{{introPrice}}`	The introductory price.
`{{productName}}`	The store's name for the product.
`{{packageId}}`	The id of the package.

A variable with no value becomes empty. A complete document:

```
{
  "version": 1,
  "id": "spring_sale",
  "defaultLocale": "en",
  "strings": {
    "en": {
      "title": "Go Pro",
      "cta": "Continue for {{price}} per {{period}}"
    },
    "de": {
      "title": "Pro freischalten",
      "cta": "Weiter mit {{price}} pro {{period}}"
    }
  },
  "colors": {
    "light": {
      "background": "#ffffff",
      "text": "#111111",
      "muted": "#666666",
      "accent": "#0a84ff",
      "accentText": "#ffffff"
    },
    "dark": {
      "background": "#101014",
      "text": "#f5f5f7",
```

```
      "muted": "#9a9aa0",
      "accent": "#0a84ff",
      "accentText": "#ffffff"
    }
  },
  "root": {
    "type": "stack",
    "axis": "y",
    "gap": 3,
    "padding": 4,
    "children": [
      { "type": "closeButton" },
      { "type": "image", "url": "https://example.com/hero.png", "height": 40 },
      { "type": "text", "text": "title", "style": "title", "align": "center" },
      {
        "type": "features",
        "items": [
          { "icon": "cloud_sync", "text": "Sync across all your devices" },
          { "icon": "block", "text": "No ads" }
        ]
      },
      { "type": "packages", "style": "list", "selected": "annual" },
      { "type": "purchaseButton", "text": "cta" },
      { "type": "restoreButton", "text": "Restore purchases" },
      {
        "type": "footer",
        "termsUrl": "https://example.com/terms",
        "privacyUrl": "https://example.com/privacy"
      }
    ]
  }
}
```

98.7. Customer center

The customer center is a ready-made form where a customer sees their active subscriptions and acts on them. One call shows it:

```
// Safe on any thread: the configuration is fetched in the background
// and the form is shown on the EDT.
CustomerCenter.show();
```

The **Customer center** page of the console decides which paths the form offers and in what order:

Path	What it does
MANAGE	Opens the store's own subscription management. On a platform with none, it opens the customer's management page, which is the billing portal for a subscription bought on the web.
RESTORE	Restores the purchases of the store account.
REFUND	Asks the store for a refund. There is one row for each subscription the store can refund.
CANCEL	Asks the customer why, reports the answer, shows the retention offer for that reason if there is one, and otherwise continues to the store's subscription management. Offered while a subscription is active.
SUPPORT	Opens your support page, or an email to your support address. Offered when one of the two is configured.

When the configuration can't be fetched, the form offers MANAGE and RESTORE. The form's texts can be translated per locale in the console. Its UIIDs are CustomerCenterForm, CustomerCenterHeader, CustomerCenterSubscription, CustomerCenterEmpty, CustomerCenterRow and CustomerCenterReason.

98.7.1. Cancel reasons and retention offers

For the CANCEL path you define a list of reasons, such as "Too expensive" or "Not using it enough." The reason a customer picks is reported to the service, and the console charts the answers.

Each reason can carry a retention offer: a product, a line of text, and optionally the id of a promotional offer. A customer who picks that reason is shown the text and can accept or decline. Accepting buys the product, under the promotional offer when one is named and the store supports it. Declining continues to the store's subscription management, where the customer cancels.

98.7.2. Promotional offers

A promotional offer is an App Store discount for existing or lapsed subscribers that the store sells only when it comes with a signature made by the developer's key. The service makes that signature for you. purchaseWithPromotionalOffer asks for it and then asks the store to sell the product under the offer:

```
CommerceManager cm = CommerceManager.getInstance();
// The ids are the ones App Store Connect shows for the offer.
if (!cm.purchaseWithPromotionalOffer("pro_monthly", "winback_50")) {
    // No signature was available, so nothing was bought. Sell the
    // product at its regular price instead.
    cm.subscribe("pro_monthly");
}
```

It may be called on the EDT. It returns false, and buys nothing, when no signature is available: the platform's store has no promotional offers, commerce isn't enabled in the build, or the service couldn't sign. Signing needs the commerce.apple.keyId and commerce.apple.privateKey secrets described under store credentials, and the key must be one App Store Connect accepts for

subscription offers. Promotional offers are an App Store feature, on iOS and on the Mac. A retention offer on any other store sells its product at the regular price.

98.8. Analytics and invites

Commerce reports what happens around a purchase to the analytics providers the app registered (see the analytics chapter), and it joins a customer to the invite that brought them in (see Invite a friend). Neither needs code. An app with no provider sends nothing, and nothing is sent for a user whose consent doesn't cover analytics.

98.8.1. Events

Every event is in the category `commerce`. The built-in paywall and the customer center send theirs as the customer uses them:

Event	Sent when	Parameters
`paywall_view`	A paywall appears	`offering`
`paywall_package_selected`	The customer picks a package	`offering`, `package`, `product`
`paywall_restore`	The customer restores purchases from a paywall	`offering`, and `package` and `product` of the selected package
`paywall_close`	The paywall goes away	`offering`
`purchase_initiated`	The store, or a web checkout, is asked to sell	`sku`, `offering`, `package`, `product`, and `store` with the value `web` for a web checkout
`purchase`	The store reports the purchase	`sku`, `offering`, `package`, `product`
`customer_center_view`	The customer center opens	None
`customer_center_action`	The customer picks a row of the customer center	`action`, which is `MANAGE`, `RESTORE`, `REFUND`, `CANCEL` or `SUPPORT`, and `product`
`subscription_cancel_reason`	The customer picks a cancel reason	`reason`, the id of the reason, and `product`
`experiment_exposure`	The app is first given a variant of an experiment	`experiment`, `variant`

An event about an offering also carries `placement` when the offering was read for a placement, and `experiment` and `variant` when an experiment chose it. A parameter with no value is left out.

`purchase_initiated` and `purchase` are the events `Purchase` has always sent, each still sent once. They gain the offering, package and experiment when the purchase was started with `purchase(CommercePackage)`, which is what the built-in paywall does. A purchase started with a bare SKU carries the `sku` alone.

A paywall you draw yourself can send the same events, so that it shows up in the same reports:

```
CommerceManager cm = CommerceManager.getInstance();
new Thread(() -> {
    Offering offering = cm.getOfferings("onboarding").getCurrent();
    if (offering == null || offering.getAnnual() == null) {
        return;
    }
    CommercePackage annual = offering.getAnnual();
    CN.callSerially(() -> {
        // The names the built-in paywall uses, so the reports read the same.
        cm.analyticsEvent("paywall_view", offering.getId(), null, null, null, null);
        cm.analyticsEvent("paywall_package_selected", offering.getId(),
                annual.getId(), annual.getProductId(), null, null);
        // purchase(CommercePackage) labels the purchase events by itself.
        cm.purchase(annual);
    });
}).start();
```

98.8.2. Segmenting by experiment

Because the paywall and purchase events carry `experiment` and `variant`, any analytics report can be split by variant: how many customers of each variant opened the paywall, picked the annual package, or bought. `experiment_exposure` is sent once for each experiment and variant an installation is given, which gives every variant its denominator even for a customer who never opens a paywall.

98.8.3. Purchases by invited users

The service knows which install belongs to which customer, so a purchase by a customer who arrived through an invitation is attributed to the inviter. The revenue it reports for that invite is verified: it's the amount of the purchase the service validated with the store, and not a value the app claimed. You don't call `Invites.conversion` for a purchase. Keep it for the conversions the service can't see, such as finishing a tutorial.

When the user logs in with `logIn`, the attribution follows the customer to the account. The app user id of commerce and the user id of analytics stay separate, and logging in here doesn't change the one you set with `Analytics.setUserId`.

98.8.4. Referral rewards

A referral reward gives something to the inviter, the invited user, or both. Configure it on the **Referral rewards** page of the console. Each of the two rewards grants either an entitlement for a number of days or an amount of a virtual currency. Entitlement days stack: a second reward extends the first rather than replacing it.

The trigger decides when the rewards are granted:

Trigger	Behavior
First purchase	The default. The rewards are granted when the invited user makes a first purchase.
Claim	The rewards are granted when the invitation is matched to the installation. This trigger requires a cap on the number of rewards per inviter, and it skips invited people who were already users of the app.

Each reward is granted once. The inviter's reward reaches the inviter's device once that device has used analytics, which ties it to the inviter's install. A refund of the invited user's purchase doesn't take a reward back.

The service grants the reward, so there's nothing to deliver from the app. An entitlement reward answers `isEntitled` like a purchased one, and a currency reward is part of the balance. When an invitation is matched to the installation, commerce asks the service for the customer again in the background, and the customer information listener hears about the reward. `getReferralRewards()` lists what was granted and why, for example to thank the user:

```
CustomerInfo info = CommerceManager.getInstance().getCustomerInfo();
for (ReferralReward reward : info.getReferralRewards()) {
    String earned = reward.isCurrency()
            ? reward.getAmount() + " " + reward.getCurrencyCode()
            : reward.getEntitlementId();
    Dialog.show("Thank you", "Your invite earned you " + earned, "OK", null);
}
// The reward itself is already in effect: an entitlement answers
// isEntitled(), and a currency is part of the balance.
boolean pro = info.isEntitled("pro");
long coins = info.getCurrencyBalance("coins");
```

A reward has an entitlement id or a currency code, an amount for a currency, an expiry date of 0 when it doesn't expire, and the reason the service recorded. The list is empty for a customer with no rewards.

98.9. Subscriber attributes and virtual currency

98.9.1. Attributes

Attributes are name and value pairs you attach to a customer. Targeting rules read them, the console shows them on the **Customers** page, and integrations use some of them to identify the customer in another system.

```
CommerceManager cm = CommerceManager.getInstance();
Map<String, Object> attributes = new HashMap<String, Object>();
attributes.put("plan_interest", "annual");
attributes.put("$email", "user@example.com");
attributes.put("campaign", null);   // a null value deletes the attribute
```

```
// setAttributes() blocks on the network, so it runs off the EDT.
new Thread(() -> cm.setAttributes(attributes)).start();
```

`setAttributes` is a blocking network call that returns `true` when the service accepted the attributes. A null value deletes an attribute, and any other value is stored as its string form. The attributes come back with the customer information, in `CustomerInfo.getAttributes()`. Names that start with `$` are reserved for the uses this chapter lists, such as `$appsflyerId`.

98.9.2. Virtual currency

A virtual currency is a balance the service keeps for each customer: gems, credits, tokens. Define a currency on the **Currencies** page with a code and a name, and list the products that grant it with the amount each grants. When the service validates a purchase of such a product, it adds the amount to the customer's balance. A consumable product that should be bought again and again is the usual choice.

The app reads balances from the customer information:

```
CustomerInfo info = CommerceManager.getInstance().getCustomerInfo();
long gems = info.getCurrencyBalance("GEMS");   // 0 when the customer holds none
Map<String, Long> all = info.getCurrencies();
```

Spending is a server-side operation, so that a modified app can't grant itself currency. Your backend adjusts a balance through the REST API described below, and the app sees the new balance after its next `refresh()`.

98.10. Stores

98.10.1. Apple App Store, on iOS and on the Mac

iOS purchases work with no setup beyond the receipt store. A native Mac build sells through the Mac App Store with the same code, and the service validates its receipts with the same Apple credentials. If the Mac app's bundle id differs from the package name of the project, enter it as the Mac bundle id on the **App settings** page of the console so that its receipts are accepted.

Point App Store Server Notifications V2 at `https://cloud.codenameone.com/api/v2/commerce/notifications/apple` in App Store Connect, so that renewals, cancellations, refunds and billing problems reach the service when they happen.

98.10.2. Google Play

Android builds sell through Google Play by default. In the Play Console, set up Real-time developer notifications and route the Pub/Sub topic to `https://cloud.codenameone.com/api/v2/commerce/notifications/google`. Google purchases are validated with Google's own server API, so the service account described under store credentials is required for them. Without it the service accepts the purchase in degraded mode and the app relies on the device's receipt.

98.10.3. Amazon Appstore

An Android app is built for one store. To build for the Amazon Appstore, set the build hint:

```
codename1.arg.android.billing.store=amazon
```

The build then uses the Amazon Appstore SDK instead of the Play Billing Library, declares the receiver Amazon's client answers through, and leaves out the `com.android.vending.BILLING` permission, which the Amazon Appstore doesn't accept. The Google Play settings `android.licenseKey` and `android.billingclient.version` aren't used. Your code doesn't change: `Purchase` and `CommerceManager` behave the same, and receipts carry the store code `Receipt.STORE_CODE_AMAZON`.

For validation, enter your Amazon shared secret (`commerce.amazon.sharedSecret`) on the **Stores** page of the console, and set the Amazon SNS topic ARN in the Amazon store settings there. The same page shows the notification address to register with Amazon. It ends in a token that identifies your app, so copy it as shown.

98.10.4. Web billing with Stripe and Paddle

On platforms with no store — the browser and the desktop — the service sells through a hosted checkout page in your own Stripe or Paddle account. The same package can therefore be bought in the App Store on a phone and with a card on the web, and both grant the same entitlement.

To set it up:

1. Enter the credentials of your account on the **Stores** page of the console: `commerce.stripe.secretKey` and `commerce.stripe.webhookSecret` for Stripe, or `commerce.paddle.apiKey` and `commerce.paddle.notificationSecret` for Paddle.
2. Register the notification address the **Stores** page shows for your app as a webhook in the Stripe or Paddle dashboard. It ends in a token that identifies your app.
3. On each package that should be sold on the web, enter its Stripe price id or its Paddle price id.
4. On the **App settings** page, enter the web URLs of your app that the checkout returns the customer to.

In the app, `purchase(CommercePackage)` does the right thing on every platform. Where the platform has a store it sells the store product. Where it has none, and the package has a web price, it opens the hosted checkout in the browser. `isWebPurchase` tells you which of the two will happen, and `purchaseOnWeb` opens the checkout explicitly:

```
CommerceManager cm = CommerceManager.getInstance();
new Thread(() -> {
    Offering current = cm.getOfferings().getCurrent();
    if (current == null || current.getMonthly() == null) {
        return;
    }
    CommercePackage pkg = current.getMonthly();
```

```
    CN.callSerially(() -> {
        if (cm.isWebPurchase(pkg)) {
            // No store on this platform: purchase(pkg) opens the
            // hosted checkout itself, as purchaseOnWeb(pkg) does.
        }
        cm.purchase(pkg);
    });
}).start();
```

The customer pays outside the app, so nothing reports the outcome to the call. Once the app is back in the foreground, run `refresh()` off the EDT, and the customer-info listeners hear what was bought. The paywall does that by itself.

To send the customer back to pages of your own after the checkout, ask for the address and open it yourself. `getWebPurchaseUrl` is a blocking call that returns null when there is no web price for the package:

```
CommerceManager cm = CommerceManager.getInstance();
new Thread(() -> {
    Offering current = cm.getOfferings().getCurrent();
    if (current == null || current.getAnnual() == null) {
        return;
    }
    // Blocking. Null return addresses use the service's own pages.
    String url = cm.getWebPurchaseUrl(current.getAnnual(),
            "https://example.com/thanks", "https://example.com/pricing");
    if (url != null) {
        CN.callSerially(() -> CN.execute(url));
    }
}).start();
```

Check the terms of each app store before you offer a web checkout inside an app that's distributed through that store.

Hosted purchase links

Every package with a web price also has a purchase link you can put on a website or in an email, with no app involved:

```
https://cloud.codenameone.com/api/v2/commerce/buy/<token>/<offeringId>/<packageId>?user=<appUserId>
```

The console shows the link, including your app's token, next to the package. Opening it redirects to the checkout for the customer named in `user`. Use the same id the app passes to `logIn`, and the purchase unlocks in the app on its next refresh.

The management portal

A customer who subscribed on the web manages the subscription in the billing portal of Stripe or

Paddle. `fetchManagementUrl()` returns the right address for the customer's newest active entitlement: a fresh portal address when it was bought on the web, and the store's subscription page otherwise. A portal address is short-lived, so ask for it when you're about to open it:

```
CommerceManager cm = CommerceManager.getInstance();
// fetchManagementUrl() asks for a billing portal when the subscription
// was bought on the web, so it blocks and runs off the EDT.
new Thread(() -> {
    String url = cm.fetchManagementUrl();
    if (url != null) {
        CN.callSerially(() -> CN.execute(url));
    }
}).start();
```

`getManagementUrl()` is the variant that never touches the network. It returns the portal address `fetchManagementUrl()` last answered with, or the store's page from the last customer information.

98.10.5. Store credentials

By default the service validates the store-signed receipt the device presents. For Apple that's enough to gate features and it works with no setup. For *server-authoritative* validation, where the service calls the stores' own server APIs to confirm the real subscription state, provide your credentials in the console. Apple and Google credentials are entered on the **Setup** page; Amazon, Stripe and Paddle credentials on the **Stores** page:

Store	Secrets	Used for
Apple	`commerce.apple.keyId`, `commerce.apple.issuerId`, `commerce.apple.privateKey` (the contents of the `.p8` file)	Confirming subscription status for iOS and Mac purchases, recording renewals at their real amount, and signing promotional offers.
Google	`commerce.google.serviceAccountJson` (the full JSON key of a service account with Android Publisher access)	Validating every Google Play purchase.
Amazon	`commerce.amazon.sharedSecret`	Validating Amazon Appstore receipts.
Stripe	`commerce.stripe.secretKey`, `commerce.stripe.webhookSecret`	Creating checkouts and portals, and verifying Stripe's notifications.
Paddle	`commerce.paddle.apiKey`, `commerce.paddle.notificationSecret`	Creating checkouts and portals, and verifying Paddle's notifications.

Secrets are stored AES-256-GCM encrypted. They're decrypted only server-side at call time and are never shown in the console again.

Store notifications are idempotent. Each is deduplicated on the id the store gives it, so a redelivery never double-counts, and a store transaction is counted once however many devices present its

receipt.

98.11. Server side

98.11.1. Lifecycle webhooks to your backend

Commerce can forward every normalized state change to your own backend. Configure a URL and a signing secret on the **Webhook** page of the console. Each event is HMAC-SHA256 signed (header `CN1-Commerce-Signature`) and carries:

- A **per-customer monotonic `sequence`**, so your consumer can reject stale events and never has to reorder defensively.
- The grant's **`state_version`**. Reconcile against this.
- An always-present **`effective_expiration_at`**.
- The event `id` for idempotent deduplication.
- The **`event_type`**.

Delivery is at-least-once, in sequence order per customer, with retries that back off exponentially. The **Webhook** page lists recent deliveries and their outcome.

Event type	Sent when
`INITIAL_PURCHASE`	A customer buys a subscription for the first time.
`RENEWAL`	A subscription renews.
`NON_RENEWING_PURCHASE`	A one-time product is bought: a lifetime unlock or a consumable.
`CANCELLATION`	The customer turns renewal off. Access continues until the period ends.
`UNCANCELLATION`	The customer turns renewal back on.
`EXPIRATION`	A subscription ends.
`BILLING_ISSUE`	A renewal payment failed.
`PRODUCT_CHANGE`	The customer moved to another product of the same subscription group.
`SUBSCRIPTION_PAUSED`	The subscription was paused.
`SUBSCRIPTION_EXTENDED`	The store extended the renewal date.
`REFUND`	A purchase was refunded.
`REFUND_REVERSED`	A refund was reversed.
`TRANSFER`	Purchases moved from one app user id to another.
`TEMPORARY_ENTITLEMENT_GRANT`	Access was granted for a short time while a purchase couldn't be validated.
`PROMOTIONAL_GRANT`	An entitlement was granted from the console or the REST API.
`PROMOTIONAL_REVOKE`	Such a grant was revoked.

98.11.2. Integrations

Integrations forward the same lifecycle events to other services, each in the format that service expects. Enable them on the **Integrations** page, where each takes its own credentials and a choice of event types to forward. A test button sends a sample event.

Destination	Settings	Customer identity
Slack	`webhookUrl`	None. A message is posted for each event.
Amplitude	`apiKey`	The app user id.
Mixpanel	`token`	The app user id.
Segment	`writeKey`	The app user id.
Firebase (Google Analytics)	`measurementId`, `apiSecret`	The `$firebaseAppInstanceId` attribute. Required.
AppsFlyer	`appId`, `devKey`	The `$appsflyerId` attribute. Required.
Adjust	`appToken`, and an event token for each kind of event: `purchaseEventToken`, `renewalEventToken`, `trialEventToken`, `cancelEventToken`	The `$adjustId` attribute. Required.
Branch	`branchKey`	The `$branchId` attribute, or the app user id when it isn't set.

The attribution services identify a device by their own id, which only their SDK on the device knows. Read it from the SDK when the app starts and store it with `setAttributes` under the reserved name in the table. An event for a customer who lacks a required attribute isn't sent to that destination. The other destinations still receive it.

98.11.3. The REST API

Your backend can read and change customers through a REST API. Create a secret key on the **API keys** page. A key starts with `sk_`, belongs to one app, and is shown once when you create it, so store it then. Send it as a bearer token to `https://cloud.codenameone.com/api/v2/commerce/v1`:

```
curl -X POST \
  -H "Authorization: Bearer sk_your_secret_key" \
  -H "Content-Type: application/json" \
  -d '{"expiresDate": 1798761600000, "reason": "support ticket 4411"}' \
  https://cloud.codenameone.com/api/v2/commerce/v1/subscribers/account-1234/entitlements/pro/grant
```

Method	Path	What it does
GET	/subscribers/{appUserId}	Returns the customer: serverTime, appUserId, originalAppUserId, managementUrl, activeSubscriptions, entitlements, attributes and currencies.
DELETE	/subscribers/{appUserId}	Deletes the customer with their grants, attributes and currency history.
POST	/subscribers/{appUserId}/attributes	Sets attributes. The body is {"attributes": {"name": "value"}}, and a null value deletes an attribute.
POST	/subscribers/{appUserId}/entitlements/{entitlementId}/grant	Grants an entitlement. The optional body fields are expiresDate, in milliseconds since the epoch, and reason. Without an expiry the grant doesn't end.
POST	/subscribers/{appUserId}/entitlements/{entitlementId}/revoke	Revokes a grant made this way. Purchases aren't affected.
POST	/receipts	Validates a receipt your backend holds. The body names appUserId, store and productId, and carries the receipt as signedTransaction for Apple, purchaseToken for Google, or signedTransaction with amazonUserId for Amazon.
POST	/receipts/import	Imports receipts in bulk from a CSV body.
GET	/offerings	Lists the offerings of the app.
GET	/subscribers/{appUserId}/currency	Returns the customer's virtual currency balances.
POST	/subscribers/{appUserId}/currency	Changes a balance. The body is code, delta, and optionally reason and reference.

A currency change with a negative delta spends. When the balance is too low the call answers 409 with the error insufficient_balance and changes nothing. reference makes the call safe to repeat: a second call with the same reference returns the first result, marked replayed, and doesn't change the balance again. Use your own order id as the reference.

An unknown customer answers 404, and a request the service can't read answers 400.

98.11.4. Granting entitlements from the console

The **Customers** page of the console has the same controls to grant and revoke entitlements as the REST API. Pick an entitlement, optionally an expiry, and grant it. This is the way to give a customer access as a goodwill gesture, to unlock an account for a reviewer, or to give your team the paid features. A granted entitlement has the provenance PROMOTIONAL, is excluded from revenue, and reaches the app on its next refresh().

98.11.5. Export and import

The **Export** page downloads two CSV files on demand, and can also deliver both every day to an Amazon S3 or Google Cloud Storage bucket you name.

File	Columns
Transactions	`createdAt`, `appUserId`, `store`, `environment`, `productId`, `eventType`, `transactionId`, `originalTransactionId`, `price`, `currency`, `usd`, `validationState`
Subscribers	`appUserId`, `entitlementId`, `active`, `productId`, `store`, `expiresDate`, `willRenew`, `provenance`

For a scheduled export, choose the destination, the bucket and a prefix, and for S3 the region. S3 takes an access key id and a secret access key, and Google Cloud Storage takes a service account key. The files are named `transactions-<day>.csv` and `subscribers-<day>.csv` under the prefix.

Import brings existing customers into the service, for example when you add Commerce to an app that already has subscribers. Upload a CSV file in the console, or post it to `/receipts/import`. The first line must be this header:

```
app_user_id,store,product_id,receipt
```

Each row is validated exactly as a receipt from a device is, so an imported subscription is checked with the store and continues to renew, expire and report events like any other. The answer lists the rows that weren't imported, with the reason for each.

98.11.6. The console

The **Commerce** section in the console at https://cloud.codenameone.com/console/index.html is account-level by default, with an app filter to narrow to one app. Beside the configuration pages this chapter has described, it reports on the business:

- **Overview** — the subscription dashboard: headline KPIs (MRR, ARR, ARPU, active subscriptions, active trials, churn, trial conversion, customers) and trend charts for MRR, active subscriptions and revenue.
- **Insights** — MRR movement (new versus churned), MRR forecast, realized-LTV curve, active subscriptions by store and by product, cohort retention, trials started, conversion to paying, refund rate over time and subscription status.
- **Customers** — each app user with their active entitlements, attributes and balances.
- **Transactions** — the recent validated-event ledger.

Commerce normalizes every active subscription to a monthly figure (MRR) and reconstructs the trends from the subscription history. Every chart pairs a graph with its underlying data table for export-friendly inspection. All money is shown in your reporting currency, and transactions in other currencies are normalized to USD through daily exchange rates.

98.12. Build hints

Commerce reuses the standard `build_key` that every Codename One cloud build already carries, so a cloud build needs no build hint to use the service. `CommerceManager.isCloudEnabled()` is true on any cloud build. These hints change the defaults:

Build hint	Default	Description
`commerce.cloud.enabled`	`true`	Set to `false` to keep every decision on the device, from the store's own receipts. Every `CommerceManager` call then defers to the `Purchase` API.
`commerce.cloud.endpoint`	*(Codename One cloud)*	The base URL of the commerce service, for example `https://commerce.example.com/api/v2/commerce`. It must be an `https` URL. Plain `http` is accepted only for a service on a loopback address — `localhost`, `127.0.0.1`, `[::1]`, or `10.0.2.2`, the host machine as the Android emulator sees it — for testing on your own machine. A build with any other value fails.
`commerce.cloud.publicKey`	*(Codename One cloud)*	The base64 encoded Ed25519 public key that responses of the service are verified against. A self-hosted service needs it: set it together with `commerce.cloud.endpoint`. While the app knows no public key, it uses no answer of the service.
`android.billing.store`	`play`	The store an Android app is built for: `play` or `amazon`.

98.12.1. Response signing and self-hosting

The answers that decide what a customer owns — customer information, purchase validation, offerings, the customer center and promotional offer signatures — are signed by the service with an Ed25519 key. Each request carries a fresh random nonce, and the signature covers that nonce together with the response. An answer recorded earlier can't be replayed to a later request, and an answer forged by something between the device and the service doesn't verify.

An answer is trusted only when it's signed and the signature verifies against the service's public key. An answer that's unsigned or wrongly signed is ignored, and so is every answer while the app knows no public key at all. The manager then becomes degraded. With a key, the app falls back to the stored answer and the store's receipts, exactly as it does when the network is down. With no key, nothing was ever stored, so the app answers from the store's own receipts alone.

A signed answer must also be the answer to this request: one that names another app user id, another application's package name or another endpoint is ignored, and a stored answer is checked the same way when it's loaded.

The stored answer is kept as the service signed it, and its signature is checked again every time the app starts. A stored answer that no longer verifies, for example after the key changed, is deleted rather than used.

The service address must use `https`. Plain `http` is accepted only on a loopback address — `localhost`,

`127.0.0.1`, `[::1]` or `10.0.2.2` — for testing on your own machine.

To run against a service of your own, set both hints. A self-hosted service needs `commerce.cloud.publicKey`; without it the app trusts none of its answers:

```
codename1.arg.commerce.cloud.endpoint=https://commerce.example.com/api/v2/commerce
codename1.arg.commerce.cloud.publicKey=<base64 of the 32 byte Ed25519 public key>
```

Use the public half of the key pair your service signs with. A key that's set but can't be read verifies nothing, so every answer is ignored and the app runs degraded. That's deliberate: a broken key must not turn verification off.

98.13. Testing in the simulator

The simulator reads the three `commerce.cloud` hints from the project's `codenameone_settings.properties`, so you can point it at a staging service or at one running on your own machine:

```
codename1.arg.commerce.cloud.endpoint=http://localhost:8080/api/v2/commerce
```

The build key is stamped by the build server, and the simulator has none. Until one is set, `isCloudEnabled()` is false there and every call defers to the simulated `Purchase` API, which is enough to exercise your purchase flow and the built-in paywall. To talk to the service from the simulator, set the build key property before the first `CommerceManager` call:

```
// In init(), before the first CommerceManager call, and only in the
// simulator: a device build carries its own build key.
if (CN.isSimulator()) {
    Display.getInstance().setProperty("build_key", "the-build-key-of-your-account");
}
```

With that in place the simulator fetches offerings, paywalls and the customer center from the service, and the purchases you make in the simulated store are sent for validation as `Receipt.STORE_CODE_SIMULATOR` receipts. You can also grant the test customer an entitlement on the **Customers** page of the console and watch `refresh()` pick it up. `getAppUserId()` returns the id to look for.

98.14. Privacy

Commerce stores entitlement state and transaction metadata (store, product id, event type, amount, validation state) keyed by your app user id, together with the attributes you set. It never stores card numbers or payment credentials. Those stay with Apple, Google, Amazon, Stripe, Paddle or your processor. Family shared purchases grant access but are excluded from revenue. Deleting a customer through the REST API removes their grants, attributes and currency history.

98.15. Setup checklist

1. Map your store products to entitlements on the **Products** page of the console, and create an offering with a package for each product you sell on the **Offerings** page.
2. In the app, install a receipt store, call `refresh()` off the EDT on start, and gate features with `isEntitled(…)`.
3. Show the offering with `Paywall.show(…)`, and add `CustomerCenter.show()` to your settings screen.
4. Call `logIn(…)` when the user signs in to your account system and `logOut()` when they sign out.
5. Point the stores' server notifications at the service, and enter your store credentials on the **Setup** and **Stores** pages.
6. Optionally, set a webhook URL and secret to receive lifecycle events on your backend, and enable the integrations you use.

Chapter 99. Monetization

Codename One integrates many built-in monetization options such as in-app purchases and subscriptions. Advertising is covered in its own chapter; see Advertising.

Many monetization options are available as third-party cn1libs [https://www.codenameone.com/cn1libs.html] that you can install through the Codename One website.

99.1. In-app purchase

In-app purchase is a helpful way to make app development profitable. Codename One supports in-app purchases of consumable and non-consumable products on Android and iOS. It also supports subscriptions. Even though the concept is simple, in-app purchase involves many moving parts, for subscriptions.

99.1.1. The SKU

In-app purchase support centers around the set of SKUs you want to sell. Each product, whether it's a one-month subscription, an upgrade to the "Pro" version, or "10 disco credits," has a SKU (stock-keeping unit). Ideally, you can use the same SKU across every store that sells your app.

99.1.2. Types of products

Four classifications for products exist:

1. **Non-consumable Product** - This is a product that the user purchases once to "own." They can't re-buy it. One example is a product that upgrades your app to a "Pro" version.
2. **Consumable Product** - This is a product that the user can buy more than once. For example, you might have a product for "10 Credits" that lets the user buy items in a game.
3. **Non-Renewable Subscription** - A subscription that you buy once, and won't be "auto-renewed" by the app store. These are almost identical to consumable products, except that subscriptions need to be transferable across all the user's devices. This means that non-renewable subscriptions require that you have a server that keeps track of the subscriptions.
4. **Renewable Subscriptions** - A subscription that the app store manages. The user will be automatically billed when the subscription period ends, and the subscription will renew.

These subscription categories may not be explicitly supported by a given store, or they may use different names. You can integrate each product type in a cross-platform way using Codename One. For example, Google Play doesn't distinguish between consumable products and non-renewable subscriptions, but iTunes does.

99.1.3. The "hello world" of in-app purchase

Start with a simple example of an app that sells `Worlds`. First, pick the SKU for the product. Here you use `com.codename1.world`:

```
public static final String SKU_WORLD = "com.codename1.world";
```

Although this example uses the package-name convention for a SKU, you can use any name you want, for example `UA8879`.

Next, the app's main class needs to implement the `PurchaseCallback` interface

Using these callbacks, the app receives notifications whenever a purchase changes. For this simple app, only `itemPurchased()` and `itemPurchaseError()` matter. The legacy `itemRefunded()`, `subscriptionStarted()`, and `subscriptionCanceled()` hooks are deprecated in the core API and are no longer dispatched by the stores. Instead of relying on callbacks for long-term entitlement state, query the current receipts at runtime with helpers such as `Purchase.wasPurchased(…)`, `Purchase.isSubscribed(…)`, or `Purchase.getReceipts()`. That keeps the UI aligned with the latest data from the underlying store.

Now in the `start()` method, add a button that lets the user buy the world:

```
public void start() {
if(current!= null){
current.show();
return;
}
Form hi = new Form("Hi World");
Button buyWorld = new Button("Buy World");
buyWorld.addActionListener(e->{
if (Purchase.getInAppPurchase().wasPurchased(SKU_WORLD)) {
Dialog.show("can't Buy It", "You already Own It", "OK", null);
} else {
Purchase.getInAppPurchase().purchase(SKU_WORLD);
}
});

hi.addComponent(buyWorld);
hi.show();
}
```

At this point, the app can track the sale of the world. To make it more useful, add `ToastBar` feedback for purchase completion:

```
@Override
public void itemPurchased(String sku) {
ToastBar.showMessage("Thanks. You now own the world", FontImage.MATERIAL_THUMB_UP);
}

@Override
public void itemPurchaseError(String sku, String errorMessage) {
ToastBar.showErrorMessage("Failure occurred: "+errorMessage);
```

```
}
```

You can test out this code in the simulator without doing any more setup and it will work. If you want the code to work on Android and iOS, you'll need to set up the app and in-app purchase settings in the Google Play and iTunes stores respectively as explained below

When the app first opens you see your button:

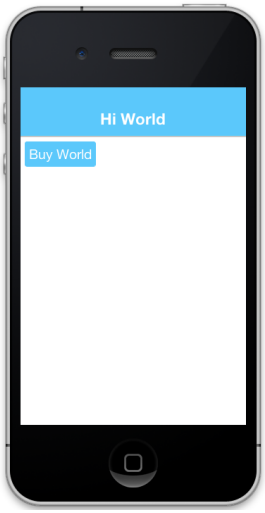


Figure 371. in-app purchase demo app

In the simulator, clicking on the "Buy World" button will bring up a prompt to ask you if you want to approve the purchase.

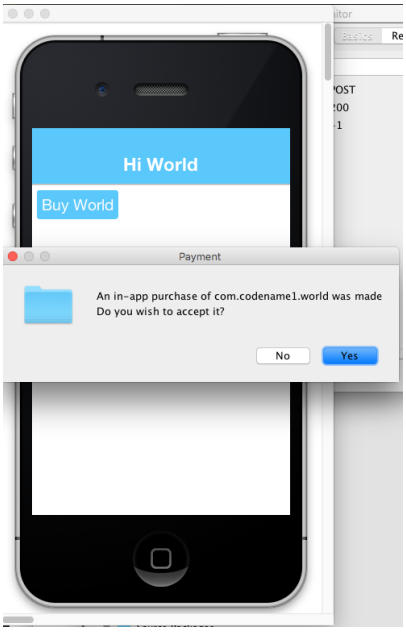

Figure 372. Approving the purchase in the simulator

Now if you try to buy the product again, it pops up the dialog to let you know that you already own it.

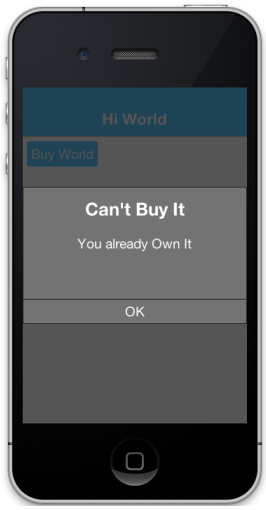

Figure 373. In App buy already owned

99.1.4. Making it consumable

In the "Buy World" example above, the "world" product was non-consumable, since you could only buy the world once. You could change it to a consumable product by disregarding whether it was purchased before & keeping track of how many times it had been purchased.

You'll use storage to keep track of the number of worlds that the user purchased. You need two methods to manage this count. One method gets the number of worlds that you own, and another adds a world to this count:

```
private static final String NUM_WORLDS_KEY = "NUM_WORLDS.dat";
public int getNumWorlds() {
 synchronized (NUM_WORLDS_KEY) {
 Storage s = Storage.getInstance();
 if (s.exists(NUM_WORLDS_KEY)) {
 return (Integer)s.readObject(NUM_WORLDS_KEY);
 } else {
 return 0;
 }
 }
}

public void addWorld() {
 synchronized (NUM_WORLDS_KEY) {
 Storage s = Storage.getInstance();
 int count = 0;
 if (s.exists(NUM_WORLDS_KEY)) {
 count = (Integer)s.readObject(NUM_WORLDS_KEY);
 }
 count++;
 s.writeObject(NUM_WORLDS_KEY, new Integer(count));
 }
}
```

Now you'll change your buy code as follows:

```
buyWorld.addActionListener(e->{
 if (Dialog.show("Confirm", "You own "+getNumWorlds()+
 " worlds. Do you want to buy another one?", "Yes", "No")) {
 Purchase.getInAppPurchase().purchase(SKU_WORLD);
 }
});
```

And your `itemPurchased()` callback will need to add a world:

```
@Override
public void itemPurchased(String sku) {
 addWorld();
 ToastBar.showMessage("Thanks. You now own "+getNumWorlds()+" worlds", FontImage.MATERIAL_THUMB_UP);
}
```

When you set up the products in the iTunes store you will need to mark the product as a consumable product or iTunes will prevent you from purchasing it more than once

99.1.5. Non-Renewable subscriptions

As you discussed before, there are two types of subscriptions:

1. Non-renewable
2. Auto-renewable

Non-renewable subscriptions are the same as consumable products, except that they're shareable across devices. Auto-renewable subscriptions will continue as long as the user doesn't cancel the subscription. They will be re-billed automatically by the appropriate app-store when the chosen period expires, and the app-store handles the management details itself.

The concept of an "Non-renewable" subscription is unique to iTunes. Google Play has no formal similar option. To create a non-renewable subscription SKU that behaves the same in your iOS and Android apps you would create it as a **regular product** in Google play, and a Non-renewable subscription in the iTunes store. You'll learn more about that in a later post when you go into the specifics of app store setup.

The `Purchase` class includes both a `purchase()` method and a `subscribe()` method. On some platforms it makes no difference which one you use, but on Android it matters. If the product is set up as a subscription in Google Play, then you **must** use `subscribe()` to buy the product. If it's set up as a regular product, then you **must** use `purchase()`. Since you enter "Non-renewable" subscriptions as regular products in the play store, you would use the `purchase()` method.

99.1.6. Promotional offers (iOS)

Apple allows you to present discounted introductory pricing to existing subscribers via promotional offers [https://developer.apple.com/documentation/storekit/skpaymentdiscount]. Codename One surfaces this capability through overloads of both `Purchase.purchase(String, PromotionalOffer)` and `Purchase.subscribe(String, PromotionalOffer)`, which forward the promotional context to StoreKit when you start the transaction. Promotional offers are only honoured by iOS, so the overloads fall back to the regular buy flow on other platforms.

To build the signed discount payload required by Apple you can use the `ApplePromotionalOffer` helper:

```
ApplePromotionalOffer offer = new ApplePromotionalOffer();
offer.setOfferIdentifier("my-intro-offer");
offer.setKeyIdentifier("A1B2C3D4");
// The nonce is one of the values your server signs, so it has to be
// the very one that produced the signature below. A fresh value
// generated here would never validate.
offer.setNonce(nonceFromYourServer);
offer.setSignature(signatureFromYourServer);
offer.setTimestamp(timestampFromYourServer);

Purchase purchase = Purchase.getInAppPurchase();
purchase.subscribe(SKU_WORLD_MONTHLY, offer);
```

Apple generates the signature and timestamp from your App Store Connect server notifications endpoint; Codename One passes them to the native StoreKit APIs. For one-time products you can call `purchase(sku, offer)` instead of `subscribe(…)`.

99.1.7. Restoring purchases and managing subscriptions

Both Apple and Google provide built-in user interfaces for restoring past purchases and managing subscription billing preferences. Codename One exposes these entry points so you can surface the native flows without reimplementing them yourself.

- Restores: Call `Purchase.isRestoreSupported()` before presenting a "Restore purchases" button. When supported (iOS implements this natively), invoke `Purchase.restore()` to prompt the operating system to re-deliver past transactions. Your app should implement `RestoreCallback` (like how you implement `PurchaseCallback`) so you can respond to individual `itemRestored(…)` events and to the completion or failure of the restore request.
- Subscription management: Use `Purchase.isManageSubscriptionsSupported()` to detect whether the platform can show the subscription management UI. When it returns `true`, calling `Purchase.manageSubscriptions(null)` opens the store-specific settings screen (Apple's subscription center on iOS and Google Play's subscription management activity on Android). On Android you can optionally pass a SKU to deep-link directly to the plan the user should manage.

Because these flows are handled by the underlying store your UI doesn't need to rebuild any billing screens. Gate the buttons on the capability checks above so that iOS and Android users get the

familiar restore/manage dialogs while other platforms can fall back to your own help copy.

99.1.8. The Server-Side

Since a subscription purchased on one user device **needs** to be available across the user's devices (Apple's rules for non-renewable subscriptions), your app will need to have a server-component. In this section, you'll gloss over that & "mock" the server interface. You'll go into the specifics of the server-side below.

The receipts API

Subscriptions, in Codename One use the "Receipts" API. It's up to you to register a receipt store with the in-app purchase instance, which allows Codename one to load receipts (from your server), and submit new receipts to your server. A `Receipt` includes information such as:

1. Store code (since you may be dealing with receipts from itunes, google play & Microsoft)
2. SKU
3. Transaction ID (store specific)
4. Expiry Date
5. Cancellation date
6. Buy date
7. Order Data (that you can use on the server-side to verify the receipt and load receipt details directly from the store it originated from).

The `Purchase` provides a set of methods for interacting with the receipt store, such as:

1. `isSubscribed([skus])` - Checks to see if the user is subscribed to any of the provided skus.
2. `getExpiryDate([skus])` - Checks the expiry date for a set of skus.
3. `synchronizeReceipts()` - Synchronizes the receipts with the receipt store. This will try to submit any pending purchase receipts to the receipt store, and the reload receipts from the receipt store.

In order for any of this to work, you must implement the `ReceiptStore` interface, and register it with the Buy instance. Your receipt store must implement two methods:

1. `fetchReceipts(SuccessCallback<Receipt[]> callback)` - Loads all the receipts from your receipt store for the current user.
2. `submitReceipt(Receipt receipt, SuccessCallback<Boolean> callback)` - Submits a receipt to your receipt store. This gives you an opportunity to add details to the receipt such as an expiry date.

99.1.9. The "hello world" of Non-Renewable subscriptions

You'll expand on the theme of "Buying" the world for this app, except, this time you will "Rent" the world for a period of time. You'll have two products:

1. A 1-month subscription

2. A 1-year subscription

Every listing in the rest of this chapter uses these declarations:

```
static final String SKU_WORLD_1_MONTH = "com.codename1.world.month";
static final String SKU_WORLD_1_YEAR = "com.codename1.world.year";

// Both periods of the same subscription group. Every Purchase method that
// asks about status or expiry takes the whole group, so keeping them in
// one array is what makes the later listings read the way they do.
static final String[] PRODUCTS = { SKU_WORLD_1_MONTH, SKU_WORLD_1_YEAR };

// There is deliberately no Purchase field here. Receipts are cached on the
// instance and loaded from storage the first time one is asked for, while
// the synchronization that refreshes them is static and may be running on
// an instance the port created. A held instance therefore keeps answering
// from the snapshot it loaded; a fresh getInAppPurchase() reads what the
// last completed synchronization persisted. It is a storage read, not a
// network call.
```

Notice that you create two separate SKUs for the 1 month and 1-year subscription. **Each subscription period must have its own SKU**. The example uses an array (`PRODUCTS`) that contains both of the SKUs. This is handy, as you'll see in the examples ahead, because the APIs for checking status and expiry date of a subscription take the SKUs in a "subscription group" as input.

Different SKUs that sell the same service/product but for different periods form a "subscription group." Conceptually, customers aren't subscribing to a particular SKU, they're subscribing to the subscription group of which that SKU is a member. As an example, if a user purchases 1-month subscription to "the world," they're actually subscribing to "the world" subscription group.

It's up to you to know the grouping of your SKUs. Any methods in the `Purchase` class that check subscription status or expiry date of a SKU should be passed **all** SKUs of that subscription group. For example, If you want to know if the user is subscribed to the `SKU_WORLD_1_MONTH` subscription, it would not be enough to call `iap.isSubscribed(SKU_WORLD_1_MONTH)`, because that wouldn't consider if the user had purchased 1-year subscription. The correct way is to always call `iap.isSubscribed(SKU_WORLD_1_MONTH, SKU_WORLD_1_YEAR)`, or `iap.isSubscribed(PRODUCTS)` since you have placed both SKUs into your PRODUCTS array.

Implementing the receipt store

The receipt store is intended to interface with a server so that the subscriptions can be synced with multiple devices, as required by Apple's guidelines. For this post you'll just store your receipts on device using internal storage. Moving the logic to a server is a simple matter that this guide covers in a future post when you cover the server-side.

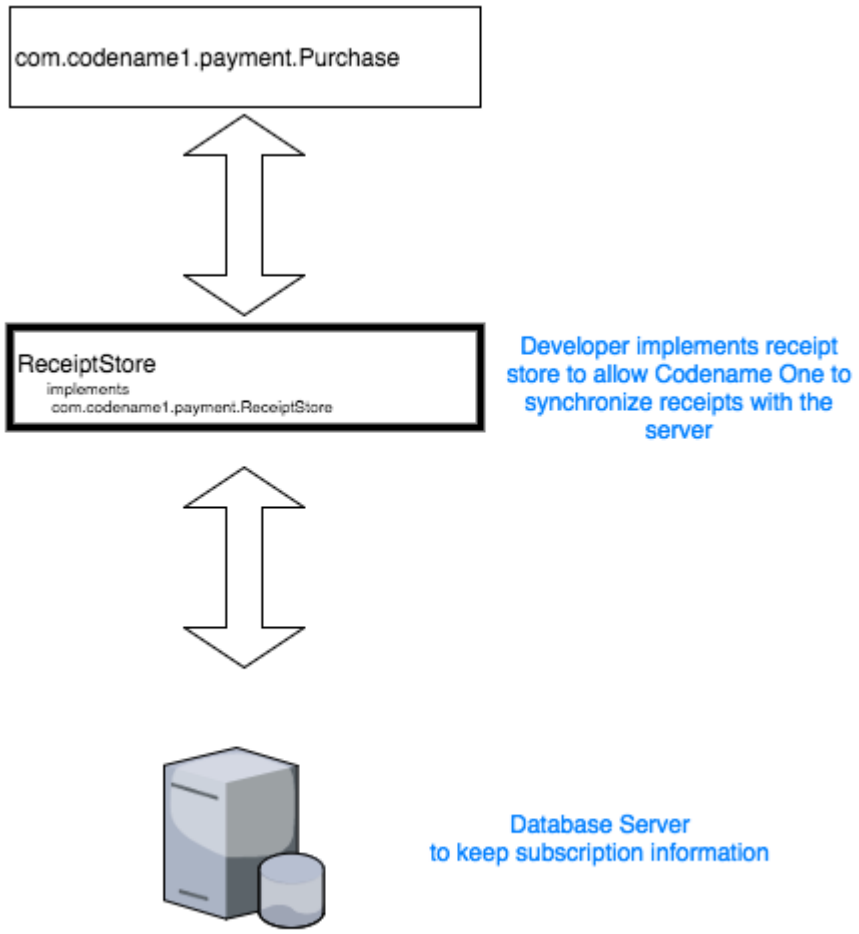

Figure 374. The Receipt store is a layer between your server and Codename One

A basic receipt store needs to implement just two methods:

1. `fetchReceipts`
2. `submitReceipt`

You'll register it in your app's init() method so that it's always available:

```
public void init(Object context) {
// ...

 Purchase.getInAppPurchase().setReceiptStore(new ReceiptStore() {

 @Override
 public void fetchReceipts(SuccessCallback<Receipt[]> callback) {
 // Fetch receipts from storage and pass them to the callback
 }

 @Override
 public void submitReceipt(Receipt receipt, SuccessCallback<Boolean> callback) {
 // Save a receipt to storage. Make sure to call callback when done.
 }
 });
```

```
}
```

These methods are designed to be asynchronous since real-world apps will always be connecting to some sort of network service. Instead of returning a value, both of these methods are passed instances of the `SuccessCallback` class. It's important to make sure to call `callback.onSuccess()` **ALWAYS** when the methods have completed, even if there is an error, or the Buy class will just assume that you're taking a long time to complete the task, and will continue to wait for you to finish.

Once implemented, your `fetchReceipts()` method will look like:

```
// static declarations used by receipt store

// Storage key where list of receipts are stored
private static final String RECEIPTS_KEY = "RECEIPTS.dat";

@Override
public void fetchReceipts(SuccessCallback<Receipt[]> callback) {
 Storage s = Storage.getInstance();
 Receipt[] found;
 synchronized(RECEIPTS_KEY) {
 // readObject() answers null when the entry cannot be read or
 // deserialized, and Purchase calls this from inside loadReceipts(), so
 // throwing would leave synchronization marked in progress for the rest of
 // the session. Answering with an empty array is worse still: loadReceipts
 // persists a non-null result, so it would overwrite the receipts already
 // known and revoke a live subscription. null fails the fetch and leaves
 // them untouched, and only a genuinely absent entry is empty.
 boolean entryExists = s.exists(RECEIPTS_KEY);
 Object raw = entryExists ? s.readObject(RECEIPTS_KEY) : null;
 if (raw instanceof List) {
 // Checking the container is not checking its contents: a list holding
 // anything else -- a key collision, an older schema, a partial write --
 // makes toArray throw ArrayStoreException, which never reaches the
 // callback and leaves synchronization stuck for the session. Copy
 // element by element and fail the fetch if one does not belong.
 List<?> stored = (List<?>) raw;
 Receipt[] copy = new Receipt[stored.size()];
 int i = 0;
 for (Object o : stored) {
 if (!(o instanceof Receipt)) {
 copy = null;
 break;
 }
 copy[i++] = (Receipt) o;
 }
 found = copy;
 } else if (entryExists) {
 found = null;
 } else {
```

```
 found = new Receipt[0];
 }
 }
 // Make sure this is outside the synchronized block
 callback.onSucess(found);
}
```

This is straight forward. You're checking to see if you already have a list of receipts stored. If so you return that list to the callback. If not you return an empty array of receipts.

`Receipt` implements `Externalizable` so you are able to write instances directly to Storage.

The `submitReceipt()` method is a little more complex, as it needs to calculate the new expiry date for your subscription:

```
@Override
public void submitReceipt(Receipt receipt, SuccessCallback<Boolean> callback) {
 Storage s = Storage.getInstance();
 boolean stored;
 synchronized(RECEIPTS_KEY) {
 // readObject() answers null when the entry cannot be read or
 // deserialized, and this runs inside synchronizeReceipts(), so throwing
 // would leave synchronization marked in progress for the rest of the
 // session. An unreadable entry is not an empty one, though: carrying on
 // as if it were would write this single receipt over every receipt the
 // user has already paid for. Report failure and write nothing, and
 // Purchase keeps the receipt pending and retries later.
 boolean entryExists = s.exists(RECEIPTS_KEY);
 Object raw = entryExists ? s.readObject(RECEIPTS_KEY) : null;
 if (entryExists && !(raw instanceof List)) {
 callback.onSucess(Boolean.FALSE);
 return;
 }
 // The container's type says nothing about its elements, and iterating a
 // list holding something else throws before the callback runs, which
 // leaves synchronization stuck for the session. Copy with a check, the
 // same way fetchReceipts() does.
 List<Receipt> receipts = new ArrayList<Receipt>();
 if (raw instanceof List) {
 for (Object o : (List<?>) raw) {
 if (!(o instanceof Receipt)) {
 callback.onSucess(Boolean.FALSE);
 return;
 }
 receipts.add((Receipt) o);
 }
 }
 // Check to see if this receipt already exists. That should not happen,
```

```
// but a store can resend one.
for (Receipt r : receipts) {
if (sameReceipt(r, receipt)) {
// Already stored. Report success, or synchronizeReceipts() never finishes.
callback.onSucess(Boolean.TRUE);
return;
}
}

// Now try to find the current expiry date
Date currExpiry = new Date();
List<String> lProducts = Arrays.asList(PRODUCTS);
for (Receipt r : receipts) {
if (!lProducts.contains(r.getSku())) {
continue;
}
if (r.getCancellationDate()!= null) {
continue;
}
if (r.getExpiryDate() == null) {
continue;
}
if (r.getExpiryDate().getTime() > currExpiry.getTime()) {
currExpiry = r.getExpiryDate();
}
}

// Now set the appropriate expiry date by adding time onto
// the end of the current expiry date
Calendar cal = Calendar.getInstance();
cal.setTime(currExpiry);
Date newExpiry = null;
if (SKU_WORLD_1_MONTH.equals(receipt.getSku())) {
cal.add(Calendar.MONTH, 1);
newExpiry = cal.getTime();
} else if (SKU_WORLD_1_YEAR.equals(receipt.getSku())) {
cal.add(Calendar.YEAR, 1);
newExpiry = cal.getTime();
}

// Purchase submits every receipt to the store, including products outside
// this subscription group. Only the subscription SKUs get an expiry date:
// stamping a consumable or a one-off purchase with the subscription's
// expiry would make isSubscribed() report it as an active subscription.
if (newExpiry != null) {
receipt.setExpiryDate(newExpiry);
}
receipts.add(receipt);
stored = s.writeObject(RECEIPTS_KEY, receipts);

}
```

```
 // Make sure this is outside the synchronized block. Report what the
 // write actually did: on a failure Purchase would otherwise record the
 // transaction as processed and drop it from the pending queue, losing a
 // receipt the user paid for.
 callback.onSucess(stored);
}

// Two receipts are the same purchase when they come from the same store
// and carry the same transaction id. The store code is part of that
// identity because a transaction id is only unique within its own store,
// as Receipt#getTransactionId() says. A null transaction id is not an
// identity either: two distinct receipts can both carry one, so fall back
// to the fields that together identify a purchase.
//
// Purchase.receiptsMatch() compares one device's pending queue, where
// every receipt comes from the same store, so it can lean on the
// transaction id alone. A ReceiptStore holds receipts from every store
// and cannot.
private static boolean sameReceipt(Receipt a, Receipt b) {
 if (!Objects.equals(a.getStoreCode(), b.getStoreCode())) {
 return false;
 }
 String aTx = a.getTransactionId();
 String bTx = b.getTransactionId();
 if (aTx != null && bTx != null) {
 return aTx.equals(bTx);
 }
 if (aTx != null || bTx != null) {
 return false;
 }
 return Objects.equals(a.getSku(), b.getSku())
 && Objects.equals(a.getPurchaseDate(), b.getPurchaseDate())
 && Objects.equals(a.getOrderData(), b.getOrderData());
}
```

The main logic of this method involves iterating through all the existing receipts to find the **latest** current expiry date, so that when the user purchases a subscription, it's added onto the end of the current subscription (if one exists) rather than going from today's date. This enables users to renew their subscription before the subscription has expired.

In the real-world, you would implement this logic on the server-side.

The iTunes store and Play store have no knowledge of your subscription durations. This is why it's up to you to set the expiry date in the `submitReceipt` method. Non-renewable subscriptions are essentially no different than regular consumable products. It's up to you to manage the subscription logic - and Apple, in particular, requires you to do so using a server.

Synchronizing receipts

In order for your app to provide you with current data about the user's subscriptions and expiry dates, you need to synchronize the receipts with your receipt store. `Purchase` provides a set of methods for doing this. You'll call one of them inside the `start()` method, and you may resynchronize at other strategic times if you suspect that the information may have changed.

The following methods can be used for synchronization:

1. `synchronizeReceipts()` - Asynchronously synchronizes receipts in the background. You won't be notified when it's complete.
2. `synchronizeReceipts(final long ifOlderThanMs, final SuccessCallback<Boolean> callback)` - Asynchronously synchronizes receipts, but only if they haven't been synchronized in the specified time. For example, In your start() method you might decide that you only want to synchronize receipts once per day. This also includes a callback that will be called when synchronization is complete.
3. `synchronizeReceiptsSync(long ifOlderThanMs)` - Synchronously synchronizes receipts, blocking until it's complete, and will only refetch if data is older than the given time (pass `0` to always refetch). This is safe to use on the EDT as it employs `invokeAndBlock` under the covers.

In your hello world app you synchronize the subscriptions in a few places.

In the `start()` method, after the form is built:

```
public void start() {
 if (current != null) {
 // A resume. The form and everything on it survived, so rebuilding it
 // would hand a second form components the first one still owns, which
 // Container rejects.
 current.show();
 } else {
 Form hi = new Form("Hello World", BoxLayout.y());

 // ... the rest of the form

 // The expiry label and the button that refreshes it, both of which
 // the next two listings build.
 addExpiryLabel(hi);
 addSyncButton(hi);

 current = hi;
 hi.show();
 }

 // Outside the branch on purpose: a subscription can be bought, renewed
 // or cancelled on another device while this one is suspended, so the
 // resume needs this as much as the launch does.
 Purchase.getInAppPurchase().synchronizeReceipts(0, success -> {
     // Whatever this brought back, the expiry label is now out of date.
```

```
        // Repaint it from the same method the manual button uses.
        if (success) {
            showRentalStatus();
            current.revalidate();
        }
    });
}
```

And you also provide a button to allow the user to manually synchronize the receipts:

```
void addSyncButton(Form hi) {
    Button syncReceipts = new Button("Synchronize Receipts");

    syncReceipts.addActionListener(e -> {
        Purchase.getInAppPurchase().synchronizeReceipts(0, success -> {
            // synchronizeReceipts reports true only when every pending
            // purchase reached the receipt store AND the receipts came
            // back. On false nothing was reloaded, so there is nothing
            // new to show and the status on screen stays as it was.
            if (success) {
                showRentalStatus();
                hi.revalidate();
            } else {
                ToastBar.showErrorMessage("Could not reach the receipt store");
            }
        });
    });

    hi.add(syncReceipts);
}
```

Expiry dates and subscription status

Now that you have a receipt store registered, and you have synchronized your receipts, you can query the `Purchase` instance to see if a SKU or set of SKUs is subscribed. Three useful methods in this realm:

1. `boolean isSubscribed(String… skus)` - Checks to see if the user is subscribed to any of the provided SKUs.
2. `Date getExpiryDate(String… skus)` - Gets the latest expiry date of a set of SKUs.
3. `Receipt getFirstReceiptExpiringAfter(Date dt, String… skus)` - This method will return the earliest receipt with an expiry date after the given date. This is needed in cases where you need to decide if the user should have access to some content based on its publication date. For example, If you published an issue of your e-zine on March 1, and the user purchased a subscription on March 15th, then they should get access to the March 1st issue even though it doesn't necessarily fall in the subscription period. Being able to fetch the first receipt after a given date makes it easier to determine if a particular issue should be covered by a subscription.

If you need to know more information about subscriptions, you can always just call `getReceipts()` to get a list of all the current receipts and determine for yourself what the user should have access to.

In the hello world app you'll use this information in a few different places. On your main form you'll include a label showing the current expiry date, painted from the receipts already on the device and repainted by whichever of the two synchronizations above comes back first:

```
// A field, not a local: the synchronization at the end of start() and the
// button above both have to reach this label.
SpanLabel rentalStatus = new SpanLabel();

void addExpiryLabel(Form hi) {
    // The receipts already on the device answer this with no round trip,
    // so the label is right the moment the form appears rather than after
    // the first synchronization comes back.
    showRentalStatus();
    hi.add(rentalStatus);
}

void showRentalStatus() {
    Purchase iap = Purchase.getInAppPurchase();
    if (iap.isSubscribed(PRODUCTS)) {
        rentalStatus.setText("World rental expires " + iap.getExpiryDate(PRODUCTS));
    } else {
        rentalStatus.setText("You do not currently have a subscription to the world");
    }
}
```

Allowing the user to purchase the subscription

You should now have all the background required to implement the Hello World Subscription app. You'll return to the code and see how the user purchases a subscription.

In the main form, you want two buttons to subscribe to the `World`, for one month and one year respectively. They look like:

```
// A fresh Purchase on every click, never one captured by the
// listener: receipts are cached per instance, so a captured one keeps
// answering from before the purchase the user just made.
//...
Button rentWorld1M = new Button("Rent World 1 Month");
rentWorld1M.addActionListener(e->{
 String msg = null;
 Purchase iap = Purchase.getInAppPurchase();
 if (iap.isSubscribed(PRODUCTS)) { ①
 msg = "you're already renting the world until "
 +iap.getExpiryDate(PRODUCTS) ②
 +". Extend it for one more month?";
```

```
 } else {
 msg = "Rent the world for 1 month?";
 }
 if (Dialog.show("Confirm", msg, "Yes", "No")) {
 iap.purchase(SKU_WORLD_1_MONTH); ③
 // Note: since this is a non-renewable subscription it's a regular
 // product in the play store - therefore you use the purchase() method.
 // If it were a "subscription" product in the play store, then you
 // would use subscribe() instead.
 }
});

Button rentWorld1Y = new Button("Rent World 1 Year");
rentWorld1Y.addActionListener(e->{
 String msg = null;
 Purchase iap = Purchase.getInAppPurchase();
 if (iap.isSubscribed(PRODUCTS)) {
 msg = "you're already renting the world until "+
 iap.getExpiryDate(PRODUCTS)+
 ". Extend it for one more year?";
 } else {
 msg = "Rent the world for 1 year?";
 }
 if (Dialog.show("Confirm", msg, "Yes", "No")) {
 iap.purchase(SKU_WORLD_1_YEAR);
 // Note: since this is a non-renewable subscription it's a regular
 // product in the play store - therefore you use the purchase() method.
 // If it were a "subscription" product in the play store, then you
 // would use subscribe() instead.
 }
});
```

① In the event handler you check if the user is subscribed by calling `isSubscribed(PRODUCTS)`. Notice that you check it against the array of both the one month and one year subscription SKUs.

② You are able to tell the user when the current expiry date is so that they can gauge whether to proceed.

③ Since this is a non-renewable subscription, you use the `Purchase.purchase()` method. See following note about `subscribe()` vs `purchase()`

99.1.10. Subscribe() vs purchase()

The `Purchase` class includes two methods for initiating a purchase:

1. `purchase(sku)`
2. `subscribe(sku)`

Which one you use depends on the type of product that's being purchased. If your product is set up as a subscription in the Google Play Store, then you should use `subscribe(sku)`. Otherwise, you should use `purchase(sku)`.

Handling purchase callbacks

The buy callbacks are like the ones implemented in the regular in-app purchase examples:

```
@Override
public void itemPurchased(String sku) {
 // Nothing reads receipts off this instance until after the call below,
 // so its cache loads from storage once the synchronization has written
 // there -- which is the point of not holding a Purchase around.
 Purchase iap = Purchase.getInAppPurchase();

 // Reload the receipts from the store. This answers false when the receipt
 // could not be submitted or fetched, and the receipt then stays pending --
 // so the expiry date below would be stale, or the epoch. Do not announce a
 // success that did not happen.
 if (!iap.synchronizeReceiptsSync(0)) {
 ToastBar.showErrorMessage("Could not confirm the purchase yet -- it will retry.");
 return;
 }
 ToastBar.showMessage("Your subscription has been extended to "+iap.getExpiryDate(PRODUCTS), FontImage.
MATERIAL_THUMB_UP);

 // The form the user is looking at still shows the status from before the
 // purchase. The toast is not a substitute for repainting it.
 //
 // iOS registers its StoreKit observer during initialization, so an
 // unfinished transaction can be re-delivered here before start() has
 // built the form. The label is a field and is safe to set; the form may
 // not exist yet, and start() paints it from the same method anyway.
 showRentalStatus();
 if (current != null) {
 current.revalidate();
 }
}

@Override
public void itemPurchaseError(String sku, String errorMessage) {
 ToastBar.showErrorMessage("Failure occurred: "+errorMessage);
}
```

Notice that, in `itemPurchased()` you don't need to explicitly create any receipts or submit anything to the receipt store. This is handled for you automatically. You do make a call to `synchronizeReceiptsSync(0)` but this is just to ensure that your toast message has the new expiry date loaded already.

99.1.12. Summary

This section demonstrated how to set up an app to use non-renewable subscriptions using in-app purchase. Non-renewable subscriptions are the same as regular consumable products except for the fact that they're shared by all the user's devices, and thus, require a server component. The app store has no knowledge of the duration of your non-renewable subscriptions. It's up to you to specify the expiry date of purchased subscriptions on their receipts when they're submitted. Google play doesn't formally have a "non-renewable" subscription product type. To implement them in Google play, you would just set up a regular product. It's how you handle it internally that makes it a subscription, and not just a regular product.

Codename One uses the `Receipt` class as the foundation for its subscriptions infrastructure. You, as the developer, are responsible for implementing the `ReceiptStore` interface to provide the receipts. The `Purchase` instance will load receipts from your ReceiptStore, and use them to determine whether the user is subscribed to a subscription, and when the subscription expires.

99.1.13. Auto-Renewable subscriptions

Auto-renewable subscriptions provide, arguably, an easier path to recurring revenue than non-renewable subscriptions because all the subscription stuff is handled by the app store. You defer almost entirely to the app store (iTunes for iOS, and Play for Android) for billing and management.

If there is a down-side, it would be that you are also subject to the rules of each app store - and they

take their cut of the revenue.

1. For more information about Apple's auto-renewable subscription features and rules see this document [https://developer.apple.com/app-store/subscriptions/].
2. For more information about subscriptions in Google play, see this document [https://developer.android.com/google/play/billing/billing_subscriptions.html].

99.1.14. Auto-Renewable vs Non-Renewable: Choosing between them

When deciding between auto-renewable and non-renewable subscriptions, as always, the answer will depend on your needs and preferences. Auto-renewables are nice because it takes the process out of your hands. You just get paid. On the other hand, there are valid reasons to want to use non-renewables. For example, You can't cancel an auto-renewable subscription for a user. They have to do that themselves. You may also want more control over the subscription and renewal process, in which case a non-renewable might make more sense.

Some developers are opposed to auto-renewable subscriptions [https://marco.org/2013/12/02/auto-renewable-subscriptions]. There isn't enough information to make a solid recommendation on this matter.

On a practical level, if you are using auto-renewable subscriptions (and so subscription products in the Google Play Store) you must use the `Purchase.subscribe(sku)` method for initiating the purchase workflow. For non-renewable subscriptions (and so regular products in the Google Play Store), you must use the `Purchase.purchase(sku)` method.

99.1.15. Learning by example

In this section you'll describe the general workflow of subscription management on the server. You also show how use Apple's and Google's web services to check receipts and stay informed of important events (such as when users cancel or renew their subscriptions).

99.1.16. Building the IAP demo project

A complete demo exists as two projects: a client app [https://gist.github.com/shannah/b61b9b6b35ea0eac923a54163f5d4deb] and a server app [https://github.com/shannah/cn1-iap-demo-server].

The client. The link is a single source file rather than a project, so create a Codename One project and paste it into your main class, adjusting the package and class name to match. It uses `RESTfulWebServiceClient`, which isn't part of the core API, so add the Generic Web Service Client [https://github.com/shannah/cn1-generic-webservice-client] cn1lib as a dependency — see Section 132.5.2, "How to use cn1libs".

Two things about reaching the server from a device. The client can't talk to `http://localhost` — on a device that name means the phone — so point it at the address your machine has on the network:

```
private static final String localHost = "http://10.0.1.32";
```

And iOS refuses unencrypted HTTP by default, so a plain `http://` address needs an App Transport Security exception through the `ios.plistInject` build hint:

```
<key>NSAppTransportSecurity</key>
<dict>
    <key>NSAllowsArbitraryLoads</key>
    <true/>
</dict>
```

That exception turns off transport security for the whole app. It's here because the demo talks to a development server on your desk; a shipped app uses HTTPS and needs none of it.

The server. It needs a Java EE application server rather than a servlet container: alongside its JAX-RS endpoints it uses a `@Stateless` bean and a container-managed `@Schedule` job to revalidate subscriptions, and neither Tomcat nor Jetty supplies those on its own.

Some of what it builds against isn't published to a public repository, so the project ships a task that installs those artifacts into your local Maven repository. Run it once after cloning, before the first build:

```
$ git clone https://github.com/shannah/cn1-iap-demo-server
$ cd cn1-iap-demo-server
$ ant install-deps
```

That task needs `ant`, `mvn` and `git` on your PATH. Check the project's own README first in case it has moved on since — it's the server's build, not Codename One's.

Create a database and a `RECEIPTS` table in it. The shape of that table is the whole storage contract between the two halves:

```
create TABLE RECEIPTS
(
    TRANSACTION_ID VARCHAR(128) not null,
    USERNAME VARCHAR(64) not null,
    SKU VARCHAR(128) not null,
    ORDER_DATA VARCHAR(32000),
    PURCHASE_DATE BIGINT,
    EXPIRY_DATE BIGINT,
    CANCELLATION_DATE BIGINT,
    LAST_VALIDATED BIGINT,
    STORE_CODE VARCHAR(20) default '' not null,
    primary key (TRANSACTION_ID, STORE_CODE)
)
```

Then point the server's persistence unit at that database, by setting the data source in its

`persistence.xml` to the one your application server exposes for it. Creating the table isn't enough on its own — until the persistence unit names the right data source, the server's `EntityManager` never reaches it.

99.1.17. Looking at the source of the app

Now that you've set up and built the app, take a look at the source code so you can see how it all works.

Client side

The example uses the Generic Webservice Client Library [https://github.com/shannah/cn1-generic-webservice-client] from inside your `ReceiptStore` implementation to load receipts from the web service, and insert new receipts to the database.

The full `ReceiptStore` implementation is in the client project linked above.

Notice that you aren't doing any calculation of expiry dates in your client app, as you did in the previous post (on non-renewable receipts). Since you are using a server now, it makes sense to move all that logic over to the server.

Its `createRESTClient()` method builds a `RESTfulWebServiceClient` using basic authentication. The idea is that your user has logged into your app at some point, so you have a username and password to send along with the receipt data and can tie the subscription to an account.

Server-Side

On the server side the REST controller is a standard JAX-RS interface. Its `ReceiptsFacadeREST` class is in the server project linked above.

The magic happens inside that `validateAndSaveReceipt()` method, which You'll cover in detail soon.

Notifications

It's important to note that you won't be notified by apple or google when changes are made to subscriptions. It's up to you to periodically "poll" their web service to find if any changes have been made. Changes you would be interested in are primarily renewals and cancellations. Set up a method to run periodically (once per day might be enough), using the scheduling mechanism on your server stack.

That method finds all the receipts in the database that haven't been validated in some period of time, and validates it. Again, the magic happens inside the `validateAndSaveReceipt()` method which you cover later.

This example only checks receipts from the iTunes and Play stores because those are the only stores that support auto-renewing subscriptions in Codename One.

99.1.18. The CN1-IAP-Validator library

For this tutorial, the example uses a purpose-built library to handle receipt validation in a way that

hides as much of the complexity as possible. It supports both Google Play receipts and iTunes receipts.

The server project linked above shows it in use.

In that project the complexity of receipt validation is reduced to entering three configuration strings:

1. `APPLE_SECRET` - This is a "secret" string that you will get from iTunes connect when you set up your in-app products.
2. `GOOGLE_DEVELOPER_API_CLIENT_ID` - A client ID that you'll get from the Google developer API console when you set up your API service credentials.
3. `GOOGLE_DEVELOPER_PRIVATE_KEY` - A PKCS8 encoded string with an RSA private key that you'll receive at the same time as the `GOOGLE_DEVELOPER_API_CLIENT_ID`.

The next section walks through the steps to get these values.

99.1.19. The `validateAndSaveReceipt()` method

`validateAndSaveReceipt()` is where the work happens, and it's worth reading in full in the server project linked above.

In many of the code snippets for the Server-side code, you'll see references to both a `Receipts` class and a `Receipt` class. This is slightly confusing. The `Receipts` class is a JPA entity the encapsulates a row from the "receipts" table of your SQL database. The `Receipt` class is `com.codename1.payment.Receipt`. It's used to interface with the IAP validation library.

99.1.20. Setting up the stores

Both stores need the same two things from you: the products themselves, and a credential your server can validate receipts with. The consoles that do it are Google's and Apple's, and both have been redesigned more than once, so follow their own documentation for the clicking — what matters here is what to end up with. Each step below links the vendor page that covers it.

Products. Create one product per SKU your app sells, and use exactly the ids your code passes to `purchase()` and `subscribe()`. A subscription needs its own SKU per period, which is why the examples above keep both in a `PRODUCTS` array and pass the whole group to the status calls.

Google Play receipt validation. Server-side validation goes through the Google Play Developer API [https://developers.google.com/android-publisher/getting_started]. Enable that API for the project, create a service account, give it access to your Play account, and download its key. The key arrives as JSON and its `client_email` and `private_key` are what your server authenticates with:

```
{
 "type": "service_account",
 "project_id": "iapdemo-152500",
 "private_key_id": "1b1d39************7d839826b8a",
 "private_key": "-----BEGIN PRIVATE KEY-----... Some private key string -----END PRIVATE KEY-----\n",
```

```
  "client_email": "iapdemo@iapdemo-152500.iam.gserviceaccount.com",
  "client_id": "117601572633333082772",
  "auth_uri": "https://accounts.google.com/o/oauth2/auth",
  "token_uri": "https://accounts.google.com/o/oauth2/token",
  "auth_provider_x509_cert_url": "https://www.googleapis.com/oauth2/v1/certs",
  "client_x509_cert_url": "https://www.googleapis.com/robot/v1/metadata/x509/iapdemo%40iapdemo-
152500.iam.gserviceaccount.com"
}
```

Apple receipt validation. Apple uses a shared secret [https://developer.apple.com/help/app-store-connect/configure-in-app-purchase-settings/generate-a-shared-secret-to-verify-receipts/] generated alongside the in-app products rather than a service account:

```
public static final String APPLE_SECRET = "your-shared-secret-here";
```

Testing before either is ready. Both validations can be switched off so the receipt store accepts what the device reports, which is how you exercise the flow before the credentials exist. Turn them back on before you ship, because with them off the server trusts the client:

```
public static final boolean DISABLE_PLAY_STORE_VALIDATION=true;
```

```
public static final boolean DISABLE_ITUNES_STORE_VALIDATION=true;
```

Test accounts. Both stores let you nominate accounts that can buy without being charged — Apple's sandbox [https://developer.apple.com/documentation/storekit/testing-in-app-purchases-with-sandbox] and Google's license testers [https://support.google.com/googleplay/android-developer/answer/6062777]. Apple's sandbox works against a development-signed build installed straight onto a device, and Google's license testers can buy from a sideloaded build once the package name and products match; it's Play's track-based testing that needs an uploaded artifact. Their docs cover the current mechanism, and Google's has changed name twice.

Chapter 100. Advertising

Codename One provides a pluggable advertising API under `com.codename1.ads`. The framework defines the formats, the consent flow and the app/UI lifecycle integration; an ad network is supplied by a separate library that implements the provider interface. The reference implementation is the Google AdMob library (`cn1-admob`), but the design is network agnostic - AdMob, AppLovin MAX, Unity LevelPlay or a custom mediation layer all plug in the same way, with no changes to the framework or the build.

The supported formats are:

- **Banner** - a small inline ad that lives in the component hierarchy (`com.codename1.ads.BannerAd`).
- **Interstitial** - a full screen ad shown at a natural break, such as between game levels (`com.codename1.ads.InterstitialAd`).
- **Rewarded** - an opt-in full screen ad that grants a reward for watching (`com.codename1.ads.RewardedAd`).
- **Rewarded interstitial** - an incentivized transition ad (`com.codename1.ads.RewardedInterstitialAd`).
- **App open** - shown when the app is brought to the foreground (`com.codename1.ads.AppOpenAd`).
- **Native** - assets you render with your own components (`com.codename1.ads.NativeAd`).

The screenshot below is the advertising sample running in the simulator against the deterministic mock provider (`cn1-ads-mock`): a news feed with an in-feed native ad (the "Sponsored" row, rendered with the app's own components) and an anchored banner at the bottom.

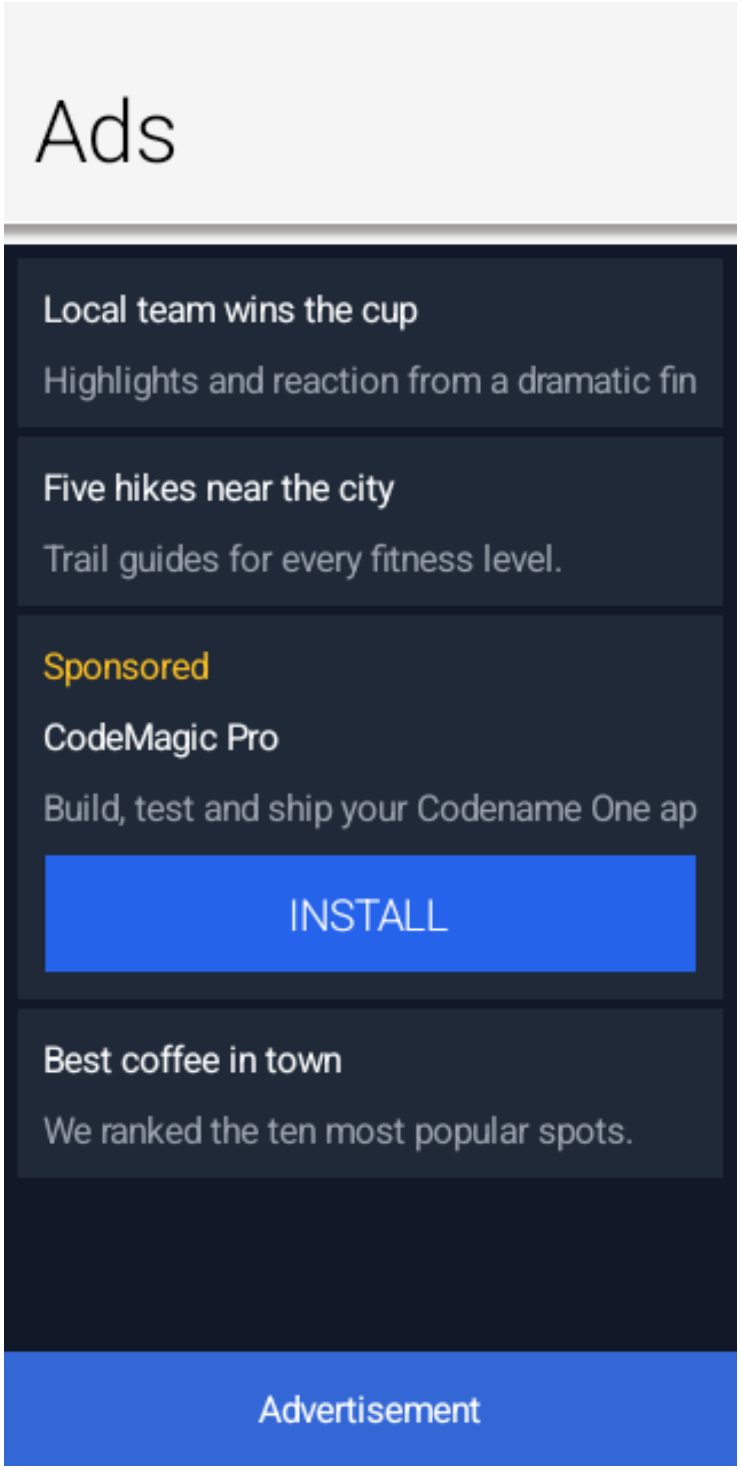

Figure 379. The advertising sample in the simulator: an in-feed native ad and a banner

100.1. Ad provider cn1libs

Several provider libraries ship with the framework. They're released to Maven Central together with the core and the AI cn1libs, sharing the same version (`${cn1.version}`), so you never mix versions. Each declares its own native SDK dependencies (Pods / Gradle dependencies / permissions), applied automatically when the library is on the classpath; you don't edit build hints by hand, except for the per-app id described under Section 100.9, "Configuring the AdMob application id".

cn1lib	Provider class	Provides
cn1-admob	com.codename1.ads.admob.AdMobProvider	Google AdMob on the Google Mobile Ads SDK (banner, interstitial, rewarded, rewarded interstitial, app open), with AdMob mediation behind it.
cn1-applovin	com.codename1.ads.applovin.AppLovinProvider	AppLovin MAX mediation (banner, interstitial, rewarded, app open).
cn1-unity-levelplay	com.codename1.ads.levelplay.LevelPlayProvider	Unity LevelPlay (ironSource) mediation (banner, interstitial, rewarded).
cn1-ads-mock	com.codename1.ads.mock.MockAdProvider	A deterministic, network-free provider that renders fixed labelled ads - for unit tests, screenshot tests and trying the API in the simulator.

Add the matching dependency to your project's `common/pom.xml`. The provider libraries use a `-lib` aggregator with `<type>pom</type>` so Maven pulls in the per-platform classifier jars:

```
<dependency>
    <groupId>com.codenameone</groupId>
    <artifactId>cn1-admob-lib</artifactId>
    <version>${cn1.version}</version>
    <type>pom</type>
</dependency>
```

`cn1-ads-mock` is a single cross-platform jar, so it needs no classifier:

```
<dependency>
    <groupId>com.codenameone</groupId>
    <artifactId>cn1-ads-mock</artifactId>
    <version>${cn1.version}</version>
</dependency>
```

100.2. Enabling a provider

Enable a provider once at startup, from your app's `init(Object)`, by calling the static `install()` method on the provider class named in the table above — `AdMobProvider.install()`, `AppLovinProvider.install()`, `LevelPlayProvider.install()` or `MockAdProvider.install()`. Each one registers its provider with `AdManager` and takes no arguments.

That single call binds the provider; the rest of your code uses only the framework API in `com.codename1.ads`. If no provider is registered the API stays safe: format support reports `false` and loads fail with `AdError.CODE_UNSUPPORTED` instead of throwing, so a build without an ad library still runs.

100.3. Initialization and consent

Collecting privacy consent is mandatory on modern platforms before personalized ads can be served: in the EEA/UK the GDPR consent form must be shown (providers wrap Google's User Messaging Platform or an equivalent), and on iOS the App Tracking Transparency prompt must be presented to access the advertising identifier. The recommended order is to initialize, gather consent, then load:

```
void startAds() {
    AdConfig cfg = new AdConfig()
            .testMode(true)
            .addTestDevice("YOUR_TEST_DEVICE_ID")
            .tagForChildDirectedTreatment(AdConfig.TAG_FALSE)
            .maxAdContentRating(AdConfig.RATING_G);

    AdManager.initialize(cfg, ready -> {
        // false when no provider was installed. It is not a report that
        // the network is up: every provider hands its config to the native
        // bridge and answers true straight away, while the SDK behind it
        // initializes asynchronously. Worth checking anyway, because with
        // no provider at all AdConsent reports consent as not required and
        // canRequestAds() answers true, so carrying on would walk into
        // loadAds() with nothing behind it.
        if (!ready) {
            showAdFreeUi();
            return;
        }

        // Consent has to be settled before the first load, not before
        // initialize: requestConsent presents the GDPR form and, on iOS,
        // the App Tracking Transparency prompt, and both need the SDK up.
        AdConsent.requestConsent(status -> {
            if (AdConsent.canRequestAds()) {
                loadAds();
            } else {
                // STATUS_REQUIRED with consent withheld. Personalized ads
                // are off the table; show the app without them rather
                // than blocking on a prompt the user already declined.
                showAdFreeUi();
            }
        });
    });
}

void loadAds() {
}

void showAdFreeUi() {
}
```

Two things about that flow are worth knowing before you rely on it.

The readiness flag says a provider was installed and took the config; it isn't a report that the network came up. Every provider passes the config to its native bridge and answers `true` immediately, while the SDK behind it initializes asynchronously — so an invalid SDK key surfaces as failing loads later, not as `false` here.

And `AdConsent.requestConsent` presents a form only where the provider implements one. AdMob does, through Google's User Messaging Platform. AppLovin MAX and Unity LevelPlay read consent from an external CMP and the IAB TCF string instead, so their implementations report `STATUS_NOT_REQUIRED` at once and `canRequestAds()` always answers `true`. On those two the consent flow is the CMP's, not this one, and it has to be in place before the first load for EEA/UK users.

On iOS 14 and later the AdMob provider starts the App Tracking Transparency prompt alongside the User Messaging Platform request and fires its consent callback when UMP finishes, without waiting for the tracking answer. The callback can therefore arrive while the system prompt is still on screen, and a load started from it runs before tracking authorization is settled. Present the ATT prompt yourself at a point you control, and load after the user has answered.

`AdConfig` also carries the global compliance flags every network requires: test mode, test device ids, child directed treatment, under-age-of-consent treatment and a maximum ad content rating.

Never ship a release build with `testMode` on, and never click live ads during development - both violate ad network program policies. Use the test ad unit ids while developing.

100.4. Banner ads

`BannerAd` is a regular Codename One component. Add it to a form (typically anchored at the top or bottom) and call `load()`:

```
BannerAd banner = new BannerAd("ca-app-pub-xxx/yyy");
form.add(BorderLayout.SOUTH, banner);
banner.load();
```

The default `SIZE_ADAPTIVE` requests an anchored adaptive banner sized to the available width, which is the recommended modern banner type.

100.5. Interstitial ads

Interstitials are event driven - load, then show when loaded, and preload the next one when the current ad is dismissed:

```
InterstitialAd ad = new InterstitialAd("ca-app-pub-xxx/yyy");
ad.setAdListener(new AdListener() {
```

```
    // Do not show from onLoaded(): onDismissed() loads the next ad,
    // which would then show itself the moment it arrives, and the user
    // never escapes the sequence.
    public void onDismissed() { ad.load(); } // preload the next
});
ad.load();

// Show it where an ad belongs -- a natural break such as the end of a
// level. Loading is asynchronous, so the readiness check belongs in the
// handler that runs at the break; straight after load() nothing is ready
// yet and the ad would never appear.
levelComplete.addActionListener(e -> {
    if (ad.isLoaded()) {
        ad.show();
    }
});
```

You can also let Codename One show an interstitial automatically on screen transitions, no more often than a given interval:

```
AdManager.bindInterstitialOnTransition(new InterstitialAd("ca-app-pub-xxx/yyy"), 60000);
```

100.6. Rewarded and rewarded interstitial ads

Register a reward listener and grant the reward when it fires. For valuable rewards, configure server-side verification. The network then posts the reward to your server, and that callback rather than the client one is what credits the user. The client listener still fires, before any verification has happened, so with verification configured it's for presentation only — credit the user there as well and you'll pay the reward twice:

```
RewardedAd ad = new RewardedAd("ca-app-pub-xxx/yyy");
ad.setServerSideVerificationOptions(new ServerSideVerificationOptions(userId, "level=7"));
// show() does nothing when no ad is loaded, so the offer starts disabled
// and goes back to disabled the moment it is spent.
watchForCoins.setEnabled(false);
watchForCoins.addActionListener(e -> {
    watchForCoins.setEnabled(false);
    ad.show(reward -> {
        // Server-side verification is configured above, so the network
        // posts the reward to your server and that is what credits the
        // user. This callback runs before anything has verified it, so
        // it is presentation only -- crediting here would pay twice.
        showRewardPending(reward.getAmount());
    });
});

ad.setAdListener(new AdListener() {
    public void onLoaded() {
```

```
        retryDelay = 1000;
        loadFailures = 0;
        // A rewarded ad is an opt-in format, so a loaded ad only enables
        // the offer. Showing it here would put a full screen ad in front
        // of a user who never asked for one.
        watchForCoins.setEnabled(true);
    }

    public void onDismissed() {
        // A shown ad is spent and a session cannot be shown twice, so
        // load the next one. Without this the offer is enabled once and
        // never again.
        ad.load();
    }

    public void onShowFailed(AdError error) {
        // Nothing was consumed, so put the offer back rather than
        // leaving it disabled for the rest of the screen.
        ad.load();
    }

    public void onFailedToLoad(AdError error) {
        // getCode() is provider specific and getDomain() says whose it
        // is: Codename One's own errors carry no domain, an adapter's
        // carry the SDK's. The numbers collide -- AppLovin reports -1
        // for an unspecified error and CODE_UNSUPPORTED is also -1 --
        // so read the constants only for a framework error. Those two
        // are genuinely permanent: an unsupported platform or a bad ad
        // unit id never becomes valid, and retrying them turns the
        // graceful no-ads path into a permanent timer.
        if (error.getDomain() == null
                && (error.getCode() == AdError.CODE_UNSUPPORTED
                    || error.getCode() == AdError.CODE_INVALID_REQUEST)) {
            return;
        }
        // A provider's code means nothing here, so treat it as possibly
        // transient -- bounded, so an unrecognized permanent failure
        // cannot retry for the life of the screen either.
        if (++loadFailures > 5) {
            return;
        }
        retryDelay = Math.min(retryDelay * 2, 60000);
        UITimer.timer(retryDelay, false, form, () -> ad.load());
    }
});
ad.load();
```

`RewardedInterstitialAd` has the same API but is shown on a transition rather than opt-in.

100.7. App open ads

App open ads are shown while the app is brought to the foreground. Let the manager and provider handle the foreground hook and freshness window for you:

```
AppOpenAd appOpen = new AppOpenAd("ca-app-pub-xxx/yyy");
AdManager.enableAppOpenAds(appOpen);

// enableAppOpenAds() loads the ad and asks the provider to show it when
// the app returns to the foreground. Whether that happens is up to the
// provider's adapter, so if yours does not implement the hook, drive it
// from the lifecycle instead -- start() runs on every foreground:
//
//     public void start() {
//         if (appOpen.isLoaded()) {
//             appOpen.show();
//         } else {
//             appOpen.load();
//         }
//     }
//
// Do one or the other, not both, or a provider that honours the hook
// shows two ads.
```

100.8. Native ads

Native ads let you render the advertiser's assets with your own components, so the ad matches the look and feel of the surrounding content. This is the format to reach for in content driven apps - a news or social feed, a store listing, a chat or a search results screen - where a banner feels bolted on but a row styled like the others fits in. The ad must still be clearly labelled (for example "Sponsored"):

```
if (NativeAdLoader.isSupported()) {
    new NativeAdLoader("ca-app-pub-xxx/yyy").load(null,
        ad -> feed.addComponent(buildSponsoredRow(ad)),  // your own layout
        err -> Log.p(err.toString()));
}
```

`NativeAd` exposes the headline, body, call-to-action, advertiser and rating that you bind to your own components. Native ad support is an optional provider capability; when the active provider doesn't support it, `NativeAdLoader` reports the format as unsupported.

100.9. Configuring the AdMob application id

The GMA SDK requires your per-app AdMob application id in the native project. Because it differs per app it's not baked into the library; set it with the standard build hints in your project's

`codenameone_settings.properties`:

```
codename1.arg.android.xapplication=<meta-data android:name="com.google.android.gms.ads.APPLICATION_ID" android:value="ca-app-pub-XXXXXXXX~YYYYYYYY"/>
codename1.arg.ios.plistInject=<key>GADApplicationIdentifier</key><string>ca-app-pub-XXXXXXXX~YYYYYYYY</string>
```

The SDK dependencies themselves (the GMA pod / Gradle dependency and the INTERNET permission) are declared by the `cn1-admob` library, so they're added automatically when the library is on the classpath.

100.10. Implementing a provider

Third party networks plug in by implementing `com.codename1.ads.spi.AdProvider` (and the optional `NativeAdProvider` capability) and calling `AdManager.registerProvider(…)` - conventionally from a static `install()` method. No framework or build-tool changes are required.

For tests and screenshots the framework ships a deterministic, network-free provider, `MockAdProvider` (in `cn1-ads-mock`), that renders fixed, labelled ads with stable sizes and colours.

Chapter 101. Analytics

The analytics API records how your application is used in the field. It's built around a small provider SPI: you register one or more providers with the `Analytics` entry point, then report screen views, events, user properties and crashes. The `Analytics` class fans every call out to all registered providers, but only after the matching consent has been granted. Consent is central to this API and is explained in Consent and privacy below.

Codename One ships several providers: a first-party service that reports into the Codename One cloud (with capabilities gated by your subscription tier), Google Analytics 4, Matomo (a privacy-first, self-hostable option), Firebase, and a logging provider for the simulator and tests. You can also write your own provider for any other backend.

The older `AnalyticsService` class still works but is deprecated. It now delegates to the API described here. See Migrating from AnalyticsService at the end of this chapter.

101.1. Registering providers

Register providers once, early in your app's lifecycle. Providers are plain objects — there is no reflection or service lookup, which keeps the mechanism safe under the obfuscation applied to release builds.

Once at least one provider is registered, report usage from anywhere in your app:

```
Analytics.screen("Home", null);

// Pick a name of your own. Do not send "purchase" yourself: Purchase
// emits that one for every completed receipt, so a manual copy counts
// the same transaction twice and skews the funnel. The automatic events
// are listed further down this chapter.
Analytics.event(AnalyticsEvent.create("tutorial_complete")
        .category("onboarding")
        .param("step", "checkout")
        .param("seconds", 42)
        .build());

Analytics.setUserProperty("plan", "pro");
Analytics.crash(throwable, "checkout failed", false);
```

`Analytics.crash` emits a lightweight exception event (for example GA4's `app_exception`) to whichever analytics backends you have registered, so exception counts appear next to your usage metrics. It's separate from Codename One Crash Protection (`com.codename1.crash.CrashProtection`), which is a dedicated pipeline that records full, symbolicated stack traces to the build cloud crash console for debugging. The two are independent: use Crash Protection to diagnose crashes, use `Analytics.crash` when you also want exception events in your analytics, and enable either or both.

101.2. Consent and privacy

The API is designed to help you comply with privacy regulations such as GDPR and CCPA. A `ConsentMode` controls what happens before the user makes an explicit choice. The default is `OPT_IN`: nothing is collected or transmitted until the application records consent.

`AnalyticsConsent.all()` grants every category and `AnalyticsConsent.none()` denies every category. The older `granted()` and `denied()` methods remain as aliases.

Consent is broken down by category, so you can honor granular choices — for example allowing crash reporting while declining behavioral analytics:

```
Analytics.setConsent(AnalyticsConsent.builder()
        .analytics(true)
        .crashReporting(true)
        .personalization(false)
        .build());
```

The consent choice is persisted, so it survives restarts. Screen views and events require the `analytics` category, crash reports require `crashReporting`, and `setUserId` requires `personalization`. Calls made without the matching consent are dropped.

101.2.1. Consent you already hold

If your application has already obtained consent through its own mechanism — a custom prompt, a third-party consent-management platform, an enterprise device-management policy, or a jurisdiction where you have determined consent isn't required — record it once at startup so reporting flows without a second prompt:

```
Analytics.setConsent(AnalyticsConsent.all());
```

You can also seed every category and then revoke just one with the builder, for example to allow analytics but not ad storage:

```
Analytics.setConsent(AnalyticsConsent.builder().all().adStorage(false).build());
```

If you would rather not gate at all, switch the default so collection is active unless the user withdraws it. This places the compliance responsibility on you as the integrator:

```
Analytics.setConsentMode(ConsentMode.OPT_OUT);
```

Note that the service records pseudonymous data rather than anonymous data. The client id described below is a persistent identifier stored on the device; it isn't tied to a real-world identity and the server discards full IP addresses, but storing and reading such an identifier for usage tracking is often treated as consent-requiring under GDPR and similar regimes. That's why opt-in is

the safe default. Relax it only when you are confident the change fits your use.

101.2.2. Client identity and erasure

Each device is identified by a pseudonymous client id. It's generated on first use and stored locally — it isn't derived from any hardware identifier. To honor an erasure request ("right to be forgotten"), reset it:

```
Analytics.resetClientId();
```

For the first-party service this can be paired with a server-side deletion of the previous id's data.

101.3. Automatic events

Codename One emits a few events for you, so the common funnels work without any wiring. Like every report these are consent-gated and do nothing until a provider is registered, so they're always safe.

Event	When it fires
`purchase_initiated`	`Purchase.purchase(sku)` is called — the start of the checkout funnel.
`purchase`	A purchase completes and its receipt is posted. The gap between this and `purchase_initiated` is your checkout drop-off.
`login`	A social login (`com.codename1.social.Login`) succeeds. The login provider class is reported in the `service` parameter.
`login_failed`	A social login fails, with the provider in `service` and the reason in `error`.
`share`	The native share sheet is invoked.
`invite_created`, `invite_shared`, `invite_share_dismissed`, `invite_opened`, `invite_install`, `invite_converted`	The invite funnel, under the `referral` category. See Section 101.6, "Invite a friend".

You can add your own events at any time with `Analytics.event(…)`; these built-ins simply save you the boilerplate for the most common funnels.

101.4. Built-in providers

101.4.1. Codename One first-party service

`CodenameOneAnalyticsProvider` batches events and posts them to the Codename One cloud, which aggregates them into the reports shown in the developer console. App identity is read from the build-injected properties, so no API key is embedded in your app.

The capabilities you actually get — screen views, custom events, user properties, retention window, raw export — are gated server-side by your subscription tier. Higher tiers retain data longer and unlock richer reporting.

101.4.2. Google Analytics 4

`GoogleAnalyticsProvider` uses the GA4 Measurement Protocol. Create it with a measurement id (`G-XXXXXXXX`) and a Measurement Protocol API secret from the GA4 admin console:

```
Analytics.addProvider(new GoogleAnalyticsProvider("G-XXXXXXXX", "API_SECRET"));
```

Screen views are sent as the GA4 `screen_view` event and crashes as `app_exception`.

101.4.3. Matomo

`MatomoAnalyticsProvider` targets Matomo (formerly Piwik) through its HTTP tracking API. Matomo can be self-hosted and supports IP anonymization, which makes it a good fit for privacy-sensitive deployments:

```
Analytics.addProvider(new MatomoAnalyticsProvider("https://matomo.example.com", 1));
```

101.4.4. Firebase

`FirebaseAnalyticsProvider` forwards to the native Firebase Analytics SDK on Android and iOS. Register it like any other provider:

```
Analytics.addProvider(new FirebaseAnalyticsProvider());
```

Firebase reports only from a native Android or iOS build, and only when two things are in place. Without both, `FirebaseAnalyticsProvider` does nothing — which is why it's always safe to register, including in the Codename One simulator and the desktop build, where it's a no-op.

First, add the Firebase configuration file for your app (downloaded from the Firebase console) to the matching platform module's resources:

- Android: `android/src/main/resources/google-services.json`
- iOS: `ios/src/main/resources/GoogleService-Info.plist`

These are Maven project paths. The `native/android` and `native/ios` directories from the old Ant projects no longer apply.

Second, enable the SDK with build hints:

```
codename1.arg.android.firebaseAnalytics=true
codename1.arg.ios.firebaseAnalytics=true
```

These hints add the Firebase Analytics Gradle dependency (Android) and the `Firebase/Analytics` pod (iOS), and make the build generate the native bridge that `FirebaseAnalyticsProvider` talks to.

You need both the configuration file and the matching build hint. If either is missing the provider stays a no-op and no events are sent. Firebase events never show up in the Codename One simulator or a desktop run — verify on a real device (or a platform emulator/simulator) with the Firebase project configured for the build.

101.4.5. Logging provider

`LoggingAnalyticsProvider` logs every call instead of sending it anywhere. It's the recommended default in the simulator and is used as the backing provider in tests.

101.5. Writing your own provider

Implement `AnalyticsProvider`, or extend `AbstractAnalyticsProvider` and override only the calls you support. The `Analytics` class handles consent gating and fan-out for you, so a provider just forwards the data to its backend.

The `init(AnalyticsContext)` callback hands you the app name, version, platform, locale and the pseudonymous client id. `onConsentChanged(AnalyticsConsent)` lets a provider reconfigure when the user updates consent. `supports(AnalyticsCapability)` lets tooling introspect which features a provider offers.

101.6. Invite a friend

`com.codename1.analytics.invite` follows an invitation through to what it caused: who sent it, who installed because of it, and what that invited cohort went on to spend. It replaces what Firebase Dynamic Links and Firebase Invites used to do, both of which have been shut down.

101.6.1. Sending an invite

```
Invite invite = Invites.create(InviteRequest.create()
        .campaign("spring")
        .channel("share_sheet")
        .title("Join me")
        .description("I am using this and thought of you.")
        .build());
Invites.share(invite, "Come and try this with me");
```

`Invites.create` returns immediately and works with no network at all, so the share sheet never waits on a server — the code is generated on the device and registered with the link service in the background. `title` and `description` drive the preview card the link shows in a messaging app.

`Invites.share` reports `invite_shared` only when the platform confirms the user shared; a dismissed sheet reports `invite_share_dismissed`. If you send the invite through your own user interface

instead, call `Invites.reportShareResult` from your share callback so the funnel still records it.

101.6.2. Receiving an invite

```
Invites.setInviteListener(new InviteListener() {
    public void inviteReceived(InviteAttribution attribution) {
        // attribution.getCampaign(), getCode(), getPayload()
        if (Invites.MATCH_APP_CLIP.equals(attribution.getMatchType())) {
            // An iOS App Clip received the link and handed the code
            // over. Exact, like every other match type.
        }
    }

    public void attributionUnavailable(String reason) {
        // The ordinary outcome: most installs are not invited.
    }
});
Invites.checkForInvite();
```

Call `checkForInvite()` from `start()`. It's a pull rather than a callback on purpose: Android delivers a link by replacing the activity intent and iOS by setting a property, and reading the launch argument is the one path that behaves the same on both. An answer that arrives before you register a listener — which happens routinely on a cold launch from a link — is held and delivered when you register.

Exactly one of the two listener methods is called per install, and neither is called again on later launches.

101.6.3. Closing the funnel

```
// Once the invited user reaches whatever the invite existed for.
Invites.conversion("signup");
Invites.conversion("subscribed", 9.99, "USD");
```

When attribution resolves it's also written as persistent analytics dimensions (`cn1_campaign`, `cn1_channel`, `cn1_invite_code`, `cn1_invite_match`). Every later event carries them, including the `purchase` event the framework already emits for you, so revenue and lifetime value per campaign come out of the reports you already have without any extra wiring. The `cn1_` prefix is reserved — don't use it for your own dimensions.

101.6.4. How exact the answer is

`InviteAttribution.getMatchType()` tells you how the attribution was made, and the three answers aren't equally trustworthy:

Match type	What it means
`MATCH_DIRECT`	The link opened an app that was already installed. Exact.
`MATCH_REFERRER`	The invite code travelled through the app store and came back verbatim. Exact. This is the Android path.
`MATCH_APP_CLIP`	An iOS App Clip received the invite link and handed the code to the app the person then installed. Exact. This is the iOS path.

Every match type is exact. The App Store carries no referrer parameter of its own, so on iOS the code travels a different road than it does on Android: tapping the invite link offers an App Clip, the clip is launched by the link itself and so receives the code exactly, and it leaves that code where the full app can read it after installation. Nothing is matched, estimated or guessed, and a referral bounty can be paid on any of these.

`Invites.setAttributionWindow(0)` stops a deferred lookup being started at all — neither the Play install referrer nor the App Clip handoff is read. An exact code the device is already holding, one that arrived on a link, is still claimed: there is nothing to defer about it.

101.6.5. Consent

Everything reported here is gated on the analytics consent category, and nothing is transmitted until consent is granted.

Nothing at all is collected about someone who only taps a link. An earlier design wrote a coarse device profile to local storage on first launch — OS version, hardware model, language, screen size — so an iOS install could be matched to a click, and the server kept a hashed fingerprint of the visitor's address for seven days to match it against. App Clips made all that unnecessary: the clip is handed the code by the link, so there is nothing to match and nothing to keep.

`Analytics.resetClientId()` erases the invite attribution along with the identity, so an erasure request can't leave a fresh pseudonymous id linked to the same inviter.

101.6.6. What the build does for you

Referencing this package makes the build wire the platform side: an `autoVerify` App Links intent filter on Android, an associated domain on iOS, and the Play Install Referrer dependency. An app that only reports analytics gets none of it.

On iOS it also generates the App Clip, because there is no attribution without one. The clip is a separate binary embedded in your app: a few hundred lines of UIKit that show your app's name, offer to install it, and record the invite code the link handed them. It's not a Codename One application and doesn't run your code. You don't write it, open it or maintain it.

Three things the generated clip needs from you, and each fails in its own way:

- The App Store identifier of your app, in `ios.invite.appStoreId`. Without it the clip still records the code, it simply shows no install sheet — which is the right behavior before your first release, when the app doesn't exist in the store yet.
- An App Group registered on your developer account. The build derives one from your package

name and adds it to `ios.app_groups`; override it with `ios.invite.appGroup` if you already have one. A group that isn't registered signs cleanly and the clip and the app can then never reach each other, which is the failure with no symptom.

- An App Clip enabled on your App ID, alongside Associated Domains.
- An Advanced App Clip Experience registered in App Store Connect for your invite link prefix. Codename One authorizes your clip for the domain; what maps a particular link to a particular clip is that experience, and until it exists tapping the invite link shows no clip card at all. The console shows the prefix to register once invites are switched on.

Set `ios.invite.appClip` to `false` only if you ship an App Clip of your own. The build then generates no clip, but your app still gets the shared App Group and the reader, so a clip of yours that writes the handoff is still picked up.

On Android, App Links verification checks the certificate the installed APK is signed with. Under Play App Signing that's Google's key, not your upload key, so add the app-signing SHA-256 from the Play Console to `android.invite.signingFingerprint`. Without it verification fails on every Play install, the link opens the browser instead of your app, and nothing reports an error.

101.7. Migrating from AnalyticsService

The deprecated `AnalyticsService` continues to compile and now routes through this API. To preserve its historical always-on behavior — which predates the consent model — `AnalyticsService.init` switches the default consent mode to `OPT_OUT`. New code should migrate to `Analytics` and manage consent explicitly:

Deprecated call	Replacement
`AnalyticsService.init(agent, domain)`	`Analytics.addProvider(new GoogleAnalyticsProvider(id, secret))`
`AnalyticsService.visit(page, referer)`	`Analytics.screen(page, referer)`
`AnalyticsService.sendCrashReport(t, msg, fatal)`	`Analytics.crash(t, msg, fatal)`
subclassing `AnalyticsService`	implement `AnalyticsProvider`

Chapter 102. Distributed tracing with OpenTelemetry

OpenTelemetry tracing follows one user action from the app through every service it touches. When the user taps the checkout button, the trace shows the tap, the requests the app made, what the backend did with each one and which database query was slow, as one timeline. Codename One produces these traces in the standard OTLP format, so any OpenTelemetry collector or tracing backend can display them.

102.1. Turning it on

Put `@OpenTelemetry` on the main class:

```
@OpenTelemetry(relay = "https://api.example.com",
        serviceName = "shop-app")
public static class ShopApp extends Lifecycle {
}
```

The build generates a bootstrap that installs `com.codename1.telemetry.Telemetry` before the app starts. From then on every `ConnectionRequest` is a span, and so is every call through a REST, gRPC-Web or GraphQL client the build generates, because they all go through `ConnectionRequest`. Each request also sends the W3C `traceparent` header, so a server that understands trace context continues the app's trace instead of starting a new one. The Codename One backend understands it (see the backend chapter), and so does any service instrumented with OpenTelemetry.

An app without the annotation doesn't reference the telemetry classes, so they aren't part of its build.

102.2. Where the spans go

There are two ways to reach a collector, and the annotation takes one of them.

`relay` sends the spans to the app's own Codename One backend, started with `cn1.otel.relay=true`. The backend adds the collector's credentials and forwards the spans. This is the recommended setup: nothing secret ships in the app, and a web build never has to reach a collector on another origin.

`endpoint` sends the spans straight to an OTLP/HTTP collector:

```
@OpenTelemetry(
        endpoint = "https://abc12345.live.dynatrace.com/api/v2/otlp",
        headers = "Authorization: Api-Token dt0c01.XXXX")
public static class ShopApp extends Lifecycle {
}
```

The header is compiled into the app, and anyone who installs the app can read it. Use a token that can ingest traces and do nothing else.

Direct exports are binary protobuf by default, which every collector accepts and some, Dynatrace among them, require. Set `protobuf = false` for JSON. Exports to a relay are always JSON, and the backend re-encodes them for its collector.

102.3. Timing what the user did

A request made on its own is a trace of its own. To group the requests that one user action causes, run the action inside a span:

```
Telemetry.run("checkout", () -> cart.submit());
```

Requests queued while `checkout` is running become its children, and so does the backend work they cause. `Telemetry.startSpan` returns a span you end yourself, for work that starts in one place and finishes in another.

102.4. Sampling and privacy

`sampleRatio` records a fraction of new traces, from 0 to 1. A trace the app decides not to record still sends `traceparent`, flagged as not sampled, and the backend's default sampler follows the app's decision. Each trace is therefore recorded completely or not at all.

A span records the request's method, host, path, and status. It never records the query string, request bodies or response bodies.

Whether trace data needs the user's consent depends on what the app records and where it sends it, so the app decides. With `requireAnalyticsConsent = true` on the annotation, or `requireAnalyticsConsent(true)` on `TelemetryConfig`, tracing runs only while the user has granted analytics consent through the `Analytics` API (see Chapter 101, *Analytics*). Without that consent, requests are sent exactly as they would be with telemetry off: no span and no `traceparent` header. Spans that were buffered before the user withdrew consent are discarded, not exported. Until the user makes a choice, the analytics consent mode decides, and the default `OPT_IN` mode means no tracing.

102.5. The web build

`traceparent` isn't one of the request headers a browser sends across origins without asking. When a web app adds it to a request for another origin, the browser first sends a CORS preflight, and a server that doesn't allow the header fails the request. The web build therefore sends trace context only to the relay's host and to the hosts listed in `propagateTo`. The other platforms send it to every host.

102.6. Configuring it in code

The annotation is a shortcut for this call, which an app can also make itself, for example to choose the endpoint at run time:

```
Telemetry.install(new TelemetryConfig()
        .relay("https://api.example.com")
        .serviceName("shop-app")
        .sampleRatio(0.2));
```

Spans are exported in batches, when 32 have ended or every ten seconds. Call `Telemetry.flush()` when the app is paused, because spans still in memory are lost if the process is reclaimed.

Chapter 103. App Review & Feedback

Both Apple and Google provide an in-app review prompt that lets the user rate your app without leaving it. Asking for a review at the right moment is one of the most effective ways to improve your store rating. Codename One exposes this through the `com.codename1.appreview.AppReview` API, which uses the native review sheet (`SKStoreReviewController` on iOS, the Play In-App Review API on Android) when it's available and falls back to a Codename One drawn rating widget everywhere else (the simulator, desktop, the web target and older OS versions).

The native prompt is the store-sanctioned way to ask for a review, so prefer it over a hand-rolled dialog: the operating system controls how often it appears and throttles excessive prompts, which keeps your app within store policy.

103.1. Asking for a review

The simplest usage is a single call at a moment that makes sense in your app — typically right after the user completed something rewarding (finished a level, saved a document, completed an order):

```
// Configure the store URL and the feedback route first -- the next
// sample does that. Where no native review prompt exists this opens the
// fallback widget, and without them a high rating opens nothing while
// low-rating feedback goes nowhere. The flow still records itself as
// completed, so the user is never asked again.
AppReview.getInstance().requestReview();
```

`requestReview()` shows the native review sheet when the platform supports it. On platforms without a native prompt it shows the built-in rating widget instead. You decide the timing.

103.2. The engagement scheduler

Rather than picking the moment yourself, you can let `AppReview` decide based on simple engagement heuristics: how many times the app was launched, how long ago it was installed, and how long since it last asked. Configure it once (for example in your app's `init` or `start` method) and call `registerSession()` on every launch — but after a form is showing, not during `init`. It prompts as soon as the thresholds are met, and on a platform with no native prompt that dialog is a `Sheet`, which needs something to show on:

```
// When no native review prompt is available the dialog falls back to
// opening this URL, and that happens on the simulator, the desktop and
// the web target as well as on a device, so every target needs an answer
// rather than everything-except-Android getting the Apple listing.
String storeUrl;
if ("ios".equals(CN.getPlatformName())) {
    storeUrl = "https://apps.apple.com/app/id0000000000";
} else if ("and".equals(CN.getPlatformName())) {
    storeUrl = "https://play.google.com/store/apps/details?id=com.example.app";
```

```
} else {
    storeUrl = "https://example.com/app";   // no store listing to send them to
}

AppReview.getInstance()
        .setMinimumLaunches(5)          // at least 5 launches
        .setMinimumDaysInstalled(3)     // and installed at least 3 days
        .setDaysBetweenPrompts(30)      // never nag more than monthly
        .setStoreUrl(storeUrl)
        .setSupportEmail("support@example.com");

// registerSession() prompts as soon as the thresholds are met, and the
// fallback dialog is a Sheet, which throws when no form is current. That
// is exactly the state during init, so configure there and record the
// session once a form is up.
form.addShowListener(new ActionListener() {
    public void actionPerformed(ActionEvent e) {
        // Once per launch. registerSession() increments the launch
        // counter, and a show listener fires again every time the user
        // navigates back here -- which would reach the thresholds after
        // a few screens rather than after the launches you configured.
        form.removeShowListener(this);
        AppReview.getInstance().registerSession();
    }
});
```

`registerSession()` records the launch and, once the thresholds are met and the user hasn't already rated or opted out, prompts. The bookkeeping (launch count, install date, last-prompt time and a completion flag) is stored in Preferences [https://www.codenameone.com/javadoc/com/codename1/io/Preferences.html] so it survives restarts. Once the user rates the app or chooses to stop, `AppReview` stops prompting. Call `reset()` to clear this state.

You can combine both styles — use `registerSession()` for the automatic cadence and still call `requestReview()` from a "Rate this app" menu item.

103.3. Smart feedback split

The fallback widget is presented as a bottom sheet, so the user can swipe it away instead of dismissing a blocking dialog. It asks for a star rating and then routes the user based on the result. A high rating (at or above the threshold set by `setHighRatingThreshold(int)`, four stars by default) sends the user to your store listing. A low rating opens a private feedback step instead, so unhappy users reach you directly rather than posting a one-star public review.

Figure 380. The Codename One fallback rating sheet, shown when no native review prompt is available

By default the low-rating feedback is collected through an e-mail to the address passed to

`setSupportEmail(String)`. To deliver feedback through your own backend, register a `FeedbackListener`:

```
AppReview.getInstance().setFeedbackListener(new FeedbackListener() {
    public boolean lowRating(int rating) {
        // return true to present your own feedback UI and suppress the
        // built-in e-mail composer
        return false;
    }

    public void feedback(int rating, String text) {
        // called with the free text the user typed in the built-in composer
        myBackend.submitFeedback(rating, text);
    }
});
```

103.4. How the platform decides

`AppReview` checks `CN.isNativeInAppReviewSupported()` to choose between the native prompt and the fallback sheet. On Android the native path is active only when the app references the app-review API — the build adds the Play In-App Review library in that case, so apps that never ask for a review carry no extra dependency. On iOS the StoreKit review controller is linked the same way, only when the API is used.

The native prompts are drawn by the operating system, so this guide can't show them as Codename One screenshots. On iOS the prompt is the StoreKit rating panel: a star selector the system overlays on your app, submitted without leaving it. On Android it's the Play In-App Review card that slides up from the bottom. Both are styled and rate-limited by the OS — you can't theme them, force them to appear, or read the outcome, which is why the fallback sheet shown above renders on every other platform.

The native review controllers hide whether the user submitted a rating, and may decline to show the prompt at all based on their own quotas. Treat a review request as best-effort; never block your UI waiting for a result.

Chapter 104. Crash Protection

Crash Protection is an opt-in service that captures uncaught exceptions in your shipping app and files them as deduplicated issues on your GitHub repository. Symbolicated stack traces, scrubbed messages, and a per-bug counter are all recorded server-side; you triage from GitHub Issues like any other bug.

The service is available on the **Pro** and **Enterprise** subscription tiers. See the pricing page [https://www.codenameone.com/pricing.html] for current limits.

104.1. What gets stored where

Three things move when you opt in:

1. **Symbol bundles** (ProGuard `mapping.txt` on Android, dSYM on iOS, debug-info-bearing binaries on Mac/Linux/Win32). Uploaded by the Codename One build server after each successful release build. Stored compressed; subject to per-tier storage quota.
2. **Crash reports** (one per device occurrence). Sent by the app at runtime via `CrashProtection.capture(t)` or the automatic EDT error handler. Scrubbed on the device before transmission (see *Privacy* below).
3. **GitHub issues** — the actual triage surface. One issue per unique crash fingerprint. Subsequent occurrences of the same fingerprint bump a counter on the issue body rather than filing duplicates.

Codename One never reads or persists the unscrubbed message body. The crash data store is the issue tracker on your repository, not a separate database. The service keeps only the minimum lookup state needed to find the right issue on the next occurrence.

104.2. Opting in

Add this line to your app's `codenameone_settings.properties`:

```
codename1.arg.crashProtection.enabled=true
```

The `codename1.arg.` prefix marks it as a build hint — when the property reaches the Codename One build server, it tells the build to upload the symbol bundle (PDB / dSYM / .debug / mapping.txt) to the crash-protection service alongside the normal release artifact.

104.2.1. Runtime hook

In your `Lifecycle.init`, with the opt-in kept where the user gives it:

```
public void init(Object context) {
    // Lifecycle.init sets the theme, the global Toolbar, the network thread
    // count and the network error listener, so an override that skips it
```

```
    // loses all of that
    super.init(context);
    // install() only registers the handler; nothing is sent while the
    // service is disabled, and disabled is the default
    CrashProtection.install();
}

/// Call this from the flow where the user agrees to send crash reports.
/// Doing it in init() would opt every user in on each launch, drain the
/// buffered reports, and undo an opt-out they had already made.
void onUserAcceptedCrashReporting() {
    CrashProtection.setEnabled(true);
}
```

`install()` registers the EDT error handler and (on Android) wires `Thread.UncaughtExceptionHandler`. It's idempotent and a no-op on the simulator. `setEnabled(boolean)` controls whether captured crashes actually get sent to the server — the captured payload is always persisted locally first, so `setEnabled(true)` after the fact drains the buffer.

You can also report a caught-but-noteworthy exception with `CrashProtection.capture(e)`.

104.3. Per-platform opt-out

Sometimes one platform's symbols are noisy or you don't ship that target. Disable a platform with:

```
codename1.arg.crashProtection.and.enabled=false
codename1.arg.crashProtection.ios.enabled=false
codename1.arg.crashProtection.mac.enabled=false
codename1.arg.crashProtection.linux.enabled=false
codename1.arg.crashProtection.win.enabled=false
```

Setting one of these to `false` makes `CrashProtection.install()` a no-op at runtime on that platform AND skips the build-time symbol upload for it. Setting to `true` (or leaving unset) keeps the platform enabled.

The runtime check uses `Display.getInstance().getPlatformName()`. Supported values: `and`, `ios`, `mac`, `linux`, `win`, `javascript`, `javase`.

104.4. Tier limits

Tier	Storage quota	Symbol retention
Pro	100 MB compressed	3 weeks
Enterprise	500 MB compressed	6 weeks

Symbol bundles are gzipped before storage. `mapping.txt` files typically compress ~10x; dSYMs ~2x. The quota admits several recent builds per app for a typical developer.

When a new symbol upload would push you over the quota, the build's symbol step is rejected with HTTP 413 (the build itself succeeds). You can free space from the **Tracked apps** tab in the console — delete an old build's symbols or remove a whole app's enrollment.

104.5. Privacy

104.5.1. What's PII

PII is short for *personally identifiable information*: any field in a crash payload that could be traced back to a specific user. The pieces of a Java exception message that are typically PII are email addresses, account numbers, phone numbers, IP addresses, full URLs to authenticated endpoints (with session tokens in the query string), and the contents of user input fields that ended up in the message via string concatenation. Stack trace frames are class / method / file / line — they describe code paths, not users, so they're not PII.

The Codename One crash-protection client runs incoming messages through a scrubber before transmission. The scrubber can be replaced with a stricter rule set if your application's exception messages routinely carry data you don't want to leave the device.

104.5.2. What gets sent

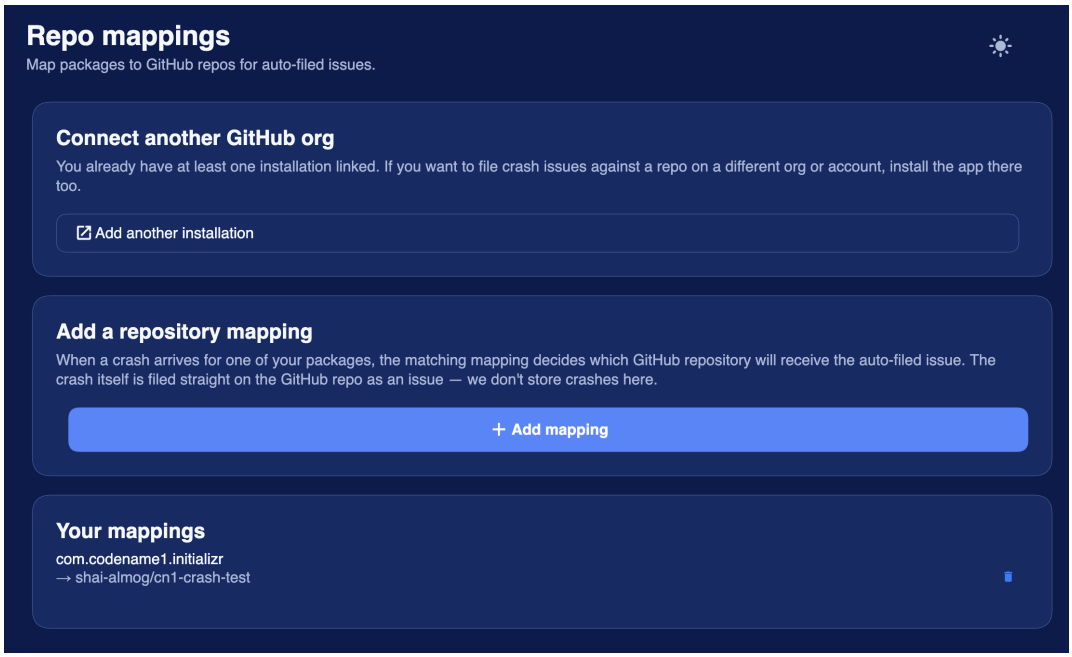
`CrashReportPayload` carries these fields. The marked one goes through `PiiScrubber` before transmission.

- `eventId` (UUID, used for idempotent dedup)
- `buildKey` (anti-spoofing token; matched against the uploaded symbol bundle)
- `packageName`, `appVersion`, `platform`, `osVersion`, `locale`
- `exceptionClass`
- `messageScrubbed` — **scrubbed**
- `frames[]` — class / method / file / line / `native` flag per frame
- `rawStack` — the pre-rendered Java stack captured via `printStackTrace`, including the cause chain and any verbatim platform formatting. It complements the structured `frames` (which `getStackTrace()` now populates on every port) and is the readable trace on the JavaScript port, where the JavaScript engine's stack has no structured frames
- `traceFormat` — how the server should read `rawStack`: `structured`, `parparvm-text`, `js-error`, or `none`. Derived, never guessed
- `mappingId` — the id of the obfuscation mapping a hardened build shipped with, so a report ties to the exact mapping even if a rebuild reused the build key; empty for unhardened builds
- `hardenLevel` — the hardening level of the build, so the server can give a specific reason for an unretraceable report
- `clientTs`

104.6. Crash reports from a hardened build

When a build is hardened (see Chapter 94, *App Hardening*), the build server retains the cross-platform obfuscation mapping and symbolicates incoming reports against it, so a hardened build's crashes still land as readable, correctly lined issues. Two things follow from how the mapping is retained: a report whose mapping has aged out of retention can no longer be retraced, and a locally hardened build — whose mapping never reached the server — can't be symbolicated at all. The ParparVM ports (iOS, tvOS, watchOS, macOS, Windows, Linux) report structured `frames`, and also carry the pre-rendered trace in `rawStack`; the JavaScript port has no structured frames, so its report relies on the `rawStack` JavaScript engine stack (`js-error`), symbolicated best-effort through the source map.

104.6.1. Default scrubber rules



`PiiScrubber` applies these by default:

- Email addresses: redacted to the first 3 characters of the local part. `joe.smith@example.com` becomes `joe***@example.com` (the full domain is preserved so the issue still tells you *which* provider was involved).
- Long digit runs: any run of 6 or more consecutive digits collapses to `[num]`. Catches phone numbers, order IDs, account numbers, ZIP+suffix, etc.
- URLs aren't scrubbed by default. Override the scrubber if your app's URLs carry session tokens.

Override `scrubMessage(String)` or `scrubFrame(String, String)` on a `PiiScrubber` subclass and register via `CrashProtection.setScrubber(myScrubber)` if you need stricter rules.

104.7. Mapping packages to repositories

In the console at https://cloud.codenameone.com/console/index.html, open **Repo mappings**:

Click **Add mapping** and supply:

1. **Package name** — the exact value from `codenameone_settings.properties`.
2. **Installation** — which authorized GitHub App installation should file the issue. Only shown if you have more than one installation linked.
3. **Repository** — pick from the dropdown of the installation's repos.

You must have authorized the Codename One Crash Protection GitHub App for at least one of your repositories first. The mapping page renders a button labeled **Connect on GitHub** that opens the App install flow on github.com. The post-install redirect brings you back to the same page with the installation already loaded; if you already have one installation and want to add another (for example a second GitHub org), the **Connect another GitHub org** card lets you link an additional one without disturbing the existing mapping.

104.8. Setup checklist

1. Pro or Enterprise subscription.
2. Add `codename1.arg.crashProtection.enabled=true` to `codenameone_settings.properties`.
3. Call `CrashProtection.install()` in `Lifecycle.init`. Call `CrashProtection.setEnabled(true)` once you have the user's consent.
4. Build your app for release. The Codename One build server uploads the symbol bundle automatically.
5. Open the console, go to **Repo mappings**, click **Connect on GitHub**, and install the App on the repo you want crashes to land in.
6. Add a mapping for your package → repo.
7. Crashes from your release builds will now appear as GitHub issues on the mapped repo.

Testing, performance and debugging

Chapter 105. Testing with JUnit 5

Codename One ships two compatible test frameworks. `com.codename1.testing.AbstractTest`, driven by the `cn1:test` Maven goal, is the only way to run tests on a physical iOS or Android device — JUnit Jupiter isn't available on ParparVM. The JavaSE simulator also exposes a standard **JUnit 5** integration so you can write tests that run through Surefire and your IDE's native test runner; those tests run only in the simulator JVM but in exchange give you reflection, mocking libraries, and the rest of the standard Java testing ecosystem.

Both styles coexist in the same project under `common/src/test/java`. You pick per test class. This chapter explains when to reach for which, walks through the JUnit annotations, and shows how the two frameworks compare side by side.

105.1. When to use JUnit versus AbstractTest

Framework	Use it for	Don't use it for
`AbstractTest` + `cn1:test`	Tests that must execute on a real device (`mvn cn1:test -Dtarget=ios` / `-Dtarget=android`). Tests that must compile under the strict Codename One device subset (no reflection, no `java.net.http.*`, no `java.nio.file.*`).	Tests that need reflection, Mockito, AssertJ, parameterized data sets, `assertThrows`, or anything else that lives outside the device subset.
`@CodenameOneTest` (JUnit 5)	Simulator-only tests. Anything that wants a full JVM at test time — reflection, mocking libraries, parameterized tests, IDE green-bar integration, `mvn test -Dtest=Foo#bar` filtering, `@BeforeEach`/`@AfterEach` lifecycle methods.	Anything that must also run on a device — JUnit Jupiter isn't available on ParparVM.

The two runners discover disjoint sets of test classes (cn1:test looks for `com.codename1.testing.UnitTest` implementers; Surefire looks for `@Test`-annotated methods), so a project can mix both. `mvn install` runs Surefire during the `test` phase and `cn1:test` from the javase module's `test` profile in the same phase — you don't lose either test pass.

105.2. Dependencies

The cn1app archetype generates a `common/pom.xml` and `javase/pom.xml` that already pull in `junit-jupiter` and `codenameone-javase` at test scope. If your project predates that wiring, add these dependency blocks yourself:

Listing 25. common/pom.xml

```
<dependencies>
    <dependency>
        <groupId>com.codenameone</groupId>
        <artifactId>codenameone-javase</artifactId>
```

```
        <scope>test</scope>
    </dependency>
    <dependency>
        <groupId>org.junit.jupiter</groupId>
        <artifactId>junit-jupiter</artifactId>
        <version>5.9.3</version>
        <scope>test</scope>
    </dependency>
</dependencies>
```

Listing 26. javase/pom.xml

```
<dependency>
    <groupId>org.junit.jupiter</groupId>
    <artifactId>junit-jupiter</artifactId>
    <version>5.9.3</version>
    <scope>test</scope>
</dependency>
```

Tests live in `common/src/test/java`. Surefire only runs from the `javase` module — the `common` module keeps Surefire skipped (`<skipTests>true</skipTests>`) to avoid running each test twice, since `javase/pom.xml` mounts the same sources via `<testSourceDirectory>${project.basedir}/../common/src/test/java</testSourceDirectory>`.

105.3. A minimal JUnit test

Run with:

```
mvn -pl javase test                                      # all JUnit + cn1:test
mvn -pl javase test -Dtest=GreetingFormTest              # one class
mvn -pl javase test -Dtest=GreetingFormTest#formShowsExpectedTitle   # one method
```

105.4. `@CodenameOneTest`

A class-level meta-annotation equivalent to `@ExtendWith(CodenameOneExtension.class)`. The extension does four things:

1. If `GraphicsEnvironment.isHeadless()` is true, throw `TestAbortedException` from `@BeforeAll`. JUnit reports the class as **skipped** rather than failed, and the Display singleton is never left half-initialized — so subsequent test classes in the same JVM aren't poisoned. This makes JUnit-style Codename One tests safe to run on a headless CI runner; they simply skip.
2. Boot `Display` once per JVM via `Display.init(null)`. The call is idempotent, so multiple `@CodenameOneTest` classes share one Display instance for the rest of the test run.
3. Apply any visual-config annotations (`@Theme`, `@DarkMode`, `@LargerText`, `@Orientation`, `@RTL`, `@SimulatorProperty`) on the EDT in one batch before each test, followed by a single theme refresh.

4. Dispatch `@RunOnEdt` test methods through `CN.callSerially` and rethrow their exceptions on the JUnit thread so stack traces stay clickable in IDEs.

105.5. @RunOnEdt

Place on a method (or on the class for all tests) when the body mutates UI state.

Class-level `@RunOnEdt` also routes `@BeforeEach`/`@AfterEach` methods through the EDT. Method-level `@RunOnEdt` is scoped to that one `@Test`.

Tests that only exercise pure model or utility code can omit `@RunOnEdt` and run on the JUnit worker thread — they're faster because nothing pumps the EDT.

105.6. @SimulatorProperty / @SimulatorProperties

Set a property visible to the simulator before the test runs.

The `scope` field selects where the value lands:

Scope	Where	When applied
`DISPLAY` (default)	`Display.getInstance().setProperty(name, value)`	After Display init. Use for properties your app reads via `Display.getProperty(…)`.
`SYSTEM`	`System.setProperty(name, value)`	Before Display init (class-level only). Use for things the simulator reads at startup, for example `java.awt.headless`. Method-level SYSTEM properties are ignored since Display is already up by the time `@BeforeEach` runs.

The JavaSE port compiles at source 1.7, which predates `@Repeatable`. To set more than one property on the same target, wrap multiple `@SimulatorProperty` entries inside `@SimulatorProperties({…})` rather than repeating the annotation directly.

105.7. @Theme

Loads a base theme resource and installs it through `UIManager.setThemeProps`, then triggers a refresh. The annotation accepts either of two mutually exclusive inputs.

By native theme. Use the `NativeTheme` enum for the themes bundled into the simulator jar — the same set the simulator's **Simulate** > **Native Theme** menu offers:

The enum carries the resource path (`NativeTheme.IOS_MODERN.resourcePath()` returns `/iOSModernTheme.res`) and the simulator-menu label (`displayName()`), so test reports can render the same name a user sees in the simulator UI.

By resource path. For app themes shipped under `src/main/resources` or `src/test/resources`, point `value` at the `.res` file with a leading slash:

If both `nativeTheme` and `value` are set, `nativeTheme` wins. If neither is set, the annotation is a no-op.

105.8. @DarkMode

Toggles dark/light mode via `Display.setDarkMode(Boolean)` and refreshes the active form.

105.9. @LargerText

Sets the accessibility text-scale multiplier — the same knob exposed by the simulator's **Simulate → Larger Text** submenu. Useful for catching layout regressions at accessibility font sizes.

`scale = 1.0f` restores the default size; common values mirror the menu's `1.3f` / `1.6f` / `2.0f` presets.

105.10. @Orientation

Forces the simulator into portrait or landscape for the test.

This calls a non-persisting setter on `JavaSEPort` and sets an explicit-portrait flag honored by `Display.isPortrait()` — so unit-test JVMs (where the canvas inherits the host window's full size and would otherwise read landscape on every wide screen) get the expected orientation back.

105.11. @RTL

Flips the look-and-feel into right-to-left mode (Arabic, Hebrew) via `UIManager.getInstance().getLookAndFeel().setRTL(…)`. The active form is revalidated so existing layouts reflow before the test body asserts.

105.12. Annotation resolution

When the same annotation appears at both the class and the method level, **method wins**. Annotations the method doesn't override are inherited from the class. Annotations that appear on neither leave Display state alone — the extension never resets a knob the caller didn't ask for. Use `@AfterEach` for cross-test cleanup if a class must leave the simulator pristine for the next one.

105.13. EDT semantics

`@RunOnEdt` dispatches the test body through `CN.callSerially(…)` and uses a latch with `wait/notify` to block the JUnit worker thread until the EDT-side runnable finishes or `timeoutMillis` elapses. Throwables from inside the EDT runnable are captured and rethrown on the JUnit thread so the assertion stack trace lands in the IDE as if the test had been invoked directly.

Without `@RunOnEdt`, the test body runs on the Surefire worker thread — fine for pure model assertions, broken for UI mutation. Forms, components, and `UIManager` are EDT-confined; touch them off the EDT and you get sporadic deadlocks and rendering glitches.

105.14. Headless behavior

`Display.init(null)` eventually calls `JavaSEPort.init(null)`, which constructs a `javax.swing.JFrame` to host the simulator canvas. JFrame construction in a headless JVM throws `HeadlessException` immediately. Therefore:

- **Local dev (macOS / Windows / Linux desktop)**: works out of the box.
- **CI with an X server or Xvfb**: works — wrap your build with `xvfb-run mvn test` if the runner is otherwise headless.
- **CI without DISPLAY, or with explicit `-Djava.awt.headless=true`**: every `@CodenameOneTest` class aborts via `TestAbortedException` from `@BeforeAll`. JUnit reports the class as **skipped**, not **failed**, and crucially the Display singleton is never left half-initialized — so subsequent test classes in the same JVM aren't poisoned.

This is why the framework's internal `CodenameOneExtensionTest` (in the Codename One sources) carries `@DisabledIfSystemProperty(named = "java.awt.headless", matches = "true")`. The extension catches the headless case AWT detects automatically (Linux without DISPLAY); the annotation catches the explicit `-Djava.awt.headless=true` case. Together they let the test class skip cleanly on a headless runner.

Pure-logic tests (no UI, no `@CodenameOneTest`) can run on any headless runner without configuration. The rest of the build runs there too: compiling the project's CSS needs no display, so `xvfb-run` is only needed around the step that runs `@CodenameOneTest` classes.

105.15. Coexistence with `cn1:test`

The two runners discover disjoint sets of classes:

- `cn1:test` looks for classes that `implements com.codename1.testing.UnitTest` (which `AbstractTest` extends).
- Surefire (JUnit Jupiter) looks for `@Test`-annotated methods.

They don't trip over each other. `mvn install` runs Surefire during the `test` phase, then the `cn1:test` execution bound in the `javase/pom.xml` `test` profile runs in the same phase. To target just one runner:

```
mvn -pl javase test                          # both runners
mvn -pl javase test -DskipTests              # skip Surefire, cn1:test still runs
mvn -pl javase test -Dtest=NoMatch           # filter Surefire to nothing,
                                             # cn1:test still runs
```

105.16. Side-by-side example

The same "sign in, assert Home is shown" check, written both ways:

JUnit 5 / Surefire

The UI driving (`TestUtils.*`) is identical — `TestUtils` is independent of the runner. What changes is the lifecycle plumbing: `shouldExecuteOnEDT()` + `runTest() returns boolean` becomes `@RunOnEdt` + `@Test void` + a standard assertion library.

105.17. Cross-reference

- For the `AbstractTest` framework's full API surface — the TestUtils [https://www.codenameone.com/javadoc/com/codename1/testing/TestUtils.html] helpers, the `screenshotTest` tolerance algorithm and baseline management — see the com.codename1.testing Javadoc [https://www.codenameone.com/javadoc/com/codename1/testing/package-summary.html].
- For the `cn1:test` Maven goal, see the test goal appendix.

Chapter 106. Performance, size & debugging

106.1. Reducing resource file size

It's easy to lose track of size/performance when you're working within the comforts of a visual tool like the Codename One Designer. When optimizing resource files you need to keep in mind one thing: it's all about image sizes.

Images will take up 95-99% of the resource file size; everything else pales in comparison.

Like every optimization the first rule is to reduce the size of the biggest images which will provide your biggest improvements, for this purpose Codename One provides the ability to see image sizes in kilobytes. To launch that feature use the menu item Images → Image Sizes (KB) in the designer.

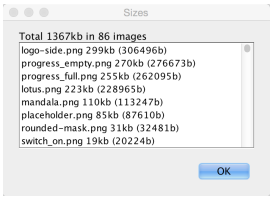


Figure 381. Image sizes window that allows you to find the biggest impact on your RAM/Storage

This produces a list of images sorted by size with their sizes. Often the top entries will be multi-images, which include HD resolution values that can be pretty large. These high-resolution images take up a significant amount of space!

Just going to the multi-images, selecting the unnecessary resolutions & deleting these images can save significant amounts of space:

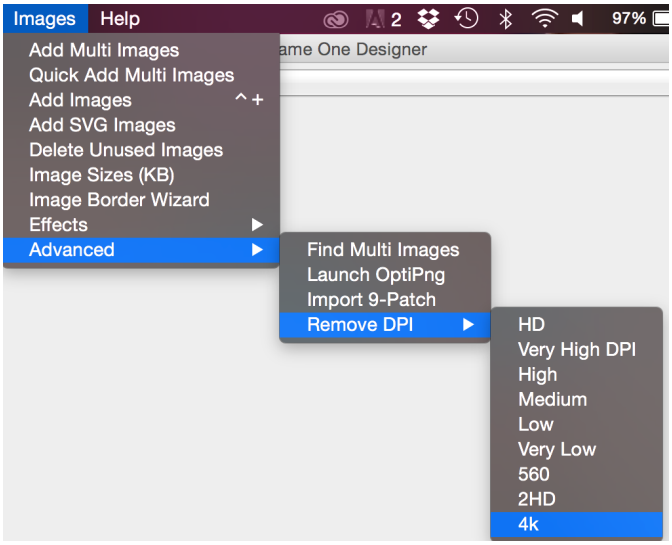

Figure 382. Removing unused DPI's

You can see the size in KB at the top right side in the designers image viewer

Applications using the old GUI builder can use the Images → Delete Unused Images menu option (it's also under the Images menu). This tool allows detecting and deleting images that aren't used

within the theme/GUI.

If you have a large image that's opaque you might want to consider converting it to JPEG and replacing the built in PNG's. Notice that JPEGs work on all supported devices and are typically smaller.

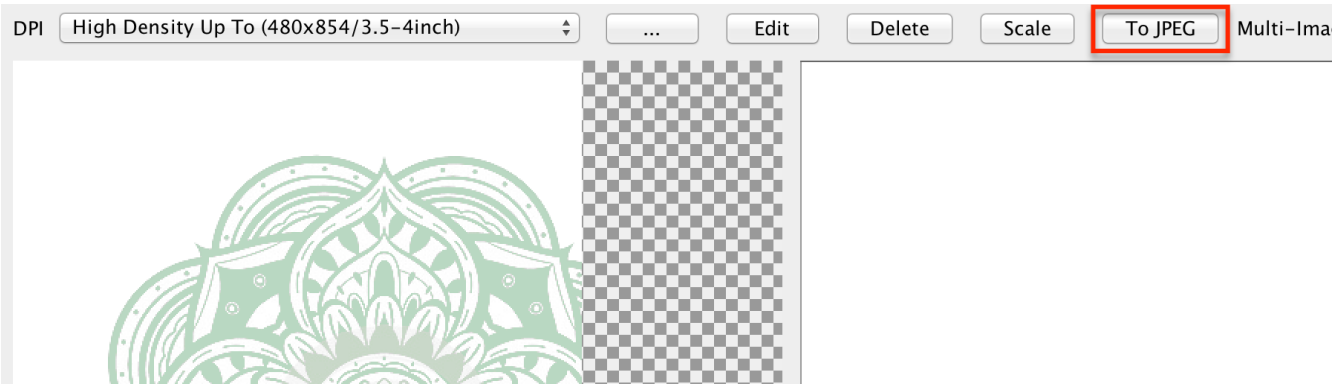

Figure 383. Convert a MultiImage to use JPEGs instead of PNGs

You can use the excellent OptiPng [https://optipng.sourceforge.net/] tool to optimize image files right from the Codename One designer. To use this feature you need to install OptiPng then select Images → Launch OptiPng from the menu. Once you do that the tool will automatically optimize all your PNG's.

When faced with size issues make sure to check the size of your res file, if your JAR file is large open it with a tool such as 7-zip and sort elements by size. Start reviewing which element justifies the size overhead.

106.2. Improving performance

As a developer you can do quite a few things to improve the performance and memory footprint of a Codename One application. This sometimes depends on specific device behaviors but some tips here are true for all devices.

The simulator contains some tools to measure performance overhead of a specific component and also detect EDT blocking logic. Other than that follow these guidelines to create more performance code:

- **Avoid round rect borders** - they have a huge overhead on all platforms. Use image borders instead (counter intuitively they're MUCH faster)
- **Avoid Gradients** - they perform poorly on most OSes. Use a background image instead
- **Use larger images** when tiling or building image borders, using a 1 pixel (or event a few pixels) wide or high image and tiling it repeatedly can be expensive
- **Shrink resource file sizes** - Otherwise data might get collected by the garbage collector and reloading data might be expensive
- **Check that you don't have too many image lock misses** - this is discussed in the graphics section
- **On some platforms mutable images are slow** - mutable images are images you can draw on (using `getGraphics()`). On some platforms they perform quite badly (for example, iOS) and

should be avoided. You can check if mutable images are fast in a platform using `Display.areMutableImagesFast()`

- * Make components either transparent or opaque * - a translucent component must paint it's parent every time. This can be expensive. An opaque component might have margins that would require that you paint the parent so there is often overdraw in such cases (overdraw means the same pixel being painted twice).

106.2.1. ParparVM native translation performance hints

For ParparVM-generated native code, Codename One now supports method-level optimization hints via annotations. These can provide good wins in hot code paths, but they come with tradeoffs and should be applied surgically.

Method-level codegen hints

- `@DisableDebugInfo`
  Suppresses generated line/debug metadata for the annotated method. This can reduce generated C size and remove some per-instruction debug overhead.
- `@DisableNullChecksAndArrayBoundsChecks`
  Suppresses generated null and array-bounds checks for the annotated method. This can reduce branch-heavy code in tight loops.

Use these on methods that are both performance-critical and well-covered by tests. These annotations intentionally trade runtime safety diagnostics for speed.

Class-level concrete implementation hints

For native ParparVM output (C/Objective-C), you can also provide a class-level hint that a base type always maps to a known concrete subclass at runtime:

- `@Concrete(name="fully.qualified.ConcreteClassName")`
  Allows the translator to bypass virtual table lookup for `invokevirtual` calls on the annotated base class. The translator first attempts a direct call on the concrete class; if the method isn't implemented there, it falls back to the annotated base class implementation. `name` is the mapping for iOS and the default target. The native Windows, Linux and macOS builds read `win`, `linux` and `mac` instead, and a target whose attribute is absent keeps ordinary virtual dispatch, so supply every target you ship.

This is useful for platform abstraction classes where one implementation is guaranteed in the native pipeline.

For example, Codename One annotates:

```
// Each target reads its own attribute: name() is the iOS and default
// mapping, and the native Windows, Linux and macOS builds read win(),
// linux() and mac(). A target whose attribute is absent simply skips
// the optimization, so all four are supplied here.
@Concrete(name = "com.codename1.impl.ios.IOSImplementation",
```

```
          win = "com.codename1.impl.windows.WindowsImplementation",
          linux = "com.codename1.impl.linux.LinuxImplementation",
          mac = "com.codename1.impl.mac.MacImplementation")
public abstract class CodenameOneImplementation {
    // ...
}
```

This hint is intended for ParparVM native translation and doesn't apply to the JavaScript back end.

Fused object layout: `@Fused`

A class annotated `@com.codename1.annotations.Fused` tells the translator that primitive arrays created in its constructors are **fully encapsulated**: they're implementation details the class never hands out. The translator then lays the owner object and those arrays out in a **single allocation block** — one allocation instead of several, one GC visit instead of several, and no pointer indirection between the object and its buffer.

```
@com.codename1.annotations.Fused
class RgbImage {
    private final int[] pixels;   // laid out INSIDE the RgbImage allocation
    private final byte[] flags;
    RgbImage(int w, int h) {
        pixels = new int[w * h];  // computed sizes (w * h) fuse too
        flags = new byte[16];
    }
}
```

The contract you accept by annotating:

- The fused arrays must never be **stored** into another object's field, a static, or an array — their lifetime is the owner's lifetime. Reading them, iterating them, and passing them as transient call arguments is fine.
- Keep the fields private and never return them from a getter. If the class hands its buffer out, don't annotate it.

Everything else stays automatic and safe: constructors that compute non-constant sizes, reflective instantiation, delegating constructors and oversized arrays (bigger than the small-object allocator handles) all fall back to ordinary separate allocations with identical semantics.

`java.lang.String` and `java.lang.StringBuilder` are fused this way internally — a typical string is one allocation, not two.

Optimizations you get without annotations

Several ParparVM optimizations are applied automatically when the translator can **prove** they're safe; knowing they exist helps you write code that benefits from them:

- **Stack-allocated string building.** Every string concatenation the compiler lowers to a `StringBuilder` chain — and any builder the translator can prove never escapes its method — is allocated on the C stack, including its initial character buffer. A typical `"a" + x + "b"` allocates **nothing** on the heap except the resulting `String`. This is proven per call site by escape analysis; passing the builder to another method or storing it in a field simply keeps that site on the ordinary heap path.
- **Tagged integers.** On 64-bit targets, `Integer.valueOf` returns a tagged immediate pointer instead of allocating — boxing an `int` for a map key is free. 32-bit-pointer targets (including Apple Watch) fall back to heap boxing automatically.
- **Closed-world devirtualization.** A virtual call with no reachable override compiles to a direct C call, which link-time optimization can then inline. `final` classes and methods make this trivially provable.
- **Compact collections.** `HashMap`/`LinkedHashMap` use open addressing over parallel arrays — no entry objects, no allocation on `put`, `clear()` is three array wipes.
- **Bounds-check elimination.** The canonical `for (int i = 0; i < arr.length; i++)` loop shape is proven safe and compiled without per-access checks — prefer it over manual index juggling.

The benchmark and correctness suite that gates these optimizations lives in `vm/benchmarks` in the repository, with run instructions in its README; every optimization must produce output bit-identical to a host JVM there before it ships.

Fast method-stack path

The translator can emit a fast method-stack prologue/epilogue (`DEFINE_METHOD_STACK_FAST_*` and `CN1_FAST_RETURN_RELEASE`) for methods that meet strict safety criteria. Methods that qualify for the stricter **frameless** form (no try/catch, no synchronization) skip the VM frame entirely — their locals become plain C locals the optimizer keeps in registers.

In practice, this tends to help for:

- Small, hot methods.
- Methods without monitor usage / exception-heavy flow.
- Methods with straightforward control flow and low instruction complexity.

Tradeoffs:

- Overly broad fast-path eligibility can regress performance if extra branches or memory writes are introduced.
- Primitive- fast-frame variants may not always outperform a straightforward full clear on all targets/compilers.

Benchmark representative workloads after enabling fast-stack behavior. Keep eligibility conservative and expand where measurement shows consistent gains.

Base64-style hot-loop guidelines

For low-level loops (for example, Base64 encode/decode):

- Prefer simple loop bodies with predictable branches.
- Cache decode/lookup tables in primitive arrays (`int[]` lookup tables can reduce per-iteration conversion overhead).
- Avoid adding "defensive" branches in the inner-most loop unless they're required for correctness in production inputs.

Build configuration matters

When benchmarking translator output, ensure native projects are compiled with optimization enabled (for example, CMake `Release` builds). Debug/default builds can hide improvements or produce misleading regressions.

If you're using the integration test harness, make sure CMake is configured with:

```
-DCMAKE_BUILD_TYPE=Release
```

Without this setting, comparison between Java and ParparVM native output is often noisy and can lead to wrong optimization conclusions.

106.3. Profile-guided optimization

A C compiler optimizes without knowing which code your application runs. It guesses which branch of an `if` is the common one, which calls are worth inlining and which functions belong next to each other in the binary. Profile-guided optimization (PGO) replaces those guesses with measurements. The build server compiles your application twice:

1. The first compile produces an *instrumented* binary that counts how often every function and branch runs.
2. The build server launches that binary and lets it run for a training period. The counts it records are the *profile*.
3. The second compile reads the profile. Code that ran often is inlined and laid out for speed, and code that never ran is kept small and out of the way.

Only the second binary is delivered. The instrumented one never leaves the build server.

PGO is available for iOS, native macOS and native Linux builds. The translated Java code, the Codename One runtime and your native sources are all compiled with the profile.

106.3.1. When to use it

PGO is at its best on workloads that run the same code over and over, which is what a benchmark does. If you publish performance numbers for your application, or compare it against another toolchain, a profile-guided build shows it at its best. How much an ordinary application gains

depends on how much of its time is spent in the code the training run exercised.

Codename One's own benchmarks are built without PGO. A profile trained on the benchmark itself would skew the result, so the published numbers describe a regular build.

106.3.2. Enabling a profile-guided build

Each target has its own build hint, so turning PGO on for one target never changes the build of another:

Build hint	Target	Where the training run happens
`ios.pgo`	iOS	An iOS simulator that the build server creates for the run and deletes afterward
`macos.pgo`	Native macOS	The build server itself
`linux.pgo`	Native Linux	The build server itself, on a virtual display

For example, to profile the iOS and macOS builds and give each run 90 seconds:

```
codename1.arg.ios.pgo=true
codename1.arg.macos.pgo=true
codename1.arg.pgo.trainingSeconds=90
```

`pgo.trainingSeconds` is shared by every target. It defaults to 60 seconds, and a value below 10 or above 300 is brought into that range.

The iOS and macOS hints and the training period are also available as build hint annotations: `@Ios(pgo = Toggle.ON)`, `@Mac(pgo = Toggle.ON)` and `@Build(pgoTrainingSeconds = 90)`. `linux.pgo` has no annotation and is set in `codenameone_settings.properties`.

Profile-guided builds are a Pro and Enterprise feature of the cloud build service. A local build doesn't read these hints.

106.3.3. What the training run measures

Nobody touches the application during the training run. It starts, shows its first form and is then left alone until the training period ends, so the profile describes start-up and whatever the application does by itself after that: loading resources, laying out and painting the first screen, timers, animations and network requests it makes without being asked.

That has two practical consequences:

- Work that only happens after a tap isn't in the profile. The compiler treats that code as cold. It still runs correctly, but it gains nothing from the profile.
- The application has to keep running for the whole period. An application that exits by itself or crashes during the run stops the build.

The build server isn't one of your users' devices. A training run has no stored login and no saved

data. Make sure the application reaches a representative screen from a clean install.

106.3.4. A profile-guided build never falls back

A build that asks for PGO either delivers a profiled binary or fails with a message that says why. It never delivers a binary built without the profile under the same name. The build stops when:

- The hint has a value other than `true` or `false`, or `pgo.trainingSeconds` isn't a whole number.
- The account isn't on a Pro or Enterprise plan.
- The application ends before the training period does, or is still running well after it.
- The training run recorded no profile data.
- The hint is combined with a setting that produces a binary the profile can't apply to. The following table lists these.

Build hint	Can't be combined with
`ios.pgo`	`ios.buildForSimulator=true`, because the profile optimizes the device binary. `ios.no_strip=true` together with `ios.buildType=debug`, because that archives the unoptimized Debug configuration. A standalone watch application.
`macos.pgo`	`macos.configuration=Debug`, which is compiled without optimization.
`linux.pgo`	A `linux.arch` that the build server can't run. Build that architecture without `linux.pgo`.

The settings and the plan are checked before any compilation starts, so a request that can't be honored fails within seconds.

A profile-guided build takes longer than a regular one. It adds a second compile, the training period, and the time to start and stop the simulator on iOS.

106.4. SIMD: Data-Parallel primitives

SIMD stands for **Single Instruction, Multiple Data**. It's a family of CPU instructions that apply the same arithmetic or logical operation to several values at once, packed together into a single wide register. On a 128-bit NEON or SSE register you can hold sixteen bytes, eight 16-bit integers, four 32-bit integers, or four 32-bit floats, and a single instruction such as `VADD` or `PADDD` then operates on every lane in parallel. For data-parallel workloads—Base64 encode/decode, pixel blending, alpha-mask compositing, color-channel manipulation, table lookups—SIMD typically delivers a 3× to 10× speedup over scalar code.

Modern mobile and desktop CPUs expose several SIMD instruction sets:

- x86/x64—MMX, SSE, SSE2/3/4, AVX, AVX2, AVX-512
- ARM/ARM64—NEON (Advanced SIMD) and SVE

Codename One exposes those primitives as portable Java method calls on `com.codename1.util.Simd` [https://www.codenameone.com/javadoc/com/codename1/util/Simd.html]. On ParparVM (iOS) the translator

lowers them to NEON intrinsics; on Android and the JavaSE simulator a pure-Java fallback in `JavaSESimd` provides the same semantics so code written against `Simd` runs everywhere and simply performs better where native SIMD is available.

106.4.1. When to use SIMD

SIMD is worth reaching for when **all** the following hold:

- You are processing a buffer of at least dozens of elements at a time.
- The operation per element is simple (add, min, blend, table lookup, interleave/unpack) and identical across elements.
- Control flow is regular—no per-element early exit, no data-dependent branches that differ across lanes.
- Data is contiguous in a primitive array (`byte[]`, `int[]`, `float[]`).

Classic fits are image pixel passes, codecs (Base64, UTF-8 validation, hex encoding), checksums, audio mixing, and vector arithmetic. Poor fits are tight loops with pointer chasing, per-element branching on complex state, or buffers smaller than a single SIMD register.

If you aren't sure whether your platform has a vectorized implementation available, call `Simd.get().isSupported()`. The fallback path still returns correct results; `isSupported()` only tells you whether you will see the speedup.

106.4.2. Getting an instance

`Simd` is accessed as a singleton:

```
Simd simd = Simd.get(); // equivalent to CN.getSimd()
if (simd.isSupported()) {
    // native SIMD is wired up on this platform
}
```

The returned object is safe to cache in a field as long as the cache is refreshed across simulator restarts (the simulator may swap the backing implementation).

106.4.3. Allocation: Alignment and provenance

SIMD load/store instructions prefer—and on some architectures require— that the memory address they read from or write to be a multiple of the register width (16 bytes on NEON and SSE). Misaligned access either throws a hardware fault on strict platforms or costs extra cycles because the CPU has to split the transaction across two cache lines. A JVM offers no guarantee that `new byte[64]` is aligned to anything beyond the platform's object-header convention, so the framework forbids passing arbitrary `new`-allocated arrays to `Simd` primitives.

Every buffer used with a `Simd` primitive must so come from one of the allocation helpers on `Simd`:

```
byte[]  bytes  = simd.allocByte(64);   // heap, 16-byte aligned, registered
```

```
int[]   ints   = simd.allocInt(32);    // heap, 16-byte aligned, registered
float[] floats = simd.allocFloat(32);  // heap, 16-byte aligned, registered
```

All three methods enforce a minimum size of 16 elements and throw `IllegalArgumentException` for anything smaller; the minimum keeps each buffer large enough to hold a full SIMD register and leaves room for alignment padding.

Don't construct SIMD buffers with `new byte[64]` and pass them to `Simd`. The simulator enforces this at runtime (see *Simulator Tracking* below) and the iOS native path assumes alignment. Passing an unregistered array yields either an `IllegalArgumentException` in the simulator or undefined results on device.

106.4.4. A minimal End-to-End example

All `Simd` ops take explicit `offset` / `length` pairs so callers can chunk a large buffer through a small scratch array without reallocating. Many methods have interleaved variants—`unpackBytesInterleaved3/4`, `packBytesInterleaved3/4`—designed for packed pixel formats (RGB, RGBA) and fused operations like `blendByMaskTestNonzero` and `replaceTopByteFromUnsignedBytes` that collapse common three- or four-pass pixel pipelines into a single vector pass.

106.4.5. Scratch allocations: `alloca*`

A SIMD primitive often needs a short-lived working buffer: somewhere to stage intermediate lanes, hold a temporary mask, or accumulate partial results. Allocating a new `byte[]` per call via `allocByte` would dominate the runtime of the primitive it was trying to accelerate—heap allocation, zero-fill, and eventual GC reclamation all add up. The natural solution is to let the compiler place these buffers on the call stack where they cost nothing to create and are reclaimed automatically when the method returns. This is what the `alloca*` family exposes:

```
byte[]  scratchB = simd.allocaByte(64);
int[]   scratchI = simd.allocaInt(32);
float[] scratchF = simd.allocaFloat(32);

// Deterministic initial contents:
byte[]  zeroed   = simd.allocaByteZeroed(64);
int[]   filled   = simd.allocaIntFilled(32, -1);
```

On the simulator (and on Android) these behave like heap allocations with registration. On ParparVM the translator intercepts each `alloca*` call and rewrites it into a C-level `__builtin_alloca` that carves a faux `JavaArrayPrototype` out of the current C stack frame. The resulting pointer masquerades as an ordinary Java array for the lifetime of the enclosing method and is reclaimed on return.

The distinction between `allocByte` and `allocaByte` mirrors the distinction between `new byte[N]` and C's `alloca(N)`:

	`alloc*` **(heap)**	`alloca*` **(stack on ParparVM)**
Cost to assign	object header + zero fill + GC bookkeeping	register adjust, essentially free
Lifetime	until last reference dropped	until enclosing method returns
Can be stored in a field	yes	**no—use-after-free on device**
Can be returned from the method	yes	**no**
Can be passed to non-`Simd` methods	yes	**no**
Initial contents	zero	undefined (use `*Zeroed` / `*Filled`)
Size limit	heap	bounded by remaining stack

`alloca*` memory, like any stack memory, starts out containing whatever the previous frame left behind. Callers that require predictable initial contents should use `allocaByteZeroed` / `allocaIntZeroed` / `allocaFloatZeroed`, or the `*Filled` variants that accept an explicit initial value, rather than rolling their own loop.

106.4.6. Rules for `alloca*` scratch arrays

Because `alloca*` memory can't outlive its defining method on ParparVM, the array it returns must be treated as method-local. The framework enforces four rules at build and run time:

1. Don't **return** an `alloca*` array from the method that allocated it.
2. Don't **store** an `alloca*` array in an instance or static **field**, or into an **object array**.
3. Don't pass an `alloca*` array to a method whose owner isn't `Simd`, `IOSSimd`, or `JavaSESimd`. Helper methods outside the SIMD package might themselves violate one of the other rules.
4. Don't pass an `alloca*` array through `invokedynamic`; dynamic dispatch can't be analyzed statically.

Inside the defining method you are free to pass the array to any number of `Simd` primitives, copy values into and out of it, combine it with other buffers, etc.

106.4.7. Build-Time verification

The Maven plugin ships a bytecode-compliance goal (`compliance-check`) that walks every method in the application's compiled classes and performs a dataflow pass whose only job is to track whether each value on the operand stack or in a local variable was produced by an `alloca*` call. The pass is

an ASM `BasicInterpreter` subclass that taints every value returned from a method on `Simd`, `IOSSimd`, or `JavaSESimd` whose name begins with `alloca` followed by an upper-case letter. The taint propagates through `DUP`, `ASTORE`/`ALOAD`, `CHECKCAST`, and every control-flow merge, so a value keeps its provenance through any amount of local plumbing.

The verifier fails the build if a tainted value reaches any of:

- `ARETURN`—"SIMD alloca value returned from method"
- `PUTFIELD` / `PUTSTATIC`—"SIMD alloca value stored into instance/static field"
- `AASTORE`—"SIMD alloca value stored into object array"
- `INVOKE*` whose owner isn't `Simd`, `IOSSimd`, or `JavaSESimd`
- `INVOKEDYNAMIC`: refused unconditionally

Every violation is reported with the offending class, method, and the hint "Keep SIMD alloca scratch arrays method-local and only pass them to SIMD methods." Because this is wired into the Maven build, code that would dereference freed stack memory on device can't ship.

A complementary guard lives inside the translator itself: `CustomInvoke.appendSimdAllocaExpression` only performs stack lowering when the length argument is a **compile-time constant**. A call like `simd.allocaByte(n)` with a variable `n` falls through to the default codegen and becomes a normal heap allocation, which avoids both unbounded stack growth and an alloca whose size the translator can't inspect.

106.4.8. Simulator tracking of aligned arrays

The JavaSE simulator runs on the desktop where there is no NEON, no `__builtin_alloca`, and no guarantee that a given `byte[]` is 16-byte aligned. To keep developer bugs from hiding on the desktop and reappearing only on device, the simulator takes a strict stance: **only arrays obtained from `Simd.alloc` / `Simd.alloca*` are accepted as inputs to SIMD primitives.***

Internally this is an identity-based registry. Every allocation helper routes its result through a registration call that stores the array's `System.identityHashCode`—the JVM's per-object identity hash, stable for the object's lifetime regardless of GC movement. Every SIMD entry point validates its array arguments against the same set and throws `IllegalArgumentException` if a caller hands it a plain `new byte[64]`:

```
java.lang.IllegalArgumentException: SIMD array argument was not
allocated using Simd.alloc*(). objectId=⋯
```

Combined with the build-time verifier, both static analysis and dynamic execution refuse to accept arrays that would not be 16-byte aligned on device. On the device itself no such validation occurs—by that point the build has already proved the invariant.

106.4.9. Built-In SIMD paths

You gain from SIMD without touching the API directly. `com.codename1.util.Base64` detects `Simd.isSupported()` at encode/decode entry points and routes the hot loop through

`unpackLookupBytesInterleaved4`, `lookupBytes`, `or`, and `shl` with cached per-call constant tables; the bodies of `Image.applyMask`, `Image.modifyAlpha`, and `Image.removeColor` use fused primitives like `replaceTopByteFromUnsignedBytes` and `blendByMaskTestNonzero` to collapse multi-pass pixel pipelines into a single vector loop.

If you are writing your own hot loop on a primitive buffer and the data is already contiguous and aligned in a `Simd.alloc*` array, reach for the `Simd` API before optimizing further with the ParparVM annotations described above—vectorization and annotation hints compose, but vectorization is the larger win.

106.5. Performance monitor

The Performance Monitor tool can be accessible via the Simulator → Performance Monitor menu option in the simulator. This launches the following UI that can help you improve application performance:

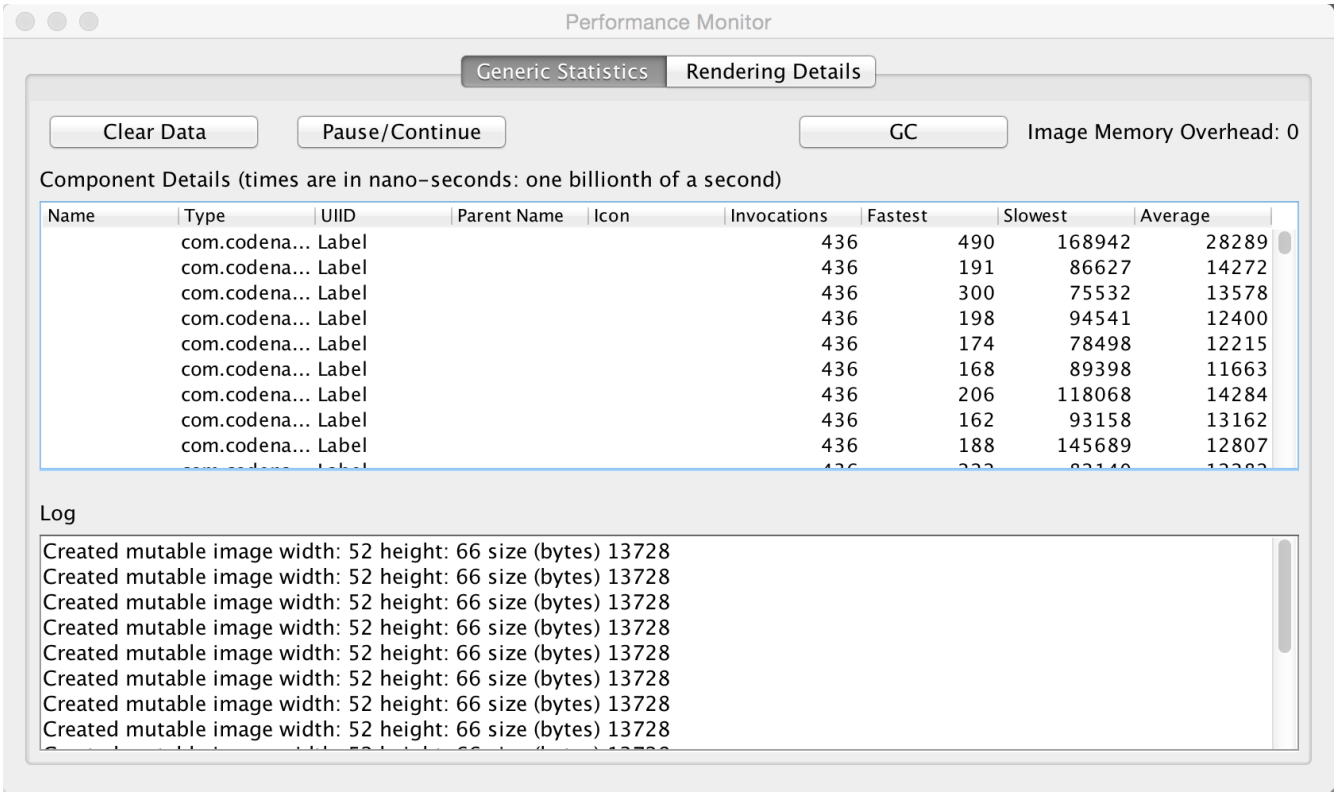

Figure 384. Main tab of the performance monitor: Logs and timings

The first tab of the performance monitor includes a table of the drawn components. Each entry includes the number of times it was drawn and the slowest/fastest and average drawing time. The toolbar across the top includes Pause/Continue buttons so you can freeze the counters while you inspect the current snapshot, a "Clear Data" action to reset the tables, and a "GC" button that invokes the simulator's garbage collector so you can see how memory usage changes.

This is useful if a `Form` is slow. You might be able to pinpoint it to a specific component using this tool.

The Log on the bottom includes debug related information. For example, it warns about the usage of mutable images which might be slow on some platforms. This also displays warnings when an unlocked image is drawn etc. A live "Image Memory Overhead" meter summarizes how much

native image memory the current form consumes so you can correlate spikes with your drawing code.

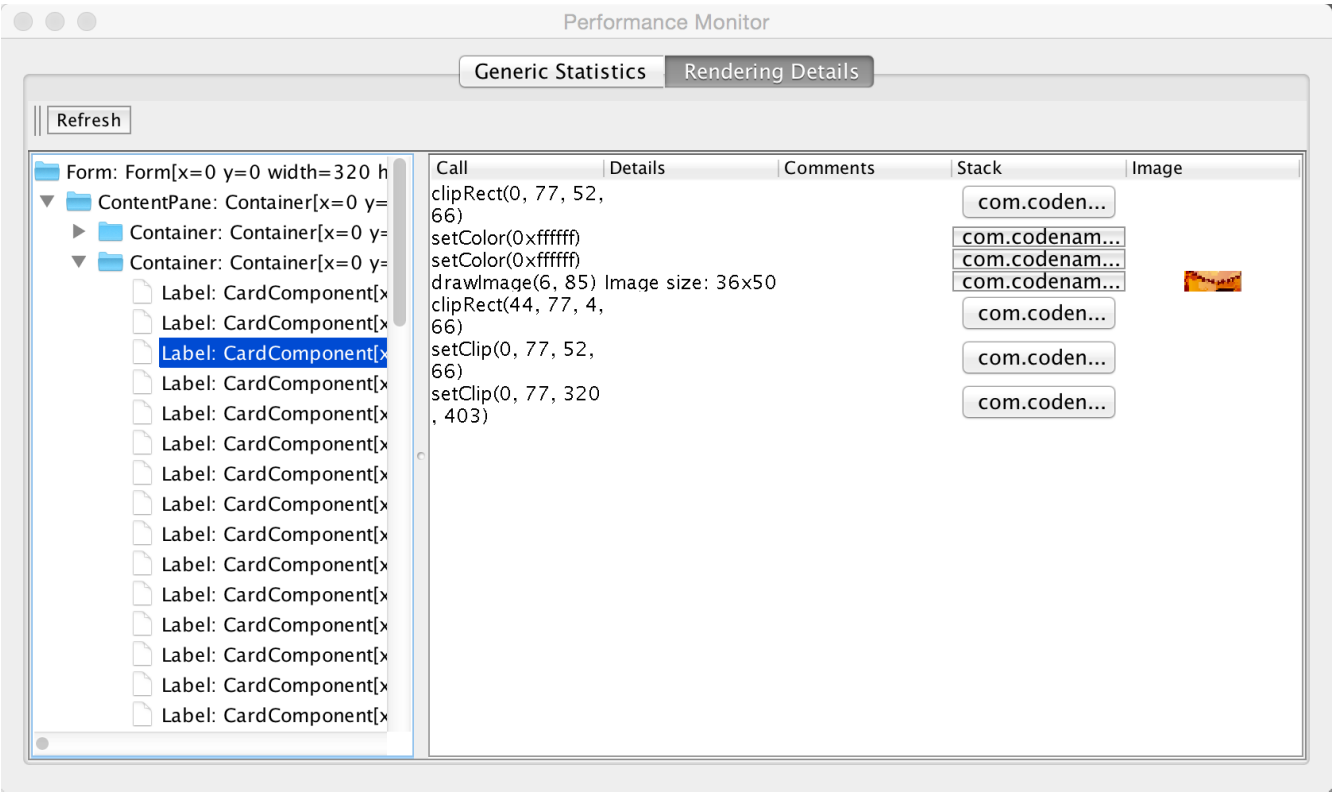

Figure 385. Rendering tree

The rendering tree view allows you to inspect the hierarchy painting. You can press the refresh button which will trigger the painting of the current `Form`. Every graphics operation is logged and so is the stack to it.

You can then inspect the hierarchy and see what was drawn by the various components. You can click the "stack" buttons to see the specific stack trace that lead to that specific drawing operation.

This is a powerful debugging tool as you can see "overdraw" within this tool. E.g if you see `fillRect` or similar APIs invoked in the parent and then again and again in the children this could show a problem.

Android devices have a nice overdraw debugging tool

106.6. Network speed

Figure 386. Network speed tool

This feature is actually more useful for general debugging but it's sometimes useful to simulate a slow/disconnected network to see how this affects performance.

For this purpose the Codename One simulator allows you to slow down networking or even fake a disconnected network to see how your application handles such cases.

106.7. Debugging Codename One sources

When you debug your app with your source code you can place breakpoints deep within Codename One and gain unique insight. You can also use the profilers and profile into Codename One to gain similar performance specific insight.

Running against the framework sources rather than the released jars is covered in working with Codename One sources.

106.8. Device testing Framework/Unit testing

Codename One includes a built in testing framework and test recorder tool as part of the simulator. This allows developers to build both functional and unit test execution on top of Codename One. It even enables sending tests for execution on the device (pro-feature).

To get started with the testing framework, launch the application and open the test recorder in the simulator menu.

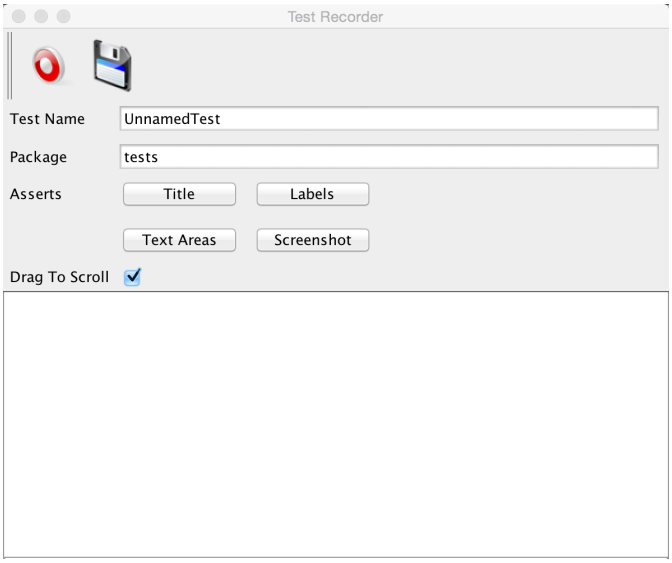

Figure 387. The test recorder tool in the simulator

Once you press record a test will be generated for you as you use the application.

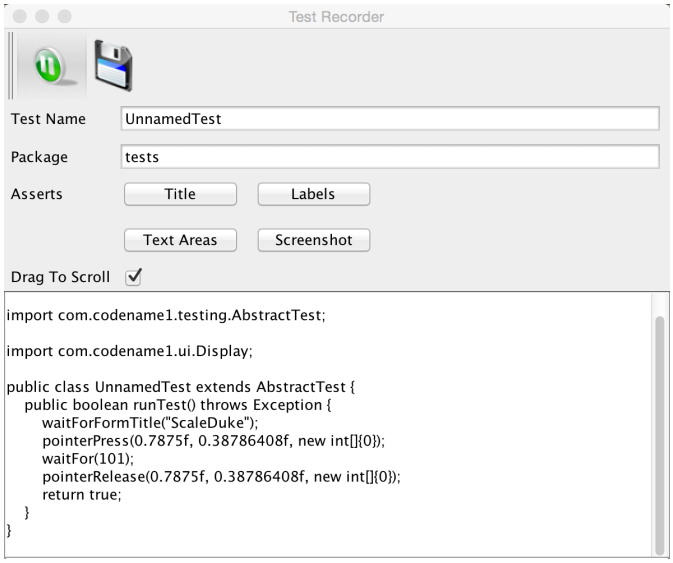

Figure 388. Test recording in progress, when done press the save icon

You can build tests using the Codename One testing package to manipulate the Codename One UI programmatically and perform various assertions.

Unlike frameworks such as JUnit which assign a method per test, the Codename One test framework uses a class per test. This allows the framework to avoid reflection and thus allows it to work on the device.

106.9. EDT error handler and sendlog

Handling errors or exceptions in a deployed product is pretty difficult, most users would throw away your app and some would give it a negative rating without providing you with the opportunity to actually fix the bug that might have happened.

Figure 389. Default error dialog

Google improved on this a bit by allowing users to submit stack traces for failures on Android devices but this requires the users approval for sending personal data which you might not need if you want to receive the stack trace and maybe some basic application state (without violating user privacy).

For quite some time Codename One had a powerful feature that allows you to both catch and report such errors, the error reporting feature uses the Codename One cloud which is exclusive for pro/enterprise users. In Codename One you catch all exceptions on the EDT (which is where most exceptions occur) and display an error to the user as you can see in the picture. This isn't helpful to you as developers who want to see the stack; furthermore you might prefer the user doesn't see an error message at all!

Codename One allows you to grab all exceptions that occur on the EDT and handle them using the method `addEdtErrorHandler` in the Display [https://www.codenameone.com/javadoc/com/codename1/ui/Display.html] class. Adding this to the Log's ability to report errors directly to you and you can get a powerful tool that will send you an email with information when a crash occurs!

This can be accomplished with a single line of code:

```
Log.bindCrashProtection(true);
```

You place this in the `init(Object)` method so all future on-device errors are emailed to you. Internally this method uses the `Display.getInstance().addEdtErrorHandler()` API to bind error listeners to the EDT. When an exception is thrown there it's swallowed (using `ActionEvent.consume()`). The `Log` data is then sent using `Log.sendLog()`.

If your crash handler runs while networking is unavailable or you want to avoid blocking the EDT, use `Log.sendLogAsync()` instead. It performs the upload in a background thread and is what Codename One's lifecycle helper falls back to when regular error reporting fails.

You can also plug in your own crash reporting pipeline by calling `Display.getInstance().setCrashReporter(CrashReport)`. The `CrashReport` [https://www.codenameone.com/javadoc/com/codename1/system/CrashReport.html] callback will receive the exception, device information, and log payload so you can forward it to services like Firebase Crashlytics or your in-house tools.

To truly gain from this feature you need to use the `Log` class for all logging and exception handling instead of APIs such as `System.out`.

To log standard printouts you can use the `Log.p(String)` method and to log exceptions with their stack trace you can use `Log.e(Throwable)`.

106.10. Kitchen sink case study

Performance is one of those vague subjects that's often taught by example.

While debugging the contacts demo (part of the new kitchen sink demo), its performance appeared sub-par. The initial assumption was that this was due to the implementation of `getAllContacts` and that there was nothing to do. Later, while debugging an unrelated issue, an anomaly was noticed during the loading of the contacts.

This led to the discovery that you're loading the same resource file over and over again for every single contact in the list!

In the new Contacts demo you have a share button for each contact, the code for constructing a `ShareButton` looks like this:

```
public ShareButton() {
    setUIID("ShareButton");
    FontImage.setMaterialIcon(this, FontImage.MATERIAL_SHARE);
    addActionListener(this);
    shareServices.addElement(new SMSShare());
    shareServices.addElement(new EmailShare());
    shareServices.addElement(new FacebookShare());
}
```

This seems reasonable until you realize that the constructors for `SMSShare`, `EmailShare` & `FacebookShare` load the icons for each of those...

These icons are in a shared resource file that you load and don't cache. The initial workaround was to cache this resource but a better solution was to convert this code:

```
public SMSShare() {
    super("SMS", Resources.getSystemResource().getImage("sms.png"));
}
```

Into this code:

```
@Override
public Image getIcon() {
    Image i = super.getIcon();
    if(i == null) {
        i = Resources.getSystemResource().getImage("sms.png");
        setIcon(i);
    }
    return i;
}
```

This way the resource uses lazy loading as needed.

This small change boosted the loading performance and probably the general performance due to less memory fragmentation.

The lesson that you should learn every day is to never assume about performance...

106.10.1. Scroll performance - threads aren't magic

Another performance pitfall in this same demo came during scrolling. Scrolling was janky (uneven/unsmooth) right after loading finished would recover after a couple of minutes.

This relates to the images of the contacts.

To hasten the loading of contacts you load them all without images. You then launch a thread that iterates the contacts and loads an individual image for a contact. Then sets that image to the contact and replaces the placeholder image.

This performed well in the simulator but didn't do too well even on powerful mobile phones. You assumed this wouldn't be a problem because you used `Util.sleep()` to yield CPU time but that wasn't enough.

Often when you see performance penalty the response is: "move it to a separate thread." The problem is that this separate thread needs to compete for the same system resources and merge its changes back into the EDT. When you perform something intensive you need to make sure that the CPU isn't needed right now...

In this and past cases you solved this using a class member indicating the last time a user interacted with the UI.

Here you defined:

```
private volatile long lastScroll;
```

The field is `volatile` because the listeners further down write it on the event dispatch thread while the loading thread reads it. Without that, the loader can keep seeing a stale timestamp and carry on decoding images while the user is still scrolling, which is the uneven scrolling this section sets out to remove.

Then you did this within the background loading thread:

```
// don't do anything while we are scrolling or animating
long idle = System.currentTimeMillis() - lastScroll;
while(idle < 1500 || contactsDemo.getAnimationManager().isAnimating() || scrollY != contactsDemo.getScrollY()) {
    scrollY = contactsDemo.getScrollY();
    Util.sleep(Math.min(1500, Math.max(100, 2000 - ((int)idle))));
    idle = System.currentTimeMillis() - lastScroll;
}
```

This effectively sleeps when the user interacts with the UI and loads the images if the user hasn't touched the UI in a while.

Notice that you also check if the scroll changes, this allows you to notice cases like the animation of scroll winding down.

All you need to do now is update the `lastScroll` variable whenever user interaction is in place. This works for user touches:

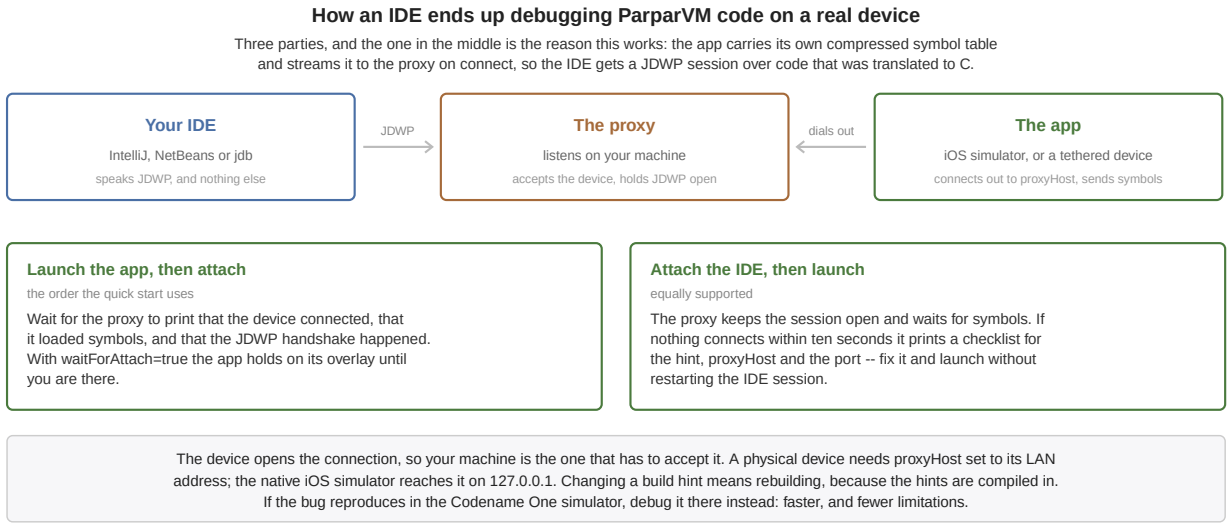
```
parentForm.addPointerDraggedListener(e -> lastScroll = System.currentTimeMillis());
```

This works for general scrolling:

```
contactsDemo.addScrollListener(new ScrollListener() {
    int initial = -1;
    @Override
    public void scrollChanged(int scrollX, int scrollY, int oldscrollX, int oldscrollY) {
        // scrolling is sensitive on devices...
        if(initial < 0) {
            initial = scrollY;
        }
        lastScroll = System.currentTimeMillis();
        // ...
    }
});
```

Due to technical constraints you can’t use a lambda in this specific case…

Chapter 107. On-Device Debugging (iOS)



The Codename One simulator runs your app on the JVM, so the IDE's normal Java debugger works against it directly. Some bugs only appear on a real device — ParparVM's threading model, iOS-specific native behaviour, performance characteristics on real hardware, memory pressure under iOS background limits, and timing around UIKit interactions are common examples. On-device debugging lets you keep using a standard Java debugger (IntelliJ IDEA, jdb, VS Code, anything that speaks JDWP) against the running iOS app on either the native iOS simulator or a physical device.

It works by adding a small listener thread to the ParparVM-generated iOS binary. The app dials out to a desktop proxy over Wi-Fi or loopback; the proxy speaks JDWP on the other side, so to the IDE everything looks like attaching to a normal remote JVM.

107.1. When to use it

- You can reproduce a bug on a built iOS app but not in the Codename One simulator — for instance a native-call issue, a layout glitch that only shows up on iOS modern theme, or an AOT-vs.-JIT numerical discrepancy.
- You want to single-step through real ParparVM-translated code and read the values its variables actually hold at runtime.
- You want to inspect object state on a tethered device while reproducing a problem a customer reported, without having to add log lines and rebuild.

If your bug is reproducible in the simulator, stay in the simulator — its debugger is faster and has fewer limitations.

107.2. Quick start (IntelliJ IDEA)

Codename One projects generated from the `cn1app-archetype` ship with three ready-made IntelliJ run configurations under the **On-Device Debug** folder in the run-config dropdown: **CN1 iOS On-Device Debug Build**, **CN1 Debug Proxy** and **CN1 Attach iOS**. The rest of this section assumes you're using them. Skip to Using jdb instead if you prefer the command-line debugger.

107.2.1. 1. Enable the build hints

In `common/codenameone_settings.properties`, uncomment the four lines the archetype generated:

```
codename1.arg.ios.onDeviceDebug=true
codename1.arg.ios.onDeviceDebug.proxyHost=127.0.0.1
codename1.arg.ios.onDeviceDebug.proxyPort=55333
# Optional: block the app at startup until the IDE attaches.
codename1.arg.ios.onDeviceDebug.waitForAttach=true
```

The build hint names start at `ios.onDeviceDebug`. Entries in `codenameone_settings.properties` use the `codename1.arg.` prefix, as shown above.

For a physical device, set `proxyHost` to the laptop's LAN IP (run `ipconfig` on Windows or `ifconfig` on macOS and Linux) instead of `127.0.0.1`. The native iOS simulator can always use `127.0.0.1`.

107.2.2. 2. Build the app as you normally do

Either the local Xcode path (`cn1:buildIosXcodeProject`) or a cloud build (`cn1:buildIosOnDeviceDebug`) will produce an app instrumented for on-device debugging once the build hints are set.

107.2.3. 3. Run the proxy from IntelliJ

Select **CN1 Debug Proxy** from the Run-config dropdown and click **Run** (the green play icon — not the bug icon; **Debug** on this config would attach IntelliJ's own debugger to the proxy process, which is not what you want). The Run tool window opens and shows:

```
On-device-debug proxy starting:
  device  : listening on tcp://0.0.0.0:55333
  jdwp    : listening on tcp://0.0.0.0:8000
  symbols : streamed from the device on connect (no local file)
[device] listening on port 55333 for ParparVM app to dial in
[jdwp] listening on port 8000 for debugger (jdb) to attach
```

When both listener lines appear, the proxy is ready for the app.

107.2.4. 4. Launch the app and wait for the device handshake

Launch the iOS app in the native iOS simulator under Xcode or on a physical device. The app contains its compressed debug symbol table and streams it to the proxy when it connects. Wait for these lines before attaching the IDE:

```
[device] connected from ...
[device] loaded symbols: ...
[jdwp] device handshake ...
```

With `waitForAttach=true`, the app remains on the "Waiting for debugger" overlay while you

complete the next step.

Attaching the IDE before launching the app is also supported. The proxy keeps the JDWP session open and waits for the device to stream its symbols. If the device still hasn't connected after ten seconds, the proxy prints a checklist for the build hint, `proxyHost`, and the device port. You can correct the problem and launch the app without restarting the IDE session; rebuild and reinstall first if you change a build hint.

107.2.5. 5. Attach the debugger from IntelliJ

Switch the Run-config dropdown to **CN1 Attach iOS** and click **Debug**. IntelliJ connects to `localhost:8000`, opens a Debug tool window, and releases the app after the debugger connection completes.

Set breakpoints, step, inspect, evaluate expressions, just like a normal remote attach. Device output from `System.out.println` / `Log.p` / `printf` / `NSLog` lands in the **CN1 Debug Proxy** Run window prefixed with `[device]`.

107.3. Quick start (NetBeans)

NetBeans uses the same proxy and connection order as IntelliJ. Generated projects ship two custom actions for it, on the project's right-click menu:

- **Build for iOS On-Device Debug** runs `cn1:buildIosOnDeviceDebug`, which forces `codename1.arg.ios.onDeviceDebug=true` for that one build. You don't need to edit `common/codenameone_settings.properties` first — the goal sets the hint itself, so a release build stays a release build.
- **Start iOS Debug Proxy** runs `cn1:ios-on-device-debugging`, which listens on `55333` for the device and `8000` for the IDE.

Install the app the first action produced, start the proxy with the second, launch the app, and wait for the device handshake and symbol-loading lines shown above. Then choose **Debug** > **Attach Debugger**, select **Java Debugger (JPDA)** and the **SocketAttach** connector, set the host to `localhost` and the port to `8000`, and attach. Keep the Codename One project open so NetBeans can resolve your source files and breakpoints.

Don't point NetBeans at port `55333`. The iPhone uses `55333` to reach the proxy. The IDE uses the proxy's JDWP port, `8000`.

If the actions are missing from an older project, they live in `tools/netbeans/nbactions.xml`; copying that file from a freshly generated project adds them.

107.4. Quick start (Maven from the command line)

If you don't want to use the IntelliJ run configs, the same flow is two terminals:

```
# Terminal 1 — start the proxy
mvn cn1:ios-on-device-debugging
```

```
# Launch the app and wait for the proxy to report that it loaded symbols.

# Terminal 2 — attach jdb after the device handshake
jdb -attach localhost:8000
```

For VS Code (Debugger for Java extension), add a launch configuration of type `java` with `"request": "attach"`, `"hostName": "localhost"`, `"port": 8000`.

107.4.1. Using jdb instead

`jdb` is a minimal Java debugger that ships with every JDK and works fine over the same JDWP socket. Useful when you don't have an IDE available, or for scripted regression checks. Source path resolution is manual:

```
jdb -attach localhost:8000 \
    -sourcepath src/main/java:$HOME/.m2/repository/com/codenameone/codenameone-core/8.0-SNAPSHOT/codenameone-core-8.0-
SNAPSHOT-sources.jar
```

The `-sourcepath` is required for `list` / `where` to render framework source — jdb won't unzip the `-sources.jar` automatically; if you prefer plain files, extract it once and point at the directory.

107.5. What works today

- Class loading: the IDE sees every class in your build.
- Line breakpoints in user code **and** in the Codename One framework classes (`com.codename1.ui.`, `com.codename1.io.`, etc.).
- Step into / over / out.
- Stack walking — full Java stack including the Codename One framework frames above your code.
- Inspecting primitive locals (int, long, float, double, boolean, byte, char, short).
- Inspecting `java.lang.String` values directly.
- Inspecting object references — class name and identity, plus field-by-field drilldown via the IDE's variables view. The proxy walks the ParparVM struct layout to read instance fields directly at known offsets, so `dump this` / "Variables" shows the same fields you'd see in a simulator debug session.
- Array inspection — `Object[]`, `int[]`, `byte[]`, etc. report their length and per-index values to the IDE so expanding e.g. `ArrayList.elementData` shows the actual element references rather than an opaque reference. Primitive element types round-trip with their JVM type tag.
- Method invocation — the IDE's "Evaluate Expression" / `print` command can call instance and static methods on objects in scope. The classic chain `Display.getInstance().getCurrent().getTitle()` evaluates to the current form's title string, so `myForm.getComponentCount()` and similar accessor calls work too. The call runs on the suspended Java thread inside a catch-all try block, so uncaught throws round-trip back as an exception

reference rather than tearing down the debugger.

- Native device output — `System.out.println`, `Log.p`, and `printf` / `NSLog` from native code are surfaced in the proxy's console (the IntelliJ **CN1 Debug Proxy** Run window when launched via the run config) prefixed with `[device]`.
- Thread list — every live Java thread appears in the IDE's Threads panel, whether it has stopped anywhere or not, named after the `java.lang.Thread` it belongs to (`EDT`, `main`, …). Suspension is reported per thread, so with several parked at once the panel shows which is which.
- Scoped locals — a local is listed only on the source lines it's actually in scope for. That matters where two variables share a JVM slot in disjoint blocks: only the one the code has reached is shown, rather than both, one of them displaying the other's storage.
- Deferred breakpoints — a breakpoint set in a class the IDE hasn't seen yet (an anonymous listener, say) resolves via the ClassPrepare events the proxy raises for every matching class.
- Pause and resume from the IDE.
- Stack frames in methods carrying no line information — synthetic lambda bodies and `java.lang.Thread.runImpl`, for instance — appear in the stack with their source line left blank, rather than ending the stack view at that frame.

107.6. Pointing the IDE at the Codename One sources

The proxy answers `Method.LineTable` and `ReferenceType.SourceFile` for framework classes, but the IDE still needs to find the actual `.java` files to render the source pane while stepping. Three options in order of convenience:

- **Maven sources jar (recommended).** The `codenameone-core-<version>-sources.jar` is published alongside the regular `codenameone-core` artifact. IntelliJ resolves it automatically once you run **Maven → Reimport** with "Sources" enabled in the Maven settings. Other IDEs work the same way as long as their Maven integration is set to download sources.
- **Local clone of the Codename One repository.** If you've already checked out the CodenameOne GitHub repository [https://github.com/codenameone/CodenameOne] (for instance to follow the contributor workflow), point the IDE at its `CodenameOne/src` directory. In IntelliJ: **Run → Edit Configurations… → CN1 Attach iOS → Configuration → Source roots → +**.
- **jdb command line.** Pass the framework source directory on the `-sourcepath`, as shown in Using jdb instead.

Without a source path, breakpoints in framework classes still trigger and locals / fields still read — you'll just see "Sources not found" in the IDE editor when stepping into framework code.

107.7. Known limitations

- **Method invocation is partial.** The debugger can call instance and static methods on Codename One framework classes and on user code: jdb's `print myForm.getTitle()` and IntelliJ's "Evaluate Expression" pop-up work for the chains you actually want (`Display.getInstance().getCurrent().getTitle()` is the canonical test). Methods on `java.io.`, `java.net.`, `java.nio.`, and `com.codename1.impl.` are unsupported — those classes are linked

against hand-written native code that has fallen out of sync with the generic invoke-thunk calling convention, so the translator skips them. The same limit applies to watch expressions.

- **Constructor invocation** isn't supported. The debugger can call existing instance methods but not `new Foo(…)`.
- **Hot-swap** isn't supported. Code changes require a rebuild and reinstall of the app.
- **Hot threads** — if your app is doing heavy work on a non-EDT thread when a breakpoint hits, that other thread continues running. Only the thread that hit the breakpoint suspends by default. Use the IDE's "suspend VM" if you need a fully frozen picture.
- **Local variable names** are present only when the user's Java sources were compiled with `-g`. Codename One's archetypes do compile with debug info by default; if a variable shows up as `v1`, `v2`, … that's because that particular class was compiled without debug info. Such a local also has no declaring scope, so the debugger lists it for the whole method rather than only where it's live.
- **Static field reads** are unsupported. Instance field reads are fully wired; static-field support requires an additional per-class static table that hasn't been emitted yet.
- **NSLog on a real device** (as opposed to the native iOS simulator) may not reach the `[device]` console. NSLog on iOS routes to `os_log` which doesn't always mirror to `stderr`. `printf` / `fprintf` / `Log.p` are unaffected and show up correctly.

107.8. Performance

The on-device-debug instrumentation is gated by a compile-time flag that's **only set in debug builds**. Release builds are completely unaffected — no listener thread, no per-line callback, no extra metadata in the binary.

In debug builds, the per-line callback adds a predictable load+branch around the macro that ParparVM already emits to record source line numbers for stack traces. When no debugger is attached, the runtime cost is close to zero. When a debugger **is** attached, expect numerical inner loops to run on the order of two to three times slower than a release build — this is normal and matches the overhead of `-g`-style debugging on other native VMs.

107.9. Debugging the generated Xcode project natively

The JDWP flow above keeps you at the Java level. For native-level work — stepping through Objective-C sources, debugging a native interface, chasing a crash inside the VM, or profiling with Instruments — debug the generated Xcode project directly:

- **Local build**: `mvn cn1:buildIosXcodeProject` writes the complete Xcode project under `target/…-ios-source/`.
- **Cloud build**: run `mvn cn1:settings`, enable **Include Source** on the **Basic** page, save, then send the build and download the sources result from the build server.

Open the `.xcworkspace` file if one was generated, otherwise the `.xcodeproj`, and run on a device or the native iOS simulator from Xcode as you would any iOS app.

The `.xcworkspace` is no longer exclusive to CocoaPods-based builds. Use it whenever it's generated, whether the project uses CocoaPods, Swift Package Manager, or both.

Inside Xcode you get LLDB and Instruments against the real binary. Your Java code appears as the C sources ParparVM generated from it — a Java method like `com.mycompany.MyClass.doStuff(int)` becomes a C function named along the lines of `com_mycompany_MyClass_doStuff___int`, so symbolic breakpoints on the translated code work too. The native-IDE path and the JDWP path are complementary: use Xcode for native frames and profiling, the JDWP proxy for source-level Java debugging.

107.10. Troubleshooting

107.10.1. The proxy reports "device disconnected" before the breakpoint fires

The app might be crashing before it reaches user code. Run the app from Xcode and watch the console — `installSignalHandlers` will intercept native crashes and rethrow them as Java exceptions you can see. If the connection drops mid-debug, check the proxy log for a device-side I/O error.

107.10.2. "Connection refused" when the device tries to reach the proxy

The device's `ios.onDeviceDebug.proxyHost` value is wrong, or a firewall is blocking the port. Verify:

- The native iOS simulator can always reach `127.0.0.1`.
- A physical device needs the laptop's **LAN IP** (not `localhost`), and the laptop's firewall must allow incoming connections on the configured port (default `55333`).
- macOS will prompt the first time the proxy listens — accept the **Allow incoming connections** dialog.

107.10.3. jdb reports "Internal exception: Unexpected JDWP Error: 100"

This means an unsupported JDWP command was invoked. The session itself survives; the most common cause is the IDE asking for something the proxy explicitly stubs (see "Known limitations" above). The debugger's own message doesn't say which command it asked for, so the proxy logs it instead:

```
[jdwp] declining unimplemented command set=2 cmd=13; the debugger
may report "Unexpected JDWP Error: 100"
```

The line is printed once per command, in the proxy's console. File an issue with the command set and number attached.

107.10.4. The app launches but the breakpoint never fires

Confirm the build hint actually took effect. Inspect the generated Xcode project's `cn1_globals.h` and

look for `#define CN1_ON_DEVICE_DEBUG` **without** a leading `//`. If the line is still commented out, the build was a release/non-debug build, or `ios.onDeviceDebug` wasn't set as a build hint.

107.10.5. Make the app wait while the proxy and IDE attach

Set `ios.onDeviceDebug.waitForAttach=true`. The app will block at startup until the proxy is connected and the IDE tells the VM to continue.

Chapter 108. On-Device Debugging (Android)

The companion to the iOS chapter, for the Android side. The motivation is the same — bugs that only reproduce on a real device or on the Android emulator — but the implementation is much simpler. The Dalvik/ART runtime already exposes a JDWP socket per debuggable process, so there is no desktop proxy and no custom protocol. The Codename One Maven plugin just orchestrates `adb`: install the APK, mark it as the debug-app, launch the activity, forward the JDWP socket onto `localhost`, and tail logcat.

Everything below assumes you have the Android platform-tools on your machine (Android Studio installs them, or the standalone package [https://developer.android.com/tools/releases/platform-tools]) and `adb` is reachable through `ANDROID_HOME`, `ANDROID_SDK_ROOT`, or `$PATH`.

108.1. When to use it

- A bug only reproduces on a physical Android device or in the Android emulator and not in the Codename One simulator.
- You want to single-step through your code while it runs on the device, with full access to locals, fields, and the `Display.getInstance()⋯` accessor chains.
- You want to attach without a USB cable — the wireless flow below covers both the legacy `adb tcpip` path and the Android 11+ `adb pair` path.

If the bug reproduces in the simulator, stay in the simulator — its debugger is faster and has zero device-side moving parts.

108.2. Quick start (IntelliJ IDEA)

Projects generated from the `cn1app-archetype` ship with two run configurations under the **On-Device Debug** folder: **CN1 Android On-Device Debug** and **CN1 Attach Android**. The flow is:

108.2.1. 1. Enable the build hint

In `common/codenameone_settings.properties`, uncomment the line the archetype generated:

```
codename1.arg.android.onDeviceDebug=true
```

The build hint name is `android.onDeviceDebug`. Entries in `codenameone_settings.properties` use the `codename1.arg.` prefix, as shown above.

This flips the generated `AndroidManifest.xml` to `debuggable="true"` and disables R8/proguard so symbols and locals survive the build. Release builds (anything without this hint) are unaffected.

108.2.2. 2. Build the APK

Either the cloud build (`cn1:buildAndroidOnDeviceDebug` — wraps `cn1:buildAndroid` and force-sets the hint above) or your usual `cn1:buildAndroid` once the hint is set. Both produce a signed, debuggable

APK in the project's `target/` directory.

For a fully local build, use `cn1:buildAndroidGradleProject` to generate the Gradle project under `target/…-android-source/` and run `./gradlew assembleDebug` from there; the Mojo will autodetect the resulting APK under `build/outputs/apk/`.

108.2.3. 3. Connect the device

Plug a device in over USB with USB debugging enabled, **or** connect wirelessly (see Wireless debugging below).

108.2.4. 4. Run the debug session from IntelliJ

Select **CN1 Android On-Device Debug** from the Run-config dropdown and click **Run** (the green play icon — not the bug icon). The Run tool window prints:

```
Using adb: /Users/you/Library/Android/sdk/platform-tools/adb
Target device: emulator-5554
Installing my-app-1.0.apk on emulator-5554
Marking com.example.myapp as the debug app (waits for debugger).
Launching com.example.myapp.MyAppStub
App PID on device: 12345

================================================================
 JDWP forwarded:  localhost:5005  ->  device pid 12345
 Attach IntelliJ: Run -> 'CN1 Attach Android' (Remote JVM Debug)
================================================================
```

After that banner, logcat output (filtered to the app's PID) streams through the Run window prefixed with `[device]`.

108.2.5. 5. Attach the debugger

Switch the Run-config dropdown to **CN1 Attach Android** and click **Debug**. IntelliJ connects to `localhost:5005` and opens a Debug tool window. The app is paused inside `Debug.waitForDebugger()` at this point — set your breakpoints, then resume from the IDE to let it proceed past boot.

Set breakpoints, step, inspect, evaluate expressions — all the normal remote-attach features work. Unlike the iOS path, there is no method-invocation or static-field limitation here; the JVM is the real Android runtime.

108.3. Wireless debugging

108.3.1. Android 11 and newer (recommended)

1. On the device: **Settings → Developer options → Wireless debugging → Pair device with pairing code**. Note the **IP & port** (for example `192.168.1.42:37051`) and the **six-digit pairing code**.

2. Pair from your laptop (this only has to be done once per network):

```
adb pair 192.168.1.42:37051
# When prompted, enter the 6-digit code shown on the device.
```

3. Connect:

```
adb connect 192.168.1.42:5555
```

   The connect port is **not** the pairing port — it's the one shown on the **Wireless debugging** screen above the **Pair device** button.

4. Run the debug session as normal. Pass the IP and port through the Mojo if you prefer to do the `adb connect` in one step:

```
mvn cn1:android-on-device-debugging \
    -Dcn1.android.onDeviceDebug.wireless=192.168.1.42:5555
```

108.3.2. Android 10 and older

1. Plug the device in over USB.
2. Switch adb to TCP/IP mode and grab the device's IP from **Settings** → **About phone** → **Status**:

```
adb tcpip 5555
adb connect 192.168.1.42:5555
```

3. Unplug the cable, then run the debug session as normal.

In either flow, the JDWP forward, app launch, and logcat stream all happen over the same Wi-Fi link.

108.4. Quick start (Maven from the command line)

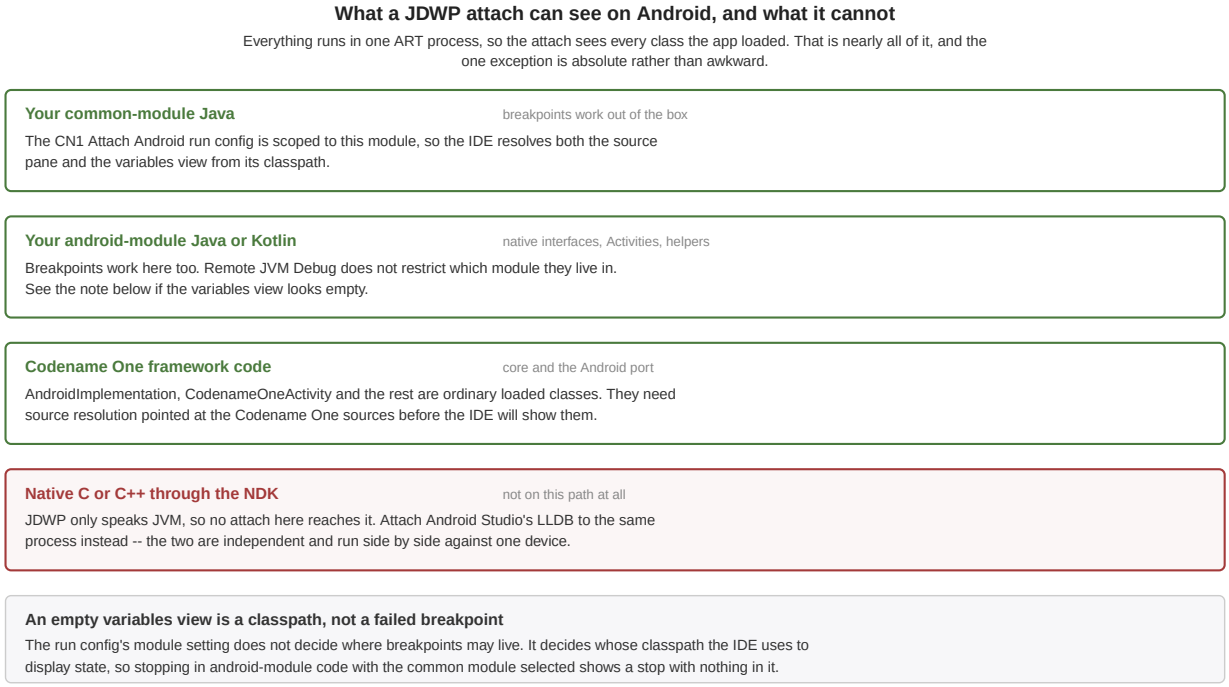
Without the IntelliJ run configs, the same flow is two terminals:

```
# Terminal 1 — build the APK once
mvn cn1:buildAndroidOnDeviceDebug

# Terminal 2 — install, launch, forward JDWP, tail logcat
mvn cn1:android-on-device-debugging
```

Attach jdb (or another JDWP client) to the forwarded port:

```
jdb -attach localhost:5005 \
    -sourcepath src/main/java:$HOME/.m2/repository/com/codenameone/codenameone-core/8.0-SNAPSHOT/codenameone-core-8.0-
SNAPSHOT-sources.jar
```



For VS Code (Debugger for Java extension), add a launch configuration of type `java` with `"request": "attach"`, `"hostName": "localhost"`, `"port": 5005`.

108.5. Useful command-line flags

The Mojo's defaults match what the archetype's run config does. The flags below exist for unusual setups:

Property	Meaning
`-Dcn1.android.onDeviceDebug.adb=<path>`	Use a specific adb executable (default: search `ANDROID_HOME`, `ANDROID_SDK_ROOT`, the standard Android Studio SDK locations, and `$PATH`).
`-Dcn1.android.onDeviceDebug.deviceSerial=<serial>`	Force a target device when more than one is online (`adb devices`).
`-Dcn1.android.onDeviceDebug.wireless=<ip:port>`	Run `adb connect <ip:port>` before everything else (covers both the Android 11 wireless-debug path and the legacy `adb tcpip` path).
`-Dcn1.android.onDeviceDebug.jdwpPort=<port>`	Local TCP port for `adb forward`. Default `5005`. Match this with the **CN1 Attach Android** run config if you change it.
`-Dcn1.android.onDeviceDebug.apk=<path>`	Skip APK autodetection and install this APK instead.
`-Dcn1.android.onDeviceDebug.skipInstall=true`	Skip the install step — the app is already on the device.
`-Dcn1.android.onDeviceDebug.waitForAttach=false`	Don't run `am set-debug-app -w`. The app launches normally and you attach the debugger afterwards. Default is `true`.

108.6. What you can step through

Everything runs in one Dalvik/ART process, so the JDWP attach sees every class loaded by the app. In practical terms:

- **Your common-module Java** (`com.<yourcompany>.<app>.`, anything under the `-common` module's `src/main/java`). Breakpoints work out of the box — this is the module the *`CN1 Attach Android` run config is scoped to, so IntelliJ resolves the source pane and the variables view from your common-module classpath.
- **Your android-module Java or Kotlin** (`src/main/java` of the `-android` module — native interface implementations, custom Activities, Android-only helpers). Open the file and set a breakpoint; the IDE's **Remote JVM Debug** config doesn't restrict which module breakpoints live in, the `<module>` setting only decides which module's classpath is used to **display** state. If the variables view ever looks empty when you stop inside `-android` code, switch the run config's **Use classpath of module** to the `-android` module and reattach.
- **Codename One framework code** in `codenameone-core` and the Android port (`com.codename1.impl.android.*` such as `AndroidImplementation` and `CodenameOneActivity`). Both need source resolution — see the next section.
- *Native C/C via the NDK* is *not* debuggable through this path. JDWP only speaks JVM. If you've added native sources through the Android NDK, attach Android Studio's LLDB to the same process for C/C debugging — the two attaches are independent and can run side-by-side against one device.

108.7. Pointing the IDE at the Codename One sources

The Android runtime serves real `.class` files, so the IDE only needs the matching `.java` files to render the source pane. The same two options cover both `codenameone-core` and the Android port (`codenameone-android`):

- **Maven sources jars (recommended).** IntelliJ resolves `codenameone-core-<version>-sources.jar` **and** `codenameone-android-<version>-sources.jar` automatically once you run **Maven** →

Reimport with "Sources" enabled in the Maven settings.

- **Local clone of the Codename One GitHub repository [https://github.com/codenameone/CodenameOne].** In IntelliJ: **Run → Edit Configurations… → CN1 Attach Android → Configuration → Source roots → +**. Add two entries: the clone's `CodenameOne/src` directory for the framework core, and `Ports/Android/src` for `AndroidImplementation` and the rest of the Android port.

Without a source path, breakpoints in framework classes still trigger and locals / fields still read — you'll just see "Sources not found" in the editor when stepping into framework code.

108.8. Debugging the generated Gradle project from Android Studio

Everything above drives a Codename One-built APK through `adb`. The alternative is to open the generated Android project itself in Android Studio and use it like any native Android app — useful when you're debugging native interface code, working on the Android port, or want Android Studio's profiler and layout inspector:

- **Local build**: `mvn cn1:buildAndroidGradleProject` writes a complete Gradle project under `target/⋯-android-source/`. Open that directory in Android Studio (current versions open it directly — no Gradle version fiddling required), connect a device, and press **Debug**.
- **Cloud build**: check the **Include Source** flag in Codename One Settings before sending the build, then download the sources result from the build server and open it the same way.

When iterating, regenerate the project rather than hand-merging files — the generated project is a build artifact, not a source of truth.

For native C/C++ added through the NDK, attach Android Studio's LLDB to the process; as noted in Section 108.6, "What you can step through", the LLDB and JDWP attaches are independent and can run side by side against one device.

108.9. Troubleshooting

108.9.1. "No Android device is online"

`adb devices` returns nothing useful. Common causes:

- The device's **USB debugging** toggle is off, or the per-laptop RSA fingerprint prompt is still pending on-device.
- The cable is power-only (some short USB-C cables are charge-only).
- For wireless: pairing expired (Android 11+) or the laptop is on a different Wi-Fi network.

108.9.2. "Multiple devices online"

Pass `-Dcn1.android.onDeviceDebug.deviceSerial=<serial>` (run `adb devices` to see serials). The emulator's serial looks like `emulator-5554`; a USB-attached phone is its hardware ID; a wireless

device is `<ip>:<port>`.

108.9.3. App installs but won't pause for the debugger

`waitForAttach` only takes effect when the APK is built with `android.onDeviceDebug=true` (or `android.xapplication_attr` containing `android:debuggable="true"`). Verify by running `adb shell dumpsys package <your.package> | grep flags` — `DEBUGGABLE` must be in the list. If it isn't, rebuild with `mvn cn1:buildAndroidOnDeviceDebug`.

108.9.4. Breakpoint never fires

Check the **CN1 Attach Android** run config:

- **Host** is `localhost`, **Port** matches the `jdwpPort` printed by the debug session.
- The **Use module classpath** dropdown is the `-common` module, so IntelliJ can resolve your `.java` files.

If a class loaded on the device doesn't match the class IntelliJ thinks is current, breakpoints stop firing with no error message. Rebuild and reinstall (`cn1:buildAndroidOnDeviceDebug` + re-run **CN1 Android On-Device Debug**).

108.9.5. logcat shows the app exiting with `Debug.waitForDebugger`-like noise

The system killed the process for taking too long to attach. Set `-Dcn1.android.onDeviceDebug.waitForAttach=false` and trigger the code path you want to debug manually after attach — Android's debug-app wait isn't bound to the breakpoint, only to process start.

108.9.6. Wireless connection drops mid-session

Wi-Fi connections to debug-mode devices are sensitive to power-saving. On the device, keep the screen on (or set **Settings → Developer options → Stay awake** while charging). For long sessions, plug into USB and use `adb -s <wireless-serial>` to keep the wireless TCP socket alive without depending on the radio.

Chapter 109. Android without Google Play Services

Many Android devices have no Google Play Services. GrapheneOS, CalyxOS, /e/OS and LineageOS without Google apps ship without it, and GrapheneOS installs it only as an ordinary app the user can remove. Huawei and Amazon devices have their own services instead. A Codename One application runs on these devices without a separate build: the same APK checks at run time whether Play services is present and uses a fallback, or reports a feature as unsupported, when it isn't.

No build hint turns this on. The Android port never calls into Play services, Play Core or Firebase without asking first, and a CI check holds it to that.

109.1. What changes without Play services

Feature	Behavior without Google Play Services
User interface, storage, networking, SQLite, media	Unchanged. None of them use Play services.
Location	Uses Android's own location manager. Background location and geofences use the framework's pending-intent updates and proximity alerts instead of the fused provider. The listener API and the `android.backgroundLocation.*` build hints are the same. An application built without Play services location uses the same fallback on Google devices too, where background location and geofences used to be unsupported.
Maps	`NativeMap` falls back to the vector `MapView` instead of the native Google map.
Push notifications	`PushClient` delivers through UnifiedPush (see below) or Huawei Push Kit when the build includes them. Without any of them, `pushRegistrationError` reports that no push service is available rather than registration never answering.
Google sign-in	`isNativeLoginSupported()` answers `false`, so `GoogleConnect` signs in through the browser OAuth flow.
On-device AI (ML Kit)	Works. The bundled models run locally.
Device attestation (Play Integrity)	`isAttestationSupported()` answers `false`.
In-app review	`isSupported()` answers `false`. The review prompt belongs to the Play Store.
Nearby connections	The transport reports `NOT_SUPPORTED`.
Wear OS data layer	Unavailable.

Feature	Behavior without Google Play Services
In-app purchase	Google Play Billing needs the Play Store; purchases are unavailable on these devices.

Test an application on such a device with the Android emulator's **AOSP** system images (`default` target), which have no Google apps.

109.2. Push notifications through UnifiedPush

UnifiedPush [https://unifiedpush.org] lets the user choose the app that holds the push connection: ntfy, NextPush, Sunup and others, called distributors. A UnifiedPush endpoint is a standard Web Push subscription, so the push service delivers to it with the **Web Push** credential the application already has. It needs no server change and no other credential.

To enable it, copy the VAPID public key from the application's Web Push credential into a build hint:

```
codename1.arg.android.unifiedPush.vapidKey=BExampleKeyOf87Base64UrlCharacters...
```

The key is 87 base64url characters. The build rejects anything else. With the hint set and `PushClient` in use, the application registers in this order:

1. Firebase Cloud Messaging, when Google Play Services is available and the build includes `google-services.json`.
2. Huawei Push Kit, when HMS Core is installed and the build includes `agconnect-services.json`.
3. UnifiedPush, otherwise. If the user has more than one distributor installed, Android asks which one to use. With none installed, `pushRegistrationError` explains that a push service is needed.

The device key the application receives starts with `cn1-web-`, and the push service routes it as a Web Push target. `android.messagingService=unifiedpush` forces UnifiedPush even without the key, for distributors that don't require one. `android.unifiedPush.connectorVersion` overrides the version of the UnifiedPush connector library the build adds.

Build, sign and ship

Chapter 110. Build hints reference

110.1. Sending arguments to the build server

When you send a build to the server, you can provide more parameters. The server incorporates those parameters into the build process as build hints.

These hints are often called "build hints" or "build arguments." They behave like compiler flags that tune the build server's behavior. That makes them useful for fast iteration on new functionality without rebuilding plugin UI for every change. They're also useful when you need to expose low-level behavior such as customizing the Android manifest XML or the iOS plist.

Launch Codename One Settings from the Maven project root, then select **Hints** in the left navigation rail. The hints use the `key=value` style.

```
mvn cn1:settings
```

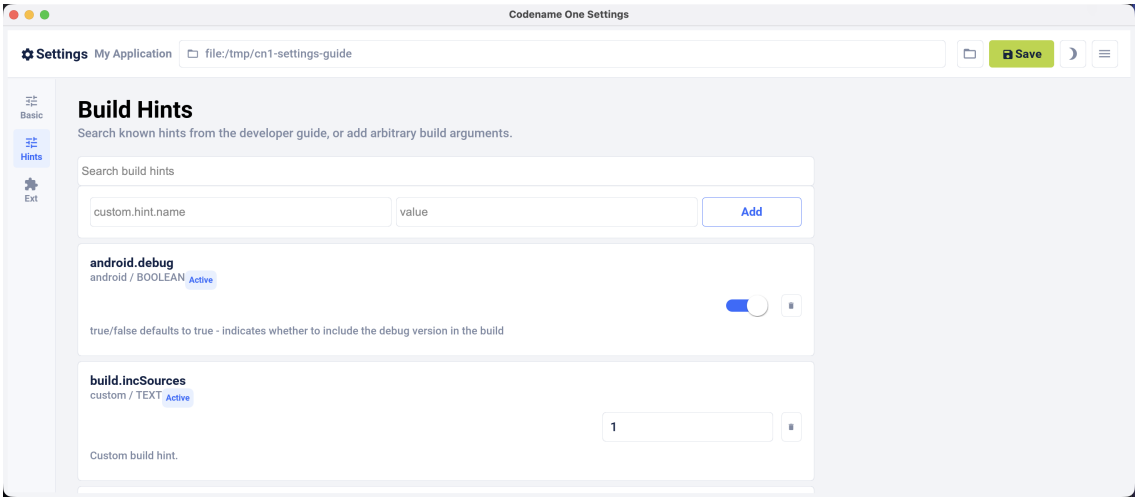


Figure 390. The build hints UI in Codename One Settings

You can also set the build hints directly in the `codenameone_settings.properties` file. When you do that, each setting must start with the `codename1.arg.` prefix. For example, `android.debug=true` becomes `codename1.arg.android.debug=true`.

Application code can read a custom build argument through `Display.getProperty()`:

```
class AppArgSnippet {
    public void readArgument() {
        String arg = Display.getInstance().getProperty("AppArg", null);
    }
}
```

The table below consolidates build hints across platforms from the annotations and build-hint catalog. It includes names, types, defaults, annotation forms, and descriptions, including aliases and open-ended hint families.

Most of the commonly used hints also have a compiler-checked form: an annotation in `com.codename1.annotations.buildhints` that you put on the application's main class. Written that way a misspelled name is an unknown symbol and an unsupported value is an unknown enum constant, instead of a properties line that is accepted, never read, and has no effect. The Annotation column below names that form where one exists. Setting the same hint both ways fails the build.

Each annotation groups the hints of one platform, and the attribute names match the part of the hint name after the prefix, so `codename1.arg.ios.pods` is `@Ios(pods = …)`:

```
@Android(themeMode = ThemeMode.MODERN, minSdkVersion = AndroidMinSdk.API_24)
@Build(nativeTheme = ThemeMode.MODERN)
@DesktopBuild(titleBar = DesktopTitleBar.NATIVE, width = 1280, height = 800)
@Ios(themeMode = ThemeMode.MODERN,
     newStorageLocation = Toggle.ON,
     pods = {"Intercom", "AFNetworking"})
public class BuildHintAnnotationSnippet {
}
```

That's the same as writing these lines in `codenameone_settings.properties`:

```
codename1.arg.and.themeMode=modern
codename1.arg.android.min_sdk_version=24
codename1.arg.nativeTheme=modern
codename1.arg.desktop.titleBar=native
codename1.arg.desktop.width=1280
codename1.arg.desktop.height=800
codename1.arg.ios.themeMode=modern
codename1.arg.ios.newStorageLocation=true
codename1.arg.ios.pods=Intercom,AFNetworking
```

Three things in that example are worth calling out.

A hint whose value is a list takes a Java array, and the build joins it with the separator that hint uses — a comma for `ios.pods`, so you never have to remember which hint wants which delimiter.

A boolean hint takes `Toggle`, not `boolean`. `Toggle.ON` and `Toggle.OFF` say what you want, and leaving the attribute out entirely means you have said nothing, so the build service applies whatever it applies today. That's why the Default column reads *(set by the build)* for these hints: the annotation records no default of its own, by design: a value compiled into your app can't follow the build service when the service changes it.

A hint with a closed set of values takes an enum, so `@Ios(themeMode = …)` offers you the four themes that exist and rejects anything else at compile time. Hints whose accepted values are open-ended stay `String`.

The long tail of hints has no annotation, and neither do the open-ended families such as `android.permission.<NAME>`, because a Java annotation can't express a map. Set those in `codenameone_settings.properties` exactly as before. You can mix the two forms in one project, as

long as no single hint is declared in both.

Build hints are the one part of Codename One that doesn't promise source compatibility, and that's deliberate.

Everywhere else, code that compiles against one release keeps compiling against the next. Here, a hint that changes its name, its type or its accepted values is meant to stop compiling, so you find out at your desk. The alternative is what the properties file has always done: accept the line, never read it, and leave you with a build that succeeds and an app that doesn't do what you asked.

The failure is always on the client side, never on the build service. A hint reaches the service as a name and a string, and the service goes on accepting the strings it always did — an app already built keeps building, and an older Codename One keeps talking to a newer service. A changed hint breaks a compile in your project, with the attribute named.

If a release does take an annotation away, the properties form of the same hint still works, so the upgrade costs a line in `codenameone_settings.properties` rather than being one you can't take.

110.2. All build hints

Table 16. Build hints

Name	Type	Default	Annotation	Description
`and.captureRecord`	string	*(none)*	*(none)*	Override alias of `android.captureRecord`, read after it and winning when set.
`and.facebook_permissions`	string	*(none)*	*(none)*	Override alias of `android.facebook_permissions`, read after it and winning when set. `IPhoneBuilder` also falls back to it when `ios.facebook_permissions` is unset.

Name	Type	Default	Annotation	Description
and.themeMode	auto, modern, hololight, legacy, custom	*(set by the build)*	@Android(themeMode)	auto, modern / material, hololight (default for existing apps), legacy, custom. auto and modern / material opt in to the CSS-generated Android Material 3 theme from native-themes/android-material/theme.css. hololight is Android Holo Light (what the framework shipped on API 14+ before this refactor). legacy loads the pre-Holo Android theme. The legacy alias cn1.androidTheme is still accepted, and and.hololight=true still maps to hololight. The default stays on hololight for existing apps until you flip in a future release. custom packages and installs no Android theme at all, for an application whose own theme is the only one.
android.NotificationChannel.description	string	Remote notifications	*(none)*	
android.NotificationChannel.enableLights	boolean	true	*(none)*	
android.NotificationChannel.enableVibration	boolean	false	*(none)*	
android.NotificationChannel.id	string	cn1-channel	*(none)*	
android.NotificationChannel.importance	int	2	*(none)*	
android.NotificationChannel.lightColor	string	*(none)*	*(none)*	
android.NotificationChannel.name	string	Notifications	*(none)*	
android.NotificationChannel.vibrationPattern	string	*(none)*	*(none)*	
android.accessibilityGuard	boolean	false	*(none)*	
android.accessibilityGuard.allow	string	*(none)*	*(none)*	
android.accessibilityGuard.mode	string	exit	*(none)*	

Name	Type	Default	Annotation	Description
android.activity.launchMode	string	*(set by the build)*	@Android(activityLaunchMode)	Allows explicitly setting the android:launchMode attribute of the main activity in android. Default is "singleTop," but for some applications you may need to change this behaviour. In particular, apps that are meant to open a file type will need to set this to "singleTask." See Android docs for the activity element [https://developer.android.com/guide/topics/manifest/activity-element.html] for more information about the android:launchMode attribute.
android.activityClassBody	string	*(none)*	*(none)*	
android.activityClassImports	string	*(none)*	*(none)*	
android.adaptiveIconBackground	string	#ffffff	*(none)*	Background color to use for adaptive icons when android.enableAdaptiveIcons=true and no background image is supplied. Defaults to #ffffff and is written as @color/ic_launcher_background.
android.adaptiveIconBackgroundImage	string	*(none)*	*(none)*	Optional path (relative to the root of the native Android project) to an image file to use as the adaptive icon background when android.enableAdaptiveIcons=true. If this property is set, it overrides android.adaptiveIconBackground.
android.allowBackup	boolean	true	*(none)*	
android.androidAuto.messaging	boolean	false	*(none)*	
android.androidAuto.minCarApiLevel	int	1	*(none)*	
android.androidAuto.navigation	boolean	false	*(none)*	
android.androidAuto.poi	boolean	false	*(none)*	
android.anyDensity	boolean	true	*(none)*	
android.apacheLegacy	boolean	false	*(none)*	

Name	Type	Default	Annotation	Description
`android.appBundle`	boolean	*(set by the build)*	`@Android(appBundle)`	Produces an Android App Bundle (.aab) rather than an APK. Required for new Play Store submissions.
`android.appReview.version`	version	`2.0.1`	*(none)*	
`android.ar.required`	boolean	`false`	*(none)*	
`android.arrcompile`	string	*(none)*	*(none)*	
`android.arrimplementation`	string	*(none)*	*(none)*	
`android.asyncPaint`	boolean	`true`	*(none)*	Boolean true/false defaults to true. Toggles the Android pipeline between the legacy pipeline (false) and new pipeline (true)
`android.background_push_handling`	boolean	`false`	*(none)*	
`android.billing.store`	string	`play`	*(none)*	The store an in-app-purchase app is built for: `play` (the default) or `amazon`. An app is built for one store. `amazon` builds against the Amazon Appstore SDK instead of the Play Billing Library, declares the receiver Amazon's client answers through, and leaves out the `com.android.vending.BILLING` permission, which the Amazon Appstore doesn't accept. `android.licenseKey` and `android.billingclient.version` are Google Play settings and aren't used. Receipts carry the store code `amazon`, the Amazon receipt id as the transaction id, and the receipt id, user id and SKU as order data for server-side verification. The Appstore SDK also requires the app's public key from the Amazon developer console, `AppstoreAuthenticationKey.pem`, among the app's Android assets. Any other value fails the build.

Name	Type	Default	Annotation	Description
android.billingclient.version	version	8.0.0	*(none)*	The Play Billing Library version an in-app-purchase app is built against, defaulting to 8.0.0. Codename One's billing implementation uses the ProductDetails API, so 8.0.0 is also the minimum: Play Billing removed the older SkuDetails API, and a build set lower is refused with an explanation rather than a page of compiler errors. The default is the lowest version Google still accepts for new apps and updates, and the only one at that level whose library is content with minSdkVersion 21; every later release requires 23. Setting a newer version raises android.min_sdk_version to match, because the library's own manifest would otherwise fail the merge.
android.blockExternalStoragePermission	boolean	false	*(none)*	Boolean true/false defaults to false. Disables the external storage (SD card) permission
android.blockLabel	boolean	false	*(none)*	Boolean true/false defaults to false. Leaves android:label off the generated <application> tag so a label set through android.xapplication_attr or a merged manifest is the one that survives. Honoured by the wear module's tag as well as the phone's.
android.blockReadMediaPermissions	boolean	*(none)*	*(none)*	Boolean true/false, defaults to the value of android.blockExternalStoragePermission. Suppresses the READ_MEDIA_VIDEO and READ_MEDIA_AUDIO permissions that playing a URI adds on API 33 and above
android.bluetooth.neverForLocation	boolean	true	*(none)*	
android.bluetooth.required	boolean	false	*(none)*	
android.buildToolsVersion	version	*(set by the build)*	@Android(buildToolsVersion)	Android build-tools version. It also selects the compile SDK, so there is no separate compile-SDK hint.

Name	Type	Default	Annotation	Description
android.call.video	boolean	false	*(none)*	Whether the manifest declares CAMERA, which video calls need. Overrides call.video on Android. CallConfiguration.videoSupported(true) is a runtime decision no scanner can see, so the build has to be told here as well; without it Calls.getCapabilities() omits CAPABILITY_VIDEO.
android.captureRecord	string	*(set by the build)*	@Android(captureRecord)	Indicates whether the RECORD_AUDIO permission should be requested. Can be enabled or any other value to disable this option
android.carAppVersion	version	1.4.0	*(none)*	
android.cn1NativesRepository	string	https://repo.codenameone.com/maven2	*(none)*	Maven repository the builder fetches the on-device AI natives (com.codenameone.natives, whisper.cpp and llama.cpp) from, when the app uses them. Defaults to the Codename One repository; a file: URL tests a local scripts/ai-natives/build.sh output.
android.credentialsPlayServicesVersion	string	*(none)*	*(none)*	
android.credentialsVersion	version	1.3.0	*(none)*	
android.cusom_layout	string	*(none)*	*(none)*	
android.cusom_layout*	string	*(none)*	*(properties file only)*	Numbered custom layout resources: android.cusom_layout1, android.cusom_layout2 and upward. The misspelling is load-bearing: it's the key the builder actually reads, so correcting it drops the layout with no warning.

Name	Type	Default	Annotation	Description
android.cusom_layout1	string	*(none)*	*(none)*	Applies to any number of layouts as long as they're in sequence (for example, android.cusom_layout2, android.cusom_layout3 etc.). Will write the content of the argument as a layout XML file and give it the name cusom_layout1.xml onwards. This can be used by native code to work with XML files
android.customActivity	string	CodenameOneActivity	*(none)*	
android.customTabsVersion	version	1.8.0	*(none)*	
android.debug	boolean	*(set by the build)*	@Android(debug)	Whether to include the debug version in the build. Left alone, this follows [#release] rather than a fixed value, so a build that selects neither still produces something installable.
android.decouplePlayServiceVersions	string	*(none)*	*(none)*	
android.delayPushCompletion	boolean	false	*(none)*	
android.disableR8	boolean	*(set by the build)*	@Android(disableR8)	Turns off R8, falling back to the older shrinker. Note that hardening requires R8, so this conflicts with harden.level.
android.disableR8FullMode	boolean	true	*(none)*	
android.disableScreenshots	boolean	false	*(none)*	
android.documentProvider.enabled	boolean	false	*(none)*	The Android counterpart of ios.documentProvider.enabled, and the supported way to declare the feature when the code that publishes lives in a cn1lib rather than in the app: the build's usage scan reads the application's own classes, so an app that only calls a library which publishes documents goes undetected. Falls back to ios.documentProvider.enabled when unset, so a project that sets one gets both.

Name	Type	Default	Annotation	Description
android.enableAdaptiveIcons	boolean	false	*(none)*	Boolean true/false defaults to false. Enables Android adaptive icon generation in Android Gradle builds. When enabled, Codename One generates mipmap launcher resources (ic_launcher, ic_launcher_foreground, and adaptive XML in mipmap-anydpi-v26) and uses them in the application manifest (android:icon and android:roundIcon).
android.enableProguard	boolean	*(set by the build)*	@Android(enableProguard)	Boolean true/false defaults to true. Allows disabling the proguard obfuscation even on release builds, notice that this isn't recommended
android.excludeBolts	boolean	false	*(none)*	
android.extendAppCompatActivity	boolean	false	*(none)*	
android.facebookSdkVersion	version	16.2.0	*(none)*	
android.facebook_permissions	string	"public_profile","email","user_friends"	*(none)*	Permissions for Facebook used in the Android build target, applicable only if Facebook native integration is used.

Name	Type	Default	Annotation	Description
`android.file_paths`	string	`` `<files-path name="app_files" path="." /><external-files-path name="app_external_files" path="." /><external-cache-path name="app_external_cache" path="." /><external-path name="external" path="." />` ``	*(none)*	The FileProvider roots written into file_paths.xml, besides the cache/intent_files one the framework always needs. A file has to be under one of these for the application to hand it to another application — when sharing, or when dragging it out. Setting this replaces the default rather than adding to it.
`android.firebaseAnalytics`	boolean	`false`	*(none)*	
`android.firebaseAnalyticsVersion`	version	`21.5.0`	*(none)*	
`android.firebaseCoreVersion`	string	*(none)*	*(none)*	
`android.firebaseMessagingVersion`	string	*(none)*	*(none)*	
`android.foldableSupport`	boolean	`false`	*(none)*	
`android.forceJava8Builder`	boolean	`false`	*(none)*	
`android.foregroundServiceType`	string	`dataSync`	*(none)*	

Name	Type	Default	Annotation	Description
`android.fridaDebugLogging`	boolean	*(none)*	*(none)*	Boolean true/false defaults to false. If true, it will add verbose debug logs during frida detection to show which check if fails on.
`android.fridaDetection`	boolean	`false`	*(none)*	Boolean true/false defaults to false. Indicates whether the app should check for the presence of the Frida [https://www.frida.re/] dynamic instrumentation toolkit on the device. If Frida is detected, the app will exit. This uses the [frida-blocker](https://github.com/shannah/frida-blocker) library to perform the frida detection.
`android.fridaVersion`	string	*(none)*	*(none)*	x.y.z The version of [frida-blocker](https://github.com/shannah/frida-blocker) to use to perform frida detection. This is only relevant if `android.fridaDetection=true`. If omitted, it will use the latest tested version in the build server.
`android.fullScreenIntent`	boolean	`false`	*(none)*	
`android.googleAdUnitId`	string	*(none)*	*(none)*	Allows integrating admob/google play ads, this is effectively identical to google.adUnitId but only applies to Android
`android.googleAdUnitTestDevice`	string	`C6783E2486F0931D9D09FABC65094FDF`	*(none)*	Device key used to mark a specific Android device as a test device for Google Play ads defaults to C6783E2486F0931D9D09FABC65094FDF
`android.gpsPermission`	boolean	`false`	*(none)*	Indicates whether the GPS permission should be requested, it's autodetected by default if you use the location API. But, some code might want to explicitly define it
`android.gradle.androidx`	list (newline delimited)	*(none)*	*(none)*	

Name	Type	Default	Annotation	Description
android.gradleDep	list (; delimited)	*(set by the build)*	@Android(gradleDep)	Gradle dependency statements to add to the app module, such as implementation 'com.example:lib:1.0'.
android.gradlePlugin	list (newline delimited)	*(none)*	*(none)*	
android.gradleVersion	string	*(none)*	*(none)*	Opts the build into Gradle 9. 9 builds with Gradle 9.8.0 and Android Gradle plugin 9.4.1 instead of the default Gradle 8 toolchain. An explicit 9.x release of 9.6.0 or newer (the oldest Gradle that plugin runs on) is also accepted, with a difference between where the build runs: a local build (android-source, or Gradle on your machine) downloads and uses exactly that release, while the Codename One build cloud has one Gradle 9 installed and builds every accepted 9.x value with its Gradle 9.8.0. Older 9.x releases and Gradle 10 are refused. Kotlin sources are compiled by the plugin's built-in Kotlin, so a hint that applies kotlin-android itself fails on this path, and so does any Gradle plugin a hint adds that still uses the variant API Android Gradle plugin 9 removed.
android.hce	boolean	false	*(none)*	
android.hceAids	string	F0010203040506	*(none)*	
android.hceCategory	string	other	*(none)*	
android.hceDescription	string	*(none)*	*(none)*	
android.hceRequireUnlock	boolean	false	*(none)*	
android.headphoneCallback	boolean	false	*(none)*	Boolean true/false defaults to false. When set to true it assumes the main class has two methods: headphonesConnected & headphonesDisconnected which it invokes appropriately as needed

Name	Type	Default	Annotation	Description
`android.health.background`	boolean	`false`	*(none)*	
`android.health.connectVersion`	string	`1.1.0-alpha07`	*(none)*	
`android.health.history`	boolean	`false`	*(none)*	
`android.health.privacyPolicyUrl`	string	*(none)*	*(none)*	
`android.health.read`	string	*(none)*	*(none)*	
`android.health.write`	string	*(none)*	*(none)*	
`android.hideOverlayWindows`	boolean	`false`	*(none)*	Boolean true/false defaults to false. Declares the `android.permission.HIDE_OVERLAY_WINDOWS` permission needed by `DeviceIntegrity.setHideOverlayWindows()` on Android 12+, for apps that call the runtime API without enabling `android.tapjackingGuard`. A normal install-time permission, so the user sees no prompt.
`android.hideStatusBar`	boolean	*(set by the build)*	`@Android(hideStatusBar)`	Hides the Android status bar.
`android.hms.pushVersion`	string	`6.3.0.302`	*(none)*	
`android.home.playServicesVersion`	string	`16.0.0-beta1`	*(none)*	
`android.includeGPlayServices`	boolean	`true`	*(none)*	**Deprecated, please android.playService.*!** Indicates whether Google Play Services should be included into the build, defaults to false but that might change based on the functionality of the application and other build hints. Adding Google Play Services support allows you to use a more refined location implementation and invoke some Google specific functionality from native code.
`android.includeMavenCentral`	boolean	`false`	*(none)*	

Name	Type	Default	Annotation	Description
`android.installLocation`	`auto`, `internalOnly`, `preferExternal`	*(set by the build)*	`@Android(installLocation)`	Maps to android:installLocation manifest entry defaults to auto. Can also be set to internalOnly or preferExternal.
`android.invite.appLinks`	boolean	`true`	*(none)*	Whether the build injects the `android:autoVerify` intent filter for the invite link domain into the main activity. Set it to `false` only when declaring the filter yourself through `android.xintent_filter`; with no filter at all an invite link opens the browser instead of the app.
`android.invite.signingFingerprint`	list (`,` delimited)	*(none)*	*(none)*	Comma separated SHA-256 signing certificate fingerprints, in colon separated hex, enrolled in the shared `assetlinks.json` alongside the one derived from the build's keystore. Apps distributed through Play App Signing must add the app signing certificate fingerprint from the Play Console here: Google re-signs the app, so the upload key the build holds isn't the certificate Android verifies against. Without it, App Links verification fails on every Play install and nothing reports an error.
`android.java8`	string	*(none)*	*(none)*	Accepted and ignored. A Java 6 source level was produced by running retrolambda over the compiled classes; retrolambda has been removed, so Android builds always use a Java 8 source level. Setting this to false logs a notice and changes nothing.
`android.keyboardOpen`	boolean	`true`	*(none)*	Boolean true/false defaults to true. Toggles the new async keyboard mode that leaves the keyboard open while you move between text components

Name	Type	Default	Annotation	Description
`android.kotlinStdlibAlignment`	boolean	`true`	*(none)*	Boolean true/false defaults to true. Kotlin 1.8.0 moved the contents of `kotlin-stdlib-jdk7` and `kotlin-stdlib-jdk8` into `kotlin-stdlib` and left the two shims empty. A build that reaches `kotlin-stdlib` 1.8 or newer through one dependency and an older `kotlin-stdlib-jdk8` through another then carries the same classes twice and fails in `checkReleaseDuplicateClasses`, naming Kotlin artifacts you never asked for. The 1.8.x line ships no Gradle module metadata to say the two overlap; from 1.9.22 JetBrains ships it. This adds that missing statement, as a Gradle capability: from 1.8.0 up, `kotlin-stdlib` provides what the shims provide, so Gradle drops the redundant shim. It moves no version, which is what keeps it out of your way — a version pin, a force, an enforced BOM, a range or a Kotlin compiler older than 1.8 all resolve exactly as they did without it. Below 1.8.0 nothing happens at all, because there the shims still hold the only copy of their classes. Set to false to manage these coordinates yourself.
`android.largeScreens`	boolean	`true`	*(none)*	
`android.licenseKey`	string	*(set by the build)*	`@Android(licenseKey)`	The license key for the Android app, this is required if you use in-app purchase on Android
`android.locales`	string	*(none)*	*(none)*	

Name	Type	Default	Annotation	Description
`android.locationButton.exclusive`	string	`auto`	*(none)*	Whether `ACCESS_FINE_LOCATION` is declared `onlyForLocationButton`, which means the system grants precise location through the location button and never any other way. Defaults to `auto`: the build infers it, declaring the flag when the application uses `LocationButton` and nothing else from the location or maps packages. Set `false` when the application reaches precise location through native Android code, which the class scan can't see because Gradle compiles it later, and `true` to declare the flag whenever the build declares the permission at all, whatever the inference would have chosen. Neither value makes the build declare a permission it otherwise would not: an application whose only location use is invisible to the class scan gets no declaration to flag, and reaches precise location through its own `android.xpermissions` entry.
`android.manifest.queries`	string	*(none)*	*(none)*	Embeds XML content into the <queries> section of the Android manifest file. This is required in Android 11 for package visibility [https://developer.android.com/training/package-visibility]. See queries element Android documentation [https://developer.android.com/guide/topics/manifest/queries-element].
`android.maps.provider`	string	*(none)*	*(none)*	Android's own native map provider, overriding `maps.provider`.

Name	Type	Default	Annotation	Description
android.messagingService	string	*(none)*	*(none)*	The Android push provider. Left unset, a build that uses PushClient picks FCM, Huawei Push Kit or both from the google-services.json and agconnect-services.json files present, and fails when none is configured. The android.unifiedPush.vapidKey hint adds UnifiedPush to that choice. fcm, huawei or unifiedpush forces one provider; none builds without push, for an app that hasn't got its push configuration yet.
android.migrateToAndroidX	boolean	true	*(none)*	
android.min_sdk_version	19, 20, 21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31, 32, 33, 34, 35, 36	*(set by the build)*	@Android(minSdkVersion)	The least SDK required to run this app, the default value changes based on functionality but can be as low as 7. This corresponds to the XML attribute android:minSdkVersion.
android.mockLocation	boolean	true	*(none)*	Boolean true/false defaults to true. Toggles the mock location permission which is on by default, this allows easier debugging of Android device location based services
android.mopubId	string	*(none)*	*(none)*	
android.multidex	boolean	*(set by the build)*	@Android(multidex)	Multidex lets an Android binary reference more than 65536 methods. Set [Toggle#OFF] to opt out, which builds a little faster and reinstates the limit.
android.nativeThemes.keepAll	boolean	false	*(none)*	true/false (defaults to false). The Android build ships only the native themes the build's theme mode can install (plus android_holo_light), unless the application's classes name and.themeMode or another theme-mode property. Set to true for an application that picks the mode through a property name it computes or reads from configuration, which no build-time scan can see; the iOS equivalent is ios.nativeThemes.keepAll.

Name	Type	Default	Annotation	Description
android.nearby.computerProfile	boolean	false	*(none)*	Offers the computer device profile in the companion-device chooser. Only read when the app uses nearby ranging, transport or companion association.
android.nearby.glassesProfile	boolean	false	*(none)*	Offers the glasses device profile in the companion-device chooser, on the same terms as android.nearby.computerProfile.
android.nearby.watchProfile	boolean	false	*(none)*	Offers the watch device profile in the companion-device chooser, on the same terms as android.nearby.computerProfile.
android.newFirebaseMessaging	boolean	*(set by the build)*	@Android(newFirebaseMessaging)	Uses the current Firebase Cloud Messaging integration. Requires AndroidX and Gradle 8.13 or newer.
android.nonconsumable	string	*(none)*	*(none)*	Comma delimited string of items that are non-consumable in the in-app purchase API
android.normalScreens	boolean	true	*(none)*	
android.onCreate	string	*(none)*	*(none)*	
android.onDeviceDebug	boolean	*(set by the build)*	@OnDeviceDebug(android)	Boolean true/false defaults to false. When true, the generated AndroidManifest.xml is marked android:debuggable="true", R8/proguard is disabled, and the build is pinned to debug-only (android.release is forced off and android.debug is forced on) so a stray hint can't ship a release-signed APK that's debuggable="true". Pair with the cn1:android-on-device-debugging Maven goal (or the bundled IntelliJ run configs) to install, launch, forward JDWP, and stream logcat through adb. Has no effect on builds that don't carry it — release builds are unaffected. See the On-Device Debugging (Android) chapter for the full flow.

Name	Type	Default	Annotation	Description
`android.permission.*`	string	*(none)*	*(properties file only)*	true/false. Whether to include a particular permission. Preferred over android.xpermissions because it avoids conflicts with libraries. See Android's Manifest.permission documentation for the full list. The optional .maxSdkVersion suffix becomes the maxSdkVersion attribute of the generated <uses-permission> tag, and .required marks the permission required.
`android.playIntegrity`	boolean	`false`	*(none)*	
`android.playIntegrity.verifyUrl`	string	*(none)*	*(none)*	
`android.playIntegrityVersion`	version	`1.4.0`	*(none)*	
`android.playService.*`	string	*(none)*	*(properties file only)*	Opts a single Google Play service in or out. The sibling <name>.minPlayServicesVersion pins its version.
`android.playService.ads`	boolean	`false`	*(none)*	
`android.playService.analytics`	string	*(none)*	*(none)*	
`android.playService.appInvite`	boolean	`false`	*(none)*	
`android.playService.auth`	string	*(none)*	*(none)*	
`android.playService.base`	string	*(none)*	*(none)*	
`android.playService.cast`	boolean	`false`	*(none)*	
`android.playService.drive`	boolean	`false`	*(none)*	
`android.playService.fitness`	boolean	`false`	*(none)*	
`android.playService.games`	boolean	`false`	*(none)*	
`android.playService.gcm`	string	*(none)*	*(none)*	
`android.playService.identity`	boolean	`false`	*(none)*	
`android.playService.indexing`	boolean	`false`	*(none)*	

Name	Type	Default	Annotation	Description
android.playServic e.location	string	*(none)*	*(none)*	
android.playServic e.maps	string	*(none)*	*(none)*	
android.playServic e.nearby	boolean	false	*(none)*	
android.playServic e.panorama	boolean	false	*(none)*	
android.playServic e.plus	boolean	false	*(none)*	
android.playServic e.safetynet	boolean	false	*(none)*	
android.playServic e.vision	boolean	false	*(none)*	
android.playServic e.wallet	boolean	false	*(none)*	
android.playServic e.wearable	boolean	false	*(none)*	
android.playServic esVersion	string	*(none)*	*(none)*	The version number of play services to build against. Experimental. **Use with caution** as building against versions other than the server default may introduce incompatibilities with some Codename One APIs.
android.proguardKe ep	list (newline delimite d)	*(set by the build)*	@Android(proguardK eep)	Arguments for the keep option in proguard allowing you to keep a pattern of files for example, -keep class com.mypackage.ProblemClass { *; }
android.proguardKe epOverride	string	Exceptio ns, InnerCla sses, Signatur e, Deprecat ed, SourceFi le, LineNumb erTable, **Annotati on**, EnclosingMethod	*(none)*	
android.pushSound	string	*(none)*	*(none)*	

Name	Type	Default	Annotation	Description
android.pushVibratePattern	string	*(none)*	*(none)*	Comma delimited long values to describe the push pattern of vibrate used for the setVibrate native method
android.release	boolean	*(set by the build)*	@Android(release)	true/false defaults to true - indicates whether to include the release version in the build
android.removeBasePermissions	boolean	false	*(none)*	Boolean true/false defaults to false. Disables the built-in permissions specifically INTERNET permission (that is, no networking...)
android.repositories	list (newline delimited)	*(set by the build)*	@Android(repositories)	Extra Gradle repositories to resolve dependencies from.
android.requestReadMediaPermissions	boolean	false	*(none)*	Boolean true/false defaults to false. Declares READ_MEDIA_IMAGES, READ_MEDIA_VIDEO and READ_MEDIA_AUDIO on API 33 and above even when the build detected no media playback. READ_MEDIA_IMAGES is only ever added by this hint
android.rootCheck	boolean	false	*(none)*	Boolean true/false defaults to false. Indicates whether the app should check for root access on the device. If root access is detected, the app will exit.
android.rootbeerVersion	version	0.1.2	*(none)*	
android.shareFilter	string	*(none)*	*(none)*	
android.sharedUserId	string	*(none)*	*(none)*	Allows adding a manifest attribute for the sharedUserId option
android.sharedUserLabel	string	*(none)*	*(none)*	Allows adding a manifest attribute for the sharedUserLabel option
android.shrinkResources	boolean	false	*(none)*	Boolean true/false defaults to false. Used only in conjunction with android.enableProguard. Strips out unused resources to reduce apk size. Since 7.0
android.signingV1	boolean	*(none)*	*(none)*	true/false Default true. See https://source.android.com/docs/security/features/apksigning

Name	Type	Default	Annotation	Description
`android.signingV2`	boolean	*(none)*	*(none)*	true/false Default true. See https://source.android.com/docs/security/features/apksigning
`android.signingV3`	boolean	*(none)*	*(none)*	true/false Default true. See https://source.android.com/docs/security/features/apksigning
`android.signingV4`	boolean	*(none)*	*(none)*	true/false Default true. See https://source.android.com/docs/security/features/apksigning
`android.smallScreens`	boolean	`true`	*(none)*	Boolean true/false defaults to true. Corresponds to the `android:smallScreens` XML attribute and allows disabling the support for small phones
`android.stack_size`	string	*(none)*	*(none)*	Size in bytes for the Android stack thread
`android.statusbar_hidden`	boolean	`false`	*(none)*	true/false defaults to false. When set to true hides the status bar on Android devices.
`android.store_ids`	string	*(none)*	*(none)*	
`android.streamMode`	string	*(none)*	*(none)*	The mode in which the volume key should behave, defaults to OS default. Allows setting it to `music` for music playback apps
`android.stringsXml`	string	*(none)*	*(none)*	Allows injecting more entries into the strings.xml file using a value that includes something like this `<string name="key1">value1</string><string name="key2">value2</string>`
`android.style`	string	*(none)*	*(none)*	Allows injecting more data into the `styles.xml` file right before the closing resources tag
`android.supportScreens`	string	*(none)*	*(none)*	
`android.supportV4`	boolean	*(none)*	*(none)*	Boolean true/false defaults to false but that can change based on usage (for example, push implicitly activates this). Indicates whether the android support v4 library should be included in the build

Name	Type	Default	Annotation	Description
`android.supportv4Dep`	list (newline delimited)	*(none)*	*(none)*	
`android.surfaces.complicationUpdateSeconds`	int	`0`	*(none)*	`UPDATE_PERIOD_SECONDS` on the generated complication service. Zero, the default, means the system never polls on a timer and the complication updates only when the app pushes new data.
`android.surfaces.exactAlarms`	boolean	`false`	*(none)*	
`android.tapjackingGuard`	boolean	`false`	*(none)*	Boolean true/false defaults to false. Switches on tapjacking / screen-overlay protection at launch, so touches that arrive while another app's window covers this one are detected and dropped. See the security chapter.
`android.tapjackingGuard.hideOverlays`	boolean	`true`	*(none)*	Boolean true/false defaults to true. Also asks Android 12+ to hide overlay windows drawn over the app, which is the only mitigation that covers native peer components, and declares the `HIDE_OVERLAY_WINDOWS` permission it requires. Only relevant if `android.tapjackingGuard=true`.
`android.tapjackingGuard.mode`	string	`block`	*(none)*	`block` (default), `strict`, `report` or `off`. `block` drops gestures that start on a fully obscured window, `report` only observes, `strict` also drops touches where only part of the window is covered (which benign system UI can trigger). Only relevant if `android.tapjackingGuard=true`.
`android.targetSDKVersion`	int	*(set by the build)*	`@Android(targetSDKVersion)`	The Android SDK the build compiles against. Unset, the build server uses the highest platform it has installed, so leaving this alone tracks the server rather than pinning a number. Not every target works: the source may have limitations, and not all SDK targets are installed.

Name	Type	Default	Annotation	Description
android.textureView	boolean	false	*(none)*	
android.theme	string	Light	*(none)*	Light or Dark defaults to Light. On Android 4+ the default Holo theme is used to render the native widgets sometimes and this indicates whether holo light or holo dark is used. This doesn't affect the Codename One theme but that might change in the future.
android.topDependency	list (newline delimited)	*(set by the build)*	@Android(topDependency)	Statements added to the top-level Gradle build file rather than the app module.
android.tv	boolean	false	*(none)*	true/false (defaults to false). Marks the build as an Android TV / Google TV app. Adds the LEANBACK_LAUNCHER intent category to the launcher activity (so the app appears on the TV home screen), declares the android.software.leanback feature, makes android.hardware.touchscreen optional (so it installs on touchless TVs), and generates a 320×180 launcher banner (@drawable/tv_banner) from the app icon. The same APK still installs and runs on phones and tablets, and CN.isTV() returns true at runtime on a TV.
android.unifiedPush.connectorVersion	string	3.3.5	*(none)*	Version of the UnifiedPush connector library (org.unifiedpush.android:connector) added when UnifiedPush is turned on.
android.unifiedPush.vapidKey	string	*(none)*	*(none)*	Turns on UnifiedPush for an app that uses PushClient, so it receives push on devices without Google Play services (GrapheneOS, LineageOS, /e/OS) through a distributor such as ntfy. The value is the public key of the app's web push (VAPID) credential: 87 base64url characters. Firebase is still used where Play services is available.

Name	Type	Default	Annotation	Description
`android.useAndroidX`	boolean	*(set by the build)*	`@Android(useAndroidX)`	Use Android X instead of support libraries. This will also run a find/replace on all source files to replace support libraries and artifacts with AndroidX equivalents.
`android.useGradle8`	string	*(none)*	*(none)*	
`android.uses_feature.*`	string	*(none)*	*(properties file only)*	Adds a <uses-feature> element named by the suffix.
`android.uses_permission.*`	string	*(none)*	*(properties file only)*	Adds a <uses-permission> element named by the suffix.
`android.versionCode`	string	*(none)*	*(none)*	Allows overriding the auto generated version number with a custom internal version number specifically used for the XML attribute `android:versionCode`
`android.watchModule`	boolean	`true`	*(none)*	Boolean true/false defaults to true. Set to false to build the phone app alone in a companion build: the wearable link stays, no watch module is generated, and the phone output matches what it was before the watch app existed.
`android.watchVersionCode`	int	*(none)*	*(none)*	The wear module's version code, stated outright. Play requires it to be higher than the phone's, so a value other than a whole number above `android.versionCode` fails the build rather than being replaced without a word. Leave it unset to derive the value from `android.watchVersionCodeOffset`.
`android.watchVersionCodeOffset`	int	`10000000`	*(none)*	How far above the phone's version code the wear module's sits when `android.watchVersionCode` is unset. The default leaves room for the phone app to keep incrementing without ever catching up.
`android.wear`	boolean	`false`	*(none)*	

Name	Type	Default	Annotation	Description
`android.wear.complicationsVersion`	string	`1.2.1`	*(none)*	Version of `androidx.wear.watchface:watchface-complications-data-source` added to the wear module. Kept out of `android.gradleDependencies` because that hint feeds the phone module too, and these libraries declare minSdk 26.
`android.wear.guavaVersion`	string	`31.1-android`	*(none)*	Version of `com.google.guava:guava` added to the wear module alongside the tiles and complications libraries, which need it at runtime.
`android.wear.protoLayoutVersion`	string	`1.2.1`	*(none)*	Version of the `androidx.wear.protolayout` libraries the generated tile service builds its layout with.
`android.wear.standalone`	string	*(none)*	*(none)*	
`android.wear.tilesVersion`	string	`1.4.1`	*(none)*	Version of `androidx.wear.tiles` added to the wear module when the app declares a tile.
`android.web_loading_hidden`	boolean	`false`	*(none)*	true/false defaults to false - set to true to hide the progress indicator that appears when loading a web page on Android.
`android.windowVersion`	version	`1.3.0`	*(none)*	
`android.xactivity`	xml	*(none)*	*(none)*	Allows injecting more attributes into the `activity` tag in the Android XML
`android.xapplication`	xml	*(set by the build)*	`@Android(xapplication)`	defaults to an empty string. Allows developers of native Android code to add text within the application block to define things such as widgets, services etc.
`android.xapplication_attr`	xml	*(none)*	*(none)*	Allows injecting more attributes into the `application`` tag in the Android XML
`android.xgradle`	list (newline delimited)	*(set by the build)*	`@Android(xgradle)`	Arbitrary text spliced into the generated app-module Gradle file.

Name	Type	Default	Annotation	Description
android.xgradle_default_config	list (newline delimited)	*(none)*	*(none)*	
android.xintent_filter	xml	*(none)*	*(none)*	Allows adding an intent filter to the main android activity
android.xlargeScreens	boolean	true	*(none)*	
android.xlayout_attr	string	*(none)*	*(none)*	
android.xmanifest	xml	*(none)*	*(none)*	
android.xpermissions	xml	*(set by the build)*	@Android(xpermissions)	more permissions for the Android manifest
desktop.adaptToRetina	boolean	*(set by the build)*	@DesktopBuild(adaptToRetina)	Boolean true/false defaults to true. When set to true some values will ve implicitly doubled to deal with retina displays and icons etc. Will use higher DPI's
desktop.fontSizes	string	*(none)*	*(none)*	Indicates the sizes in pixels for the system fonts as a comma delimited string containing 3 numbers for small,medium,large fonts.
desktop.fullscreen	boolean	*(set by the build)*	@DesktopBuild(fullscreen)	Starts the desktop build in full-screen mode.
desktop.height	int	*(set by the build)*	@DesktopBuild(height)	Height in pixels for the form in desktop builds, will be doubled for retina grade displays. Defaults to 600.
desktop.interactiveScrollbars	boolean	*(set by the build)*	@DesktopBuild(interactiveScrollbars)	Enables grab-able, click-to-page desktop scrollbars.
desktop.resizable	boolean	*(set by the build)*	@DesktopBuild(resizable)	Boolean true/false defaults to true. Indicates whether the UI in the desktop build is resizable

Name	Type	Default	Annotation	Description
desktop.theme	string	*(none)*	*(none)*	Name of the theme res file (without the ".res" extension) to use as the "native" theme. By default this is native indicating iOS theme on Mac and Windows Metro on Windows. If its something else then the app will try to load the file /themeName.res (placed in native/Java SE directory).
desktop.themeMac	string	*(none)*	*(none)*	Same as desktop.theme but specific to macOS
desktop.themeMode	string	*(set by the build)*	@DesktopBuild(themeMode)	Which native theme a desktop build installs, and the one hint that decides whether a desktop application looks like the platform it's running on. One desktop binary runs on Windows, macOS and Linux, so the value is resolved against the machine the application starts on rather than at build time. auto, native and modern are one value under three spellings and select the host's own look: Fluent, Aqua or Adwaita. Naming a theme outright with fluent, aqua or adwaita pins that one look on every machine instead, which is what an application with a deliberate cross-platform identity wants. legacy, which is also the default, keeps whatever the application was built and tested against before these themes existed, and custom installs no framework theme at all so the application's own is the only one loaded. The per-value and per-platform tables, and how this relates to the iOS, Android, macOS and cross-platform theme hints, are on the @DesktopBuild annotation itself. Read by the JavaSE port at runtime rather than by a builder, so unlike most hints here it changes what the running application does rather than what's produced for it.
desktop.themeWin	string	*(none)*	*(none)*	Same as desktop.theme but specific to Windows

Name	Type	Default	Annotation	Description
desktop.title	string	*(none)*	*(none)*	
desktop.titleBar	native, custom, toolbar	*(set by the build)*	@DesktopBuild(titleBar)	How the desktop window is framed: native for the OS title bar and menu bar, custom for an undecorated window with a Codename One drawn title bar, or toolbar for the legacy in-app Toolbar. An unrecognized value falls back to native with a warning.
desktop.width	int	*(set by the build)*	@DesktopBuild(width)	Width in pixels for the form in desktop builds, will be doubled for retina grade displays. Defaults to 800.
desktop.win.cef	boolean	*(none)*	*(none)*	Whether to use CEF for media and BrowserComponent instead of JavaFX in windows desktop builds. true/false. Default value is false (Jan 2021), but this will be changed to true in a future version.
desktop.windowsOutput	string	*(none)*	*(none)*	Can be exe or msi depending on desired results
KeepScreenOn	boolean	false	*(none)*	
androidx.appcompat.version	string	*(none)*	*(none)*	
block_server_registration	boolean	*(none)*	*(none)*	true/false flag defaults to false. By default Codename One applications register with the Codename One server. Setting this to true blocks them from sending information to the Codename One cloud, which is kept for statistical purposes and may be used to provide more installation stats in the future.

Name	Type	Default	Annotation	Description
`build.cn1Version`	string	*(none)*	*(none)*	Pro/Enterprise only. Pins the cloud build to a specific released Codename One version using the Maven release scheme (for example `7.0.182`), or to `master` to build against the current development head. The build server fetches that version's framework artifacts. Pro accounts can target versions published within the last two months; Enterprise within the last six months. Requesting an older version, a version that was never published, or using this hint without a Pro/Enterprise subscription fails the build with an explanatory error. See Versioned builds.
`build.incSources`	string	*(none)*	*(none)*	
`build.testReporter`	string	*(none)*	*(none)*	
`build.unitTest`	string	*(none)*	*(none)*	
`call.video`	boolean	`false`	*(none)*	Whether video calls are offered, on both platforms. `ios.call.video` and `android.call.video` override it per platform.
`cn1.androidTheme`	string	*(none)*	*(none)*	Deprecated alias for and.themeMode (AndroidGradleBuilder.java:4097). Both names configure one setting, so declaring this alongside @Android(themeMode) is a conflict.
`cn1.buildKey`	string	*(none)*	*(none)*	
`cn1.entitled`	boolean	`true`	*(none)*	
`cn1.harden.forceOff`	string	*(none)*	*(none)*	
`cn1.hardenLevel`	string	`off`	*(none)*	
`cn1.hardened`	boolean	`false`	*(none)*	
`cn1.hardening.libraryJars`	string	*(none)*	*(none)*	
`cn1.mappingId`	string	*(none)*	*(none)*	

Name	Type	Default	Annotation	Description
`cn1.nativeTheme`	string	*(none)*	*(none)*	Deprecated alias for nativeTheme (AndroidGradleBuilder.java:4099, IPhoneBuilder.java:947). Both names configure one setting, so declaring this alongside @Build(nativeTheme) is a conflict.
`codename1.mac.appid`	string	*(none)*	*(none)*	Mac Native cloud builds only. The Mac bundle identifier registered in App Store Connect / Apple Developer. Distinct from `codename1.ios.appid` because Apple treats the iOS and Mac App Store records as separate products. Required for cloud Mac builds.
`codename1.mac.certificate`	string	*(none)*	*(none)*	Mac Native cloud builds only. Path to the `.p12` file containing the Mac signing certificate(s) — *Mac App Distribution* (3rd Party Mac Developer Application) for App Store builds, *Developer ID Application* for Developer ID builds, or both bundled into the same P12 when `macNative.distribution=both`. Not interchangeable with the iOS distribution certificate. Required for cloud Mac builds.
`codename1.mac.certificatePassword`	secret	*(none)*	*(none)*	Mac Native cloud builds only. Password to unlock the P12 referenced by `codename1.mac.certificate`. Required for cloud Mac builds.
`codename1.mac.provision`	string	*(none)*	*(none)*	Mac Native cloud builds only. Path to the Mac provisioning profile (`.provisionprofile`). Apple issues distinct provisioning profiles for Mac App Store and Developer ID distribution — pass the one that matches the chosen channel.
`commerce.cloud.enabled`	boolean	`true`	*(none)*	Whether `CommerceManager` asks the Codename One Commerce service for entitlements. Set it to `false` to keep every decision on the device, from the store's own receipts.

Name	Type	Default	Annotation	Description
commerce.cloud.endpoint	string	*(none)*	*(none)*	The base url of the Commerce service CommerceManager talks to, for a self-hosted or staging service, for example https://commerce.example.com/api/v2/commerce. Must be an http or https url; a build with any other value fails.
commerce.cloud.publicKey	string	*(none)*	*(none)*	The base64 encoded Ed25519 public key that Commerce responses are verified against. Set it together with commerce.cloud.endpoint when the service signs with its own key; a response that fails the check is ignored and the app falls back to the store's receipts.
db.legacy	string	*(none)*	*(none)*	
delayPushCompletion	boolean	false	*(none)*	
facebook.appId	string	*(set by the build)*	@Build(facebookAppId)	The application ID for an app that requires native Facebook login integration, this defaults to null which means native Facebook support shouldn't be in the app
facebook.clientToken	secret	*(none)*	*(none)*	The client token for an app that requires native Facebook login integration, this is required if the facebook.appId is set.
gcm.sender_id	string	*(set by the build)*	@Build(gcmSenderId)	The Android/chrome push identifier, see the push section for more details
google.adUnitId	string	*(none)*	*(none)*	Allows integrating Admob/Google Play ads into the application see this [https://www.codenameone.com/blog/adding-google-play-ads.html]
gradleDependencies	list (newline delimited)	*(none)*	*(none)*	
harden.*	string	*(none)*	*(properties file only)*	The whole hardening namespace is swept into the hardening engine's configuration, so a hint added there reaches it without a dedicated reader.

Name	Type	Default	Annotation	Description
`harden.*.enabled`	string	*(none)*	*(properties file only)*	Enables or disables hardening for one platform slice.
`harden.allowUnhardenedLocalBuild`	boolean	*(set by the build)*	`@Hardening(allowUnhardenedLocalBuild)`	Permits a local or source build to run with hardening requested but not applied. Without it such a build is refused, so a hardened app is never shipped from a target that can't actually harden it.
`harden.controlFlow`	`off`, `on`	*(set by the build)*	`@Hardening(controlFlow)`	Overrides control-flow obfuscation independently of harden.level.
`harden.ios.enabled`	boolean	`true`	*(none)*	
`harden.keep`	text_block	*(set by the build)*	`@Hardening(keep)`	Keep rules in ProGuard syntax, one per line, for classes that are resolved by name at runtime and so can't be found by the automatic analysis. Same syntax as android.proguardKeep, so existing rules port directly. Rules are separated by newlines only, because a semicolon is legal inside a rule body such as { *; }.
`harden.level`	`off`, `standard`, `aggressive`, `paranoid`	*(set by the build)*	`@Hardening(level)`	Master switch for app hardening: off, standard, aggressive or paranoid. An unrecognized value fails the build rather than being treated as off.
`harden.mac.enabled`	boolean	`true`	*(none)*	
`harden.rename`	boolean	*(set by the build)*	`@Hardening(rename)`	Overrides symbol renaming independently of harden.level.
`harden.strings`	`off`, `constants`, `all`	*(set by the build)*	`@Hardening(strings)`	Overrides string obfuscation independently of harden.level: off, constants or all.
`harden.tv.enabled`	boolean	`true`	*(none)*	
`harden.watch.enabled`	boolean	`true`	*(none)*	

Name	Type	Default	Annotation	Description
invite.domain	string	cloud.codenameone.com	*(none)*	The host that serves Codename One invite links (https://<host>/i/<slug>/<code>). Changing it points the generated Android App Link intent filter and the iOS associated domain at a different link service; the matching apple-app-site-association and assetlinks.json must be served from that host.
invite.slug	string	*(none)*	*(none)*	This app's path segment in its invite links (https://<host>/i/<slug>/<code>), shown in the invite settings of the build console. Set it so the generated Android App Link filter matches only this app's own links. The link domain is shared by every invite-enabled app, so when this is unset the filter matches every invite link on the domain and a device with two such apps installed may show a chooser or open the other one.
java.version	int	8	*(none)*	Valid values include 5 or 8. Indicates the JVM version that should be used for server compilation, this is defined by default for newly created apps based on the Java 8 mode selection
mac.desktop-vm	string	*(none)*	*(none)*	The JVM the should be bundled with Mac desktop build. Mac desktop builds only. Supported values: zuluFx8, zulu11, zuluFx11
maps.provider	string	*(none)*	*(none)*	Selects the native map provider. android.maps.provider and ios.maps.provider override it for one platform.

Name	Type	Default	Annotation	Description
nativeTheme	modern, native, legacy, custom	*(set by the build)*	@Build(nativeTheme)	native, modern, legacy, custom (default unset). Cross-platform override that sets ios.themeMode and and.themeMode together when those aren't set explicitly. modern = liquid glass + Material 3, legacy = iOS 7 flat + Holo Light, custom disables the framework native theme entirely: no platform theme is packaged or installed on any port, desktop included, for an application whose own theme sets includeNativeBool: false. The legacy alias cn1.nativeTheme is still accepted. native and custom are the two values that reach the desktop too. native is modern plus the desktop: it additionally selects the host's own desktop theme — Fluent, Aqua or Adwaita — the way desktop.themeMode = auto does. modern stops short of the desktop on purpose, because it predates the desktop themes by years and an application that set it for its phone builds never asked for its desktop screens to be redrawn. desktop.themeMode overrides this hint either way, and the full per-platform table is on the @DesktopBuild annotation.
nativeVerify	string	*(none)*	*(none)*	strict or warn turns on ParparVM's native signature check for this build; anything else leaves it off, which is the default. ParparVM encodes the whole Java signature in the C function name, so a native spelled even slightly differently never reaches the linker as an error: the correctly named symbol is simply absent, the dead-code pass reads that as unused, and the feature ships inert. ios.nativeVerify, linux.nativeVerify and windows.nativeVerify override it for one platform.

Name	Type	Default	Annotation	Description
noExtraResources	boolean	*(set by the build)*	@Build(noExtraResources)	true/false (defaults to false). Blocks codename one from injecting its own resources when set to true, the only effect this has is in slightly reducing archive size. This might have adverse effects on some features of Codename One so it isn't recommended.
pgo.trainingSeconds	int	*(set by the build)*	@Build(pgoTrainingSeconds)	How long, in seconds, the instrumented application runs when ios.pgo, macos.pgo or linux.pgo is on. Defaults to 60; a value below 10 or above 300 is brought into that range. Ignored when no profile-guided build is requested. See Profile-guided optimization in the developer guide.
python.virtualThreadStack	string	1MB	*(none)*	The C stack each request's virtual thread gets in a Python backend: bytes, or a number followed by KB or MB, such as 2MB. Raise it for a handler with deep recursion. CN1_HTTP_VT_STACK can still raise it at start-up; the larger of the two applies.
requireKotlinStdlib	string	*(none)*	*(none)*	
tvMain	string	*(none)*	*(none)*	
var.*	string	*(none)*	*(properties file only)*	Defines a variable that any other hint can interpolate as ${var.name}, with ${var.name:default} for a fallback.
vserv.allowSkipping	boolean	true	*(none)*	
vserv.category	int	29	*(none)*	
vserv.countryCode	string	null	*(none)*	
vserv.locale	string	en_US	*(none)*	
vserv.networkCode	string	null	*(none)*	
vserv.scaleMode	boolean	false	*(none)*	
vserv.transition	int	300000	*(none)*	
vserv.zone	string	*(none)*	*(none)*	
watchMain	string	*(none)*	*(none)*	
watchStandalone	boolean	false	*(none)*	

Name	Type	Default	Annotation	Description
`xxx.minPlayServicesVersion`	string	*(none)*	*(none)*	This is a special case build hint. You can use any prefix to the build hint and the convention is to use your cn1lib name. It's identical to `android.minPlayServicesVersion` with the exception that the "highest version wins." That way if your cn1lib requires play services 9+ and uses: `myLib.minPlayServicesVersion=9.0.0` and another library has `otherLib.minPlayServicesVersion=10.0.0` then play services will be 10.0.0
`ios.*.appext.*`	string	*(none)*	*(properties file only)*	Per-app-extension signing. ios.debug.appext.<Name>.* and ios.release.appext.<Name>.* are collapsed to unqualified keys before the request is sent.
`ios.NFCReaderUsageDescription`	string	*(none)*	*(none)*	
`ios.NS*UsageDescription`	string	*(none)*	*(properties file only)*	Info.plist privacy strings. The commonly used keys are catalogued individually and exposed through @IosPrivacy; this entry covers the open tail that the builder sweeps by prefix.
`ios.NSBluetoothAlwaysUsageDescription`	string	*(set by the build)*	`@IosPrivacy(bluetothAlwaysUsageDescription)`	Why the app uses Bluetooth. Supplied automatically when the app references `com.codename1.bluetooth`; set it to say something more specific than the default.
`ios.NSBluetoothPeripheralUsageDescription`	string	*(set by the build)*	`@IosPrivacy(bluetothPeripheralUsageDescription)`	The pre-iOS 13 spelling of the Bluetooth usage description, supplied and overridable on the same terms.
`ios.NSBonjourServices`	string	*(none)*	*(none)*	
`ios.NSCalendarsFullAccessUsageDescription`	string	*(set by the build)*	`@IosPrivacy(calendarsFullAccessUsageDescription)`	The text iOS shows when the app first asks for the calendars full access. It becomes the `NSCalendarsFullAccessUsageDescription` key in `Info.plist`. The App Store rejects an app that touches this resource without one.

Name	Type	Default	Annotation	Description
ios.NSCalendarsUsageDescription	string	*(set by the build)*	@IosPrivacy(calendarsUsageDescription)	The text iOS shows when the app first asks for the calendars. It becomes the NSCalendarsUsageDescription key in Info.plist. The App Store rejects an app that touches this resource without one.
ios.NSCalendarsWriteOnlyAccessUsageDescription	string	*(set by the build)*	@IosPrivacy(calendarsWriteOnlyAccessUsageDescription)	The text iOS shows when the app first asks for the calendars write only access. It becomes the NSCalendarsWriteOnlyAccessUsageDescription key in Info.plist. The App Store rejects an app that touches this resource without one.
ios.NSCameraUsageDescription	string	*(set by the build)*	@IosPrivacy(cameraUsageDescription)	The text iOS shows when the app first asks for the camera. It becomes the NSCameraUsageDescription key in Info.plist. The App Store rejects an app that touches this resource without one.
ios.NSHealthShareUsageDescription	string	*(set by the build)*	@IosPrivacy(healthShareUsageDescription)	The text iOS shows when the app first asks for the health share. It becomes the NSHealthShareUsageDescription key in Info.plist. The App Store rejects an app that touches this resource without one.
ios.NSHealthUpdateUsageDescription	string	*(set by the build)*	@IosPrivacy(healthUpdateUsageDescription)	The text iOS shows when the app first asks for the health update. It becomes the NSHealthUpdateUsageDescription key in Info.plist. The App Store rejects an app that touches this resource without one.
ios.NSLocalNetworkUsageDescription	string	*(set by the build)*	@IosPrivacy(localNetworkUsageDescription)	The text iOS shows when the app first asks for the local network. It becomes the NSLocalNetworkUsageDescription key in Info.plist. The App Store rejects an app that touches this resource without one.
ios.NSLocationAlwaysAndWhenInUseUsageDescription	string	*(set by the build)*	@IosPrivacy(locationAlwaysAndWhenInUseUsageDescription)	The text iOS shows when the app first asks for the location always and when in use. It becomes the NSLocationAlwaysAndWhenInUseUsageDescription key in Info.plist. The App Store rejects an app that touches this resource without one.

Name	Type	Default	Annotation	Description
`ios.NSLocationAlwaysUsageDescription`	string	*(set by the build)*	`@IosPrivacy(locationAlwaysUsageDescription)`	The text iOS shows when the app first asks for the location always. It becomes the `NSLocationAlwaysUsageDescription` key in `Info.plist`. The App Store rejects an app that touches this resource without one.
`ios.NSLocationWhenInUseUsageDescription`	string	*(set by the build)*	`@IosPrivacy(locationWhenInUseUsageDescription)`	The text iOS shows when the app first asks for the location when in use. It becomes the `NSLocationWhenInUseUsageDescription` key in `Info.plist`. The App Store rejects an app that touches this resource without one.
`ios.NSMicrophoneUsageDescription`	string	*(set by the build)*	`@IosPrivacy(microphoneUsageDescription)`	The text iOS shows when the app first asks for the microphone. It becomes the `NSMicrophoneUsageDescription` key in `Info.plist`. The App Store rejects an app that touches this resource without one.
`ios.NSNearbyInteractionAllowOnceUsageDescription`	string	*(set by the build)*	`@IosPrivacy(nearbyInteractionAllowOnceUsageDescription)`	The pre-iOS 16 spelling of the nearby-interaction usage description, supplied automatically when the app references the nearby APIs.
`ios.NSNearbyInteractionUsageDescription`	string	*(set by the build)*	`@IosPrivacy(nearbyInteractionUsageDescription)`	Why the app measures distance and direction to nearby devices. Supplied automatically when the app references the nearby APIs; set it to say something more specific than the default.
`ios.NSRemindersFullAccessUsageDescription`	string	*(set by the build)*	`@IosPrivacy(remindersFullAccessUsageDescription)`	The text iOS shows when the app first asks for the reminders full access. It becomes the `NSRemindersFullAccessUsageDescription` key in `Info.plist`. The App Store rejects an app that touches this resource without one.
`ios.NSRemindersUsageDescription`	string	*(set by the build)*	`@IosPrivacy(remindersUsageDescription)`	The text iOS shows when the app first asks for the reminders. It becomes the `NSRemindersUsageDescription` key in `Info.plist`. The App Store rejects an app that touches this resource without one.

Name	Type	Default	Annotation	Description
`ios.NSSpeechRecognitionUsageDescription`	string	*(set by the build)*	`@IosPrivacy(speechRecognitionUsageDescription)`	Why the app sends speech for recognition. Supplied automatically when the app references the speech APIs; set it to say something more specific.
`ios.NSXXXUsageDescription`	string	*(none)*	*(none)*	iOS privacy flags for using certain APIs. Starting with Xcode 8, you're required to add usage description strings for certain APIs. Find a full list of the available keys in Apple's docs [https://developer.apple.com/library/content/documentation/General/Reference/InfoPlistKeyReference/Articles/CocoaKeys.html]. Some relevant ones include `ios.NSCameraUsageDescription`, `ios.NSContactsUsageDescription`, `ios.NSLocationAlwaysUsageDescription`, `NSLocationUsageDescription`, `ios.NSMicrophoneUsageDescription`, `ios.NSPhotoLibraryAddUsageDescription`, `ios.NSSpeechRecognitionUsageDescription`, `ios.NSSiriUsageDescription`
`ios.UIRequiredDeviceCapabilities`	string	*(none)*	*(none)*	
`ios.actionSheetStyle`	string	*(none)*	*(none)*	
`ios.add_libs`	list (; delimited)	*(set by the build)*	`@Ios(addLibs)`	A semicolon separated list of libraries that should be linked to the app to build it
`ios.afterFinishLaunching`	string	*(none)*	*(none)*	Objective-C code that can be injected into the iOS app delegate at the bottom of the body of the didFinishLaunchingWithOptions callback method
`ios.appAttest`	boolean	`false`	*(none)*	
`ios.appAttest.environment`	string	*(none)*	*(none)*	
`ios.appUsesNonExemptEncryption`	string	*(none)*	*(none)*	

Name	Type	Default	Annotation	Description
ios.app_groups	string	*(none)*	*(none)*	Space-delimited list of app groups that this app belongs to as described in Apple's documentation [https://developer.apple.com/library/content/documentation/Miscellaneous/Reference/EntitlementKeyReference/Chapters/EnablingAppSandbox.html#//apple_ref/doc/uid/TP40011195-CH4-SW19]. These are added to the entitlements file with key com.apple.security.application-groups.
ios.appext.NAME.provisioningURL	string	*(none)*	*(none)*	Cloud device builds only. URL of the provisioning profile for a generic app extension dropped into ios/app_extensions/NAME/ (or a generated extension such as CN1Widgets), used when the extension folder doesn't bundle a .mobileprovision itself. The profile is installed on the build machine and added to the export options per bundle id. Used for both debug and release builds unless a qualified variant (below) is set. An extension is signed against its own App ID, so a device build with no profile for it — by any of the three carriers — is refused unless the app's own profile is a wildcard that covers the extension's bundle id.
ios.applicationDidEnterBackground	string	*(none)*	*(none)*	Objective-C code that can be injected into the iOS callback method (message) applicationDidEnterBackground.

Name	Type	Default	Annotation	Description
ios.applicationQueriesSchemes	list (, delimited)	*(set by the build)*	@Ios(applicationQueriesSchemes)	Comma separated list of url schemes that canExecute will respect on iOS. If the url scheme isn't mentioned here canExecute will return false starting with iOS 9. Notice that this collides with ios.plistInject when used with the <key>LSApplicationQueriesSchemes</key>… value so you should use one or the other. For example, to enable canExecute for a url like myurl://xys you can use: myurl,myotherurl
ios.application_exits	boolean	*(none)*	*(none)*	true/false (defaults to false). Indicates whether the application should exit on home button press. The default is to exit, leaving the application running is only tested at the moment.
ios.associatedDomains	string	*(none)*	*(none)*	Comma-delimited list of domains associated with this app. Each domain should be prefixed by a supported prefix. For example, "applinks:" or "webcredentials:." See Apple's documentation on Associated domains [https://developer.apple.com/documentation/security/password_autofill/setting_up_an_app_s_associated_domains?language=objc] for more information.
ios.backgroundProcessingIds	string	*(none)*	*(none)*	
ios.background_modes	string	*(none)*	*(none)*	
ios.beforeFinishLaunching	text_block	*(set by the build)*	@Ios(beforeFinishLaunching)	Objective-C code that can be injected into the iOS app delegate at the top of the body of the didFinishLaunchingWithOptions callback method
ios.bitcode	boolean	false	*(none)*	true/false defaults to false. Enables bitcode support for the build.

Name	Type	Default	Annotation	Description
ios.blockScreenshotsOnEnterBackground	boolean	false	*(none)*	true/false (defaults to false). Indicates that app should prevent iOS from taking screenshots when app enters background. Described here [https://shannah.github.io/cn1-recipes/#_hiding_sensitive_data_when_entering_background].
ios.bluetooth.background	string	*(none)*	*(none)*	
ios.buildType	string	debug	*(none)*	
ios.bundleVersion	version	*(set by the build)*	@Ios(bundleVersion)	Indicates the version number of the bundle, this is useful if you want to create a minor version number change for the beta testing support
ios.call.appGroup	string	*(none)*	*(none)*	The App Group the call directory extension shares with the app. The extension runs in its own process, so the blocked-number list is handed over through the group rather than passed in. Defaults to group.<packageName>.
ios.call.directory.buildSettings.*	string	*(none)*	*(properties file only)*	Xcode build settings for the generated call directory extension target. PRODUCT_BUNDLE_IDENTIFIER is read in two places — the target's own settings and the CN1CallDirectoryExtensionIdentifier the host plist carries — so an override has to reach both or the app asks the system to reload an identifier nothing installed.
ios.call.icon	string	*(none)*	*(none)*	A template image in the bundle shown beside the call in the system UI.
ios.call.providerName	string	*(none)*	*(none)*	The name shown above a call in the system call UI. Defaults to the app's display name. Baked into Info.plist because CallKit needs it during launch, before any of your code has run.
ios.call.pushTTL	int	30	*(none)*	Seconds a pushed call waits for your code before the system ends it as unanswered.
ios.call.recents	boolean	true	*(none)*	Whether calls appear in the system call log.

Name	Type	Default	Annotation	Description
ios.call.ringtone	string	*(none)*	*(none)*	A sound file in the bundle to ring incoming calls with. Defaults to the system ringtone.
ios.call.unknownCaller	string	*(none)*	*(none)*	The name shown when a VoIP push carries no displayName.
ios.call.video	boolean	false	*(none)*	Whether the provider offers video calls. Overrides call.video on iOS.
ios.carplay.audio	boolean	false	*(none)*	
ios.carplay.messaging	boolean	false	*(none)*	
ios.carplay.navigation	boolean	false	*(none)*	
ios.carplay.poi	boolean	false	*(none)*	
ios.cn1NativesRepository	string	https://repo.codenameone.com/maven2	*(none)*	Maven repository the builder fetches the on-device AI natives (com.codenameone.natives, whisper.cpp and llama.cpp) from, when the app uses them. Defaults to the Codename One repository; a file: URL tests a local scripts/ai-natives/build.sh output.
ios.continuity.sync	boolean	*(none)*	*(none)*	Whether this project wants the iCloud key-value store behind com.codename1.continuity.sync. Left unset the build decides from the bytecode, which is usually what you want. Set false when the App ID has no iCloud capability and the app can live without a synced store: the entitlement is dropped and SyncedStore reports itself unsupported at runtime rather than the build failing to sign. Set true to say so explicitly, which is what lets the signing preflight check the profile before the build is sent. Handing work to a nearby device is unaffected either way — that half needs no entitlement.
ios.convertSignalsToExceptions	boolean	true	*(none)*	
ios.criticalAlerts	boolean	false	*(none)*	

Name	Type	Default	Annotation	Description
ios.crypto.gcm	boolean	true	*(none)*	Whether AES-GCM is compiled into the crypto library. On by default wherever the crypto API is used; set false to leave it out and keep the binary smaller. The secure vault needs it.
ios.debug.archs	string	*(none)*	*(none)*	Can be set to "armv7" to force iOS debug builds to be 32 bit. By default, debug builds are 64 bit only.
ios.debug.distributionMethod	string	*(none)*	*(none)*	Specifies distribution type for debug iOS builds only. This is used for enterprise or ad-hoc builds (using values "enterprise" and "ad-hoc" respectively).
ios.debug.teamId	string	*(none)*	*(none)*	Specifies the team ID associated with the iOS debug provisioning profile and certificate.
ios.delayPushCompletion	boolean	false	*(none)*	
ios.dependencyManager	auto, cocoapods, spm, both, none	*(set by the build)*	@Ios(dependencyManager)	Which native dependency manager to use: auto picks one from whichever of ios.pods and ios.spm.packages is set, and cocoapods, spm or both require the matching hint to be set. An unrecognized value fails the build.
ios.deployment_target	version	*(set by the build)*	@Ios(deploymentTarget)	Minimum iOS version the build targets. Set it to the lowest iOS you actually support; a higher value excludes older devices from the App Store listing.
ios.detectJailbreak	boolean	false	*(none)*	true/false (defaults to false). When true, the iOS app will exit on launch if it detects that it’s running on a jailbroken device.
ios.devLocale	string	*(none)*	*(none)*	
ios.disableScreenshots	boolean	false	*(none)*	
ios.distributionMethod	string	*(none)*	*(none)*	Specifies distribution type for debug iOS builds. This is used for enterprise or ad-hoc builds (using values "enterprise" and "ad-hoc" respectively).

Name	Type	Default	Annotation	Description
ios.documentProvider.appGroup	string	*(none)*	*(none)*	App Group id starting with 'group.' shared by the app and the generated CN1Documents extension, defaulting to 'group.' followed by the app's package name. This id carries everything the two processes share: the app publishes its index into the group and the extension reads it from there, so without it the published location appears empty.
ios.documentProvider.buildSettings.*	string	*(none)*	*(properties file only)*	Overrides an Xcode build setting for the generated document provider extension. Applied last, so it wins over the generated defaults.
ios.documentProvider.deploymentTarget	version	16.0	*(none)*	Minimum OS version the generated extension runs on. At or above 16.0 the extension is an NSFileProviderReplicatedExtension; below it Codename One generates the deprecated NSFileProviderExtension instead. The host app's own deployment target is unaffected.
ios.documentProvider.displayName	string	*(none)*	*(none)*	Name shown for this location in the file browser. Defaults to the app's display name.
ios.documentProvider.enabled	boolean	false	*(none)*	Declares that this project publishes documents to the system file browser. The build detects a reference to com.codename1.documents on its own, so this is redundant for the build itself; it exists because the Certificate Wizard and the signing preflight work without reading bytecode and need to know that the CN1Documents extension will be generated.
ios.documentProvider.extension	boolean	true	*(none)*	Set false to skip the iOS lowering entirely — no extension target, no app group, no plist keys — leaving com.codename1.documents an inert no-op at runtime.
ios.enableAutoplayVideo	boolean	false	*(none)*	Boolean true/false defaults to false. Makes videos "autoplay" when loaded on iOS

Name	Type	Default	Annotation	Description
`ios.enableBadgeClear`	boolean	`true`	*(none)*	Boolean true/false defaults to true. Clears the badge value with every load of the app, this is useful if the app doesn't manually keep track of number values for the badge
`ios.enableGalleryMultiselect`	boolean	`false`	*(none)*	
`ios.enableStatusBar7`	boolean	`true`	*(none)*	
`ios.entitlements.*`	string	*(none)*	*(properties file only)*	Adds an arbitrary entitlement key to the generated entitlements file.
`ios.entitlements.com.apple.developer`	string	*(none)*	*(none)*	
`ios.entitlements.com.apple.developer.applesignin`	string	*(none)*	*(none)*	
`ios.entitlements.com.apple.developer.healthkit`	boolean	`false`	*(none)*	
`ios.entitlements.com.apple.developer.homekit`	string	*(none)*	*(none)*	
`ios.entitlements.com.apple.developer.networking.HotspotConfiguration`	string	*(none)*	*(none)*	
`ios.entitlements.com.apple.developer.nfc.hce`	string	*(none)*	*(none)*	
`ios.entitlements.com.apple.developer.nfc.readersession.formats`	string	*(none)*	*(none)*	
`ios.entitlementsInject`	xml	*(none)*	*(none)*	Content to inject into the iOS entitlements file. This should be in the Plist XML format. See Apple Entitlements Documentation [https://developer.apple.com/documentation/bundleresources/entitlements?language=objc].
`ios.facebook.usePods`	boolean	`true`	*(none)*	
`ios.facebook.version`	string	`~>5.6.0`	*(none)*	

Name	Type	Default	Annotation	Description
ios.facebook_permissions	string	*(none)*	*(none)*	Permissions for Facebook used in the Android build target, applicable only if Facebook native integration is used.
ios.failOnWarning	boolean	false	*(none)*	
ios.fieldNullChecks	boolean	false	*(none)*	
ios.fileSharingEnabled	boolean	false	*(none)*	
ios.firebaseAnalytics	boolean	false	*(none)*	
ios.firebaseAnalyticsVersion	string	*(none)*	*(none)*	
ios.force64	boolean	false	*(none)*	
ios.glAppDelegateBody	string	*(none)*	*(none)*	Objective-C code that can be injected into the iOS app delegate within the body of the file before the end. This only makes sence for methods that aren't already declared in the class
ios.glAppDelegateHeader	text_block	*(set by the build)*	@Ios(glAppDelegateHeader)	Objective-C code that can be injected into the iOS app delegate at the top of the file. For example, if you need to include headers or make special imports for other injected code
ios.googleAdUnitId	string	*(none)*	*(none)*	Allows integrating admob/google play ads, this is effectively identical to google.adUnitId but only applies to iOS
ios.googleAdUnitIdPadding	string	*(none)*	*(none)*	Indicates the amount of padding to pass to the Google Ads placed at the bottom of the screen with google.adUnitId
ios.googleAdUnitTestDevice	string	97cfc76e5efbc6dfa7eb2e6857b613a0	*(none)*	
ios.gplus.clientId	string	*(none)*	*(none)*	
ios.hceAids	string	*(none)*	*(none)*	
ios.headphoneCallback	boolean	false	*(none)*	Boolean true/false defaults to false. When set to true it assumes the main class has two methods: headphonesConnected & headphonesDisconnected which it invokes appropriately as needed

Name	Type	Default	Annotation	Description
ios.health.backgroundDelivery	boolean	false	*(none)*	
ios.health.recalibrateEstimates	boolean	false	*(none)*	
ios.health.required	boolean	false	*(none)*	
ios.home.appGroup	string	*(none)*	*(none)*	
ios.home.commissioning	boolean	true	*(none)*	
ios.home.commissioning.buildSettings.*	string	*(none)*	*(properties file only)*	Overrides an Xcode build setting for the Matter commissioning extension.
ios.home.commissioning.displayName	string	*(none)*	*(none)*	
ios.home.commissioning.fabric	string	*(none)*	*(none)*	
ios.home.commissioning.vendorId	string	0xFFF1	*(none)*	
ios.home.required	boolean	false	*(none)*	
ios.includeNullChecks	boolean	true	*(none)*	
ios.includePush	boolean	*(set by the build)*	@Ios(includePush)	true/false (defaults to false). Whether to include the push capabilities in the iOS build. Notice that the IDE plugin has an "Include Push" check box you **should** use under the iOS section.
ios.intents.appIntents	boolean	true	*(none)*	
ios.intents.minDeploymentTarget	string	*(none)*	*(none)*	
ios.interface_orientation	string	*(set by the build)*	@Ios(interfaceOrientation)	UIInterfaceOrientationPortrait by default. Indicates the orientation, one or more of (separated by colon :): UIInterfaceOrientationPortrait, UIInterfaceOrientationPortraitUpsideDown, UIInterfaceOrientationLandscapeLeft, UIInterfaceOrientationLandscapeRight. Notice that the IDE plugin has an "Interface Orientation" combo box you **should** use under the iOS section.

Name	Type	Default	Annotation	Description
`ios.invite.appClip`	boolean	`true`	*(none)*	Whether the build generates and embeds the App Clip that makes invite attribution exact on iOS. The App Store carries no referrer of its own, so without the clip an iOS install can't be attributed at all. Set it to `false` only if you ship an App Clip of your own: the build then generates no clip, but the app still carries the shared app group and the reader, so a clip of yours that writes the handoff below is still picked up. This is the ONLY hint that suppresses the clip: `ios.invite.universalLinks=false` means you manage the associated domains yourself and leaves the clip, the shared app group and the reader in place, because an app that configured its own domains correctly still needs them. THE HANDOFF, for a clip of your own. Write one entry into the `NSUserDefaults` suite named by `ios.invite.appGroup`, under the key `cn1-invite-app-clip-handoff`. The value is a dictionary with `code`, a string holding the invite code taken from the last path segment of the invite url, and `clicked`, a number holding the tap time as whole seconds since the epoch. `clicked` may be omitted, and the App Clip is the only thing that ever observes that time — the invocation never reaches the redirect — so a clip that drops it leaves every attribution dated zero. A code containing a newline is rejected on the way in. Then call `synchronize` on the suite before returning. A clip is killed without notice the moment the App Store sheet takes over, and the write IS the attribution — there is no second chance to make it. Don't clear the entry after writing it. The installed app reads it, keeps it

Name	Type	Default	Annotation	Description
ios.invite.appGroup	string	*(none)*	*(none)*	The app group the invite App Clip hands the invite code to the installed app through. Defaults to group.<package name>.cn1invite, and is added to ios.app_groups automatically. It must start with group. and must be registered on your developer account, or the clip and the app both sign and neither can read what the other wrote.
ios.invite.appStoreId	string	*(none)*	*(none)*	The numeric App Store identifier of this app, which the invite App Clip uses to offer the full app through SKOverlay. Leave it unset before your first release: the clip still records the invite code, it simply shows no install sheet until the app exists in the store.
ios.invite.buildSettings.*	string	*(none)*	*(properties file only)*	Xcode build settings for the generated invite App Clip target. The clip is a separate application bundle embedded in the app, so its deployment target and device family are its own and an override reaches only it.
ios.invite.universalLinks	boolean	true	*(none)*	Whether the build appends applinks: for the invite link domain to ios.associatedDomains and requests the matching com.apple.developer.associated-domains entitlement. Set it to false to manage both yourself. The provisioning profile must grant the Associated Domains capability either way, or invite links open Safari instead of the app with no error reported.
ios.keyboardOpen	boolean	true	*(none)*	Flips between iOS keyboard open mode and autofold keyboard mode. Defaults to true which means the keyboard will remain open and not fold automatically when editing moves to another field.

Name	Type	Default	Annotation	Description
`ios.keychainAccessGroup`	string	*(none)*	*(none)*	Space-delimited list of keychain access groups that this app has access to as described in Apple's documentation [https://developer.apple.com/library/content/documentation/Security/Conceptual/keychainServConcepts/02concepts/concepts.html#//apple_ref/doc/uid/TP30000897-CH204-SW11]. These are added to the entitlements file with the key `keychain-access-groups`.
`ios.launchPlaceholder`	boolean	`true`	*(none)*	
`ios.locationUsageDescription`	string	*(none)*	*(none)*	This flag is required for iOS 8 and newer if you're using the location API. It needs to include a description of the reason for which you need access to the users location
`ios.lowMemCamera`	boolean	`false`	*(none)*	
`ios.maps.provider`	string	*(none)*	*(none)*	iOS's own native map provider, overriding `maps.provider`.
`ios.metal.colorSpace`	string	`sRGB`	*(none)*	Selects the `CAMetalLayer.colorspace` for the Metal renderer. Accepts `sRGB` (default), `displayP3`, `deviceRGB`, `linearSRGB`, `extendedSRGB`, `extendedLinearSRGB`, or `none`. See Working with iOS / Choosing a color space [#_choosing_a_color_space_for_the_metal_renderer] for the full table.
`ios.minDeploymentTarget`	version	*(set by the build)*	`@Ios(minDeploymentTarget)`	The null and empty-string reads of this hint are presence checks; 6.0 is the substantive one.
`ios.mopubAdSize`	string	`MOPUB_BANNER_SIZE`	*(none)*	
`ios.mopubId`	string	*(none)*	*(none)*	
`ios.mopubTabletAdSize`	string	`MOPUB_LEADERBOARD_SIZE`	*(none)*	
`ios.mopubTabletId`	string	*(none)*	*(none)*	
`ios.multitasking`	boolean	`true`	*(none)*	Set to true to enable iOS multitasking and split-screen support. This only works if `ios.xcode_verson=9.2`.

Name	Type	Default	Annotation	Description
ios.nativeThemes.keepAll	boolean	false	*(none)*	true/false (defaults to false). The iOS and native macOS builds ship only the one native theme the build's own theme mode/generation will install, plus any theme the application's own classes name as a string ("Name.res", or the bare name passed to Resources.openLayered). Set to true for an application that opens a native theme by a name it computes or reads from configuration, which no build-time scan can see — the JavaScript build's equivalent escape hatch is javascript.pruneThemes=false.
ios.nativeVerify	string	*(none)*	*(none)*	nativeVerify for the iOS translation alone.
ios.nearby.accessoryServices	list (, delimited)	*(none)*	*(none)*	Bluetooth service UUIDs published as NSAccessorySetupBluetoothServices, so AccessorySetupKit can show a picker for them. Unset publishes none.
ios.nearby.background	boolean	false	*(none)*	Requests the nearby-interaction entitlement and the background mode that go with ranging while backgrounded. Off by default because the entitlement has to be on the provisioning profile, and requesting it without one fails signing for every ranging app.
ios.nearby.serviceType	string	*(none)*	*(none)*	Bonjour service type the nearby transport advertises. Derived from the package name when unset.
ios.newStorageLocation	boolean	*(set by the build)*	@Ios(newStorageLocation)	Stores app files under the documents directory rather than caches, which is the location Apple recommends but which may break compatibility with an app that already shipped. Described in this issue [https://github.com/codenameone/CodenameOne/issues/1480]
ios.noUIWebView	boolean	true	*(none)*	
ios.no_strip	boolean	false	*(none)*	

Name	Type	Default	Annotation	Description
ios.notificationPermissionAtLaunch	boolean	false	*(none)*	true/false (defaults to false). Backward-compatibility flag for the pre-issue-#4876 behavior. By default, the iOS notification permission prompt is deferred until the app calls Push.register() or schedules a LocalNotification, matching the Android flow and giving the developer a chance to display a rationale screen first. Set this hint to true to restore the legacy behavior in which the prompt fires automatically inside application:didFinishLaunchingWithOptions: as soon as the app launches. Existing apps relying on the prompt being shown at launch should set this to true; new apps should leave it disabled and trigger the prompt explicitly when they're ready to ask for permission.
ios.objC	boolean	*(set by the build)*	@Ios(objC)	Added the -ObjC compile flag to the project files which some native libraries require
ios.onDeviceDebug	boolean	*(set by the build)*	@OnDeviceDebug(ios)	Boolean true/false defaults to false. When true, the iOS build links a small JDWP listener thread (cn1_debugger) into the binary and the ParparVM translator emits source-line and locals metadata so a desktop proxy can serve the running app to any JDWP-speaking debugger. Has no effect on release builds. See the On-Device Debugging (iOS) chapter for the full flow.
ios.onDeviceDebug.proxyHost	string	*(set by the build)*	@OnDeviceDebug(iosProxyHost)	Hostname or IP address the device-side listener dials to reach the desktop proxy. Default 127.0.0.1 (correct for the native iOS simulator). For a physical device, set this to the developer laptop's LAN IP. Has no effect unless ios.onDeviceDebug=true.

Name	Type	Default	Annotation	Description
ios.onDeviceDebug.proxyPort	int	*(set by the build)*	@OnDeviceDebug(iosProxyPort)	TCP port on ios.onDeviceDebug.proxyHost where the proxy is listening for the device. Default 55333. Has no effect unless ios.onDeviceDebug=true.
ios.onDeviceDebug.waitForAttach	boolean	*(set by the build)*	@OnDeviceDebug(iosWaitForAttach)	Boolean true/false defaults to false. When true, the app blocks at startup until the proxy connects and the IDE tells the VM to continue. Useful when the breakpoint to investigate fires during app boot. Has no effect unless ios.onDeviceDebug=true.
ios.openURLInject	xml	*(none)*	*(none)*	
ios.optimizer	string	on	*(none)*	
ios.pgo	boolean	*(set by the build)*	@Ios(pgo)	Cloud builds only, Pro plan and above. Profile-guided optimization: compiles the application twice. An instrumented build runs unattended on an iOS simulator for pgo.trainingSeconds, and the profile it records drives the optimizer for the binary that ships. The build fails when the profile can't be collected, rather than deliver a binary built without one. Can't be combined with ios.buildForSimulator. See Profile-guided optimization in the developer guide.
ios.plistInject	xml	*(set by the build)*	@Ios(plistInject)	entries to inject into the iOS plist file during build.
ios.pods	list (, delimited)	*(set by the build)*	@Ios(pods)	A comma separated list of Cocoa Pods [https://cocoapods.org/] that should be linked to the app to build it. For example, AFNetworking ~> 2.6, ORStackView ~> 3.0, SwiftyJSON ~> 2.3
ios.pods.build.*	string	*(none)*	*(properties file only)*	Overrides an Xcode build setting for the generated CocoaPods project.
ios.pods.build.CLANG_ALLOW_NON_MODULAR_INCLUDES_IN_FRAMEWORK_MODULES	string	*(none)*	*(none)*	
ios.pods.build.CLANG_ENABLE_MODULES	string	*(none)*	*(none)*	

Name	Type	Default	Annotation	Description
ios.pods.platform	version	*(set by the build)*	@Ios(podsPlatform)	Sets the Cocoapods 'platform' for the Cocoapods. Some Cocoapods require a minimum platform level. For example, ios.pods.platform=7.0.
ios.pods.sources	list (, delimited)	*(set by the build)*	@Ios(podsSources)	Extra CocoaPods spec repositories to search, in addition to the default trunk.
ios.pods.use_frameworks!	boolean	false	*(none)*	
ios.prerendered_icon	boolean	*(set by the build)*	@Ios(prerenderedIcon)	true/false defaults to false. The iOS build process adapts the submitted icon for iOS conventions (adding an overlay) that might not be appropriate on some icons. Setting this to true leaves the icon unchanged (only scaled).
ios.project_type	ios, ipad, iphone	*(set by the build)*	@Ios(projectType)	one of ios, ipad, iphone (defaults to ios). Indicates whether the resulting binary is targeted to the iphone only or ipad only. Notice that the IDE plugin has a "Project Type" combo box you **should** use under the iOS section.
ios.release.archs	string	*(none)*	*(none)*	Can be set to "arm64" to only build iOS release builds for 64 bit. By default, release builds are both 32 and 64 bit.
ios.release.distributionMethod	string	*(none)*	*(none)*	Specifies distribution type for release iOS builds only. This is used for enterprise or ad-hoc builds (using values "enterprise" and "ad-hoc" respectively).
ios.release.teamId	string	*(none)*	*(none)*	Specifies the team ID associated with the iOS release provisioning profile and certificate.
ios.rpmalloc	string	*(none)*	*(none)*	true/false Use rpmalloc [https://github.com/rampantpixels/rpmalloc] instead of malloc/free for memory allocation in ParparVM. This will cause the deployment target to be changed to a minimum of iOS 8.0.
ios.shareAppGroup	string	*(none)*	*(none)*	

Name	Type	Default	Annotation	Description
ios.spm.packages	list (; delimited)	*(set by the build)*	@Ios(spmPackages)	Swift Package Manager packages to link, one per entry, each written as identity|url|requirement.
ios.spm.products.*	string	*(none)*	*(properties file only)*	Selects which products of a Swift Package Manager package to link, keyed by package identity.
ios.statusBarFG	string	*(none)*	*(none)*	
ios.statusbar_hidden	boolean	*(none)*	*(none)*	true/false defaults to false. Hides the iOS status bar if set to true.
ios.superfastBuild	boolean	false	*(none)*	
ios.surfaces.appGroup	string	*(none)*	*(none)*	
ios.surfaces.buildSettings.*	string	*(none)*	*(properties file only)*	Overrides an Xcode build setting for the external-surfaces extension.
ios.surfaces.deploymentTarget	version	16.1	*(none)*	
ios.surfaces.extension	boolean	true	*(none)*	
ios.surfaces.frequentUpdates	boolean	false	*(none)*	
ios.swiftVersion	version	5.0	*(none)*	
ios.teamId	string	*(set by the build)*	@Ios(teamId)	Specifies the team ID associated with the iOS provisioning profile and certificate. Use ios.debug.teamId and ios.release.teamId to specify different team IDs for debug and release builds respectively.
ios.testFlight	boolean	*(none)*	*(none)*	Boolean true/false defaults to false and works only for pro accounts. Enables the testflight support in the release binaries for easy beta testing. Notice that the IDE plugin has a "Test Flight" check box you **should** use under the iOS section.

Name	Type	Default	Annotation	Description
ios.themeGeneration	26, 27	*(set by the build)*	@Ios(themeGeneration)	26 (default) or 27: which iOS design generation the modern theme targets. Consulted only when [#themeMode()] resolves to modern/liquid; every other mode ignores it. Unset means 26, so an application that says nothing keeps the theme it has. 27 selects the generation built from native-themes/ios-modern/gen27.css.
ios.themeMode	auto, modern, ios7, legacy, custom	*(set by the build)*	@Ios(themeMode)	auto (default), modern, ios7, legacy, custom. auto (unset) keeps the existing iOS 7 flat theme so pre-refactor screenshot goldens and apps see no behavior change. modern / liquid opts in to the CSS-generated iOS Modern (liquid-glass) theme shipped from native-themes/ios-modern/theme.css. ios7 / flat is the same as auto - pre-liquid iOS 7 flat theme; legacy / iphone loads the pre-iOS 7 iPhone theme. The auto → modern flip is planned for a future release. custom packages and installs no iOS theme at all, for an application whose own theme is the only one.
ios.timeSensitiveNotifications	boolean	false	*(none)*	
ios.twoDigitVersion	boolean	false	*(none)*	
ios.urlScheme	string	*(set by the build)*	@Ios(urlScheme)	Allows intercepting a URL call using the syntax <string>urlPrefix<string>
ios.urlSchemes	string	*(none)*	*(none)*	
ios.useAVKit	boolean	true	*(none)*	Use AVKit for video components on iOS rather than MPMoviePlayerController on iOS versions 8 through 12. iOS 13 will always use AVKit, and iOS 7 and lower will always use MPMoviePlayerController. Default value false
ios.useJavascriptCore	boolean	false	*(none)*	

Name	Type	Default	Annotation	Description
`ios.usePhotoKitForMultigallery`	boolean	`false`	*(none)*	
`ios.usePrintf`	boolean	`false`	*(none)*	
`ios.useWKWebView`	boolean	`true`	*(none)*	
`ios.usesBackgroundProcessing`	boolean	`false`	*(none)*	
`ios.viewDidLoad`	string	*(none)*	*(none)*	Objective-C code that can be injected into the iOS callback method (message) `viewDidLoad`
`ios.viewDidLoadInclude`	string	*(none)*	*(none)*	

Name	Type	Default	Annotation	Description
ios.vpn.tunnel	boolean	false	*(none)*	Generates the iOS packet tunnel: a Network Extension carrying a virtual machine, running the VpnTunnel subclass named by ios.vpn.tunnel.class. Two things have to be true, and this hint is the second: the app references com.codename1.vpn.tunnel, and the App ID holds com.apple.developer.networking.networkextension, which Apple grants case by case rather than self-serve. Setting this hint is the project asserting the grant — generating the target without it fails codesigning with an error naming an entitlement nobody asked for, which is why referencing the package alone never produces one. BOTH App IDs need the grant: the extension is the provider, and the app drives it through NETunnelProviderManager, which is Network Extension API as well — so the build writes the entitlement into the app and into the extension, and refuses before the archive if either provisioning profile doesn't grant it. A device archive also needs a provisioning profile for the extension's own App ID, <packageName>.vpntunnel, passed as ios.appext.CN1VpnTunnel.provisioningData or .provisioningURL. Left false, the build produces no extension and Tunnels.isSupported() answers false. The extension carries the translated program and the virtual machine and NO networking stack: com.codename1.io.Socket and everything else that reaches Util.getImplementation() finds nothing there, and ParparVM's java.net is URI and URL. An iOS tunnel can therefore inspect, rewrite, drop and forward packets, but it can't relay them to a remote server — on Android it can, because the tunnel runs in the app's own process. The extension is a

Name	Type	Default	Annotation	Description
ios.vpn.tunnel.buildSettings.*	string	*(none)*	*(properties file only)*	Xcode build settings for the generated packet tunnel extension target. PRODUCT_BUNDLE_IDENTIFIER is read in two places — the target's own settings and the CN1VpnTunnelExtensionIdentifier the host plist carries, which is how the app names the provider it starts — so an override has to reach both or the app asks the system to start an extension installed under some other name.
ios.vpn.tunnel.class	string	*(none)*	*(none)*	Which `VpnTunnel` subclass the generated packet tunnel extension runs, fully qualified — for example `com.example.MyTunnel`. Required when `ios.vpn.tunnel` is true. It has to be named rather than discovered: `VpnTunnel` is a class rather than an interface, so the shared class scanner skips it, and an app may have several subclasses while an extension runs exactly one. A wrong guess would build the wrong tunnel into the extension and fail at link on a symbol nobody wrote. The build checks the name against the compiled classes and refuses one it can't find, rather than letting the generated entry point fail javac on a source file the developer never wrote. It has to be a class this project compiles: the translator reads loose class files, so a tunnel that lives only inside a submitted library jar is never translated and can't be the extension's entry point.
ios.wallet.appGroup	string	*(none)*	*(none)*	App Group id starting with `group.` shared by the app and the generated Wallet extensions. The app publishes pass entries into this group through `com.codename1.payment.WalletExtension` and the group is added to the app and extension entitlements automatically. Required when `ios.wallet.extension=true`.

Name	Type	Default	Annotation	Description
`ios.wallet.authEndpoint`	string	*(none)*	*(none)*	HTTPS URL the generated login UI extension POSTs `{"username","password"}` to; the JSON response's `token` is stored in the App Group for the provisioning request. Required when `ios.wallet.includeUI=true`.
`ios.wallet.extension`	boolean	`false`	*(none)*	Boolean true/false defaults to false. Generates an Apple Wallet issuer provisioning extension (the "From apps on your iPhone" flow in the Wallet app) and embeds it in the build. Requires `ios.wallet.appGroup` and `ios.wallet.issuerEndpoint`. See the Apple Wallet Extension chapter.
`ios.wallet.generateRequestInject`	string	*(none)*	*(none)*	Swift injected at the generate-request marker of the non-UI Wallet extension.
`ios.wallet.generateResponseInject`	string	*(none)*	*(none)*	Swift injected at the generate-response marker of the non-UI Wallet extension.
`ios.wallet.includeUI`	boolean	`false`	*(none)*	Boolean true/false defaults to false. Also generates the Wallet authorization UI extension - a login form shown inside the Wallet app when the app reports that authentication is required. Requires `ios.wallet.authEndpoint`.
`ios.wallet.issuerEndpoint`	string	*(none)*	*(none)*	HTTPS URL of the issuer backend endpoint that produces the encrypted provisioning payload. The generated extension POSTs Apple's certificates/nonce plus the card identifier and auth token there as JSON. Required when `ios.wallet.extension=true`.
`ios.wallet.nonuiExtensionName`	string	`WalletNonUIExtension`	*(none)*	
`ios.wallet.nonuiImportsInject`	string	*(none)*	*(none)*	Extra `import` lines for the non-UI Wallet extension.
`ios.wallet.passEntriesInject`	string	*(none)*	*(none)*	Swift injected where the non-UI Wallet extension lists its pass entries.
`ios.wallet.remotePassEntriesInject`	string	*(none)*	*(none)*	Swift injected where the non-UI Wallet extension lists its remote pass entries.

Name	Type	Default	Annotation	Description
`ios.wallet.statusInject`	string	*(none)*	*(none)*	Swift injected at the status marker of the non-UI Wallet extension.
`ios.wallet.uiAuthRequestInject`	string	*(none)*	*(none)*	Swift injected at the auth-request marker of the UI Wallet extension.
`ios.wallet.uiAuthResponseInject`	string	*(none)*	*(none)*	Swift injected at the auth-response marker of the UI Wallet extension.
`ios.wallet.uiExtensionName`	string	`WalletUIExtension`	*(none)*	
`ios.wallet.uiImportsInject`	string	*(none)*	*(none)*	Extra `import` lines for the UI Wallet extension.
`ios.wallet.uiViewDidLoadInject`	string	*(none)*	*(none)*	Swift injected into `viewDidLoad` of the UI Wallet extension.

Name	Type	Default	Annotation	Description
`ios.xcode_version`	26, 27	*(set by the build)*	`@Ios(xcodeVersion)`	Which Xcode the build server compiles with. Unset lets the server choose: it prefers its own default and falls back to the newest Xcode it carries, so a server that hasn't been re-imaged keeps building. Naming one opts out of that fallback — a version the server doesn't have fails the build rather than substituting a toolchain nobody asked for, which would archive against an unintended SDK with nothing in the log to say so. Builds are claimed off a shared queue, so an Xcode that some servers carry and others don't makes a build pass or fail at random. That's a fleet out of step and worth reporting, not a hint to tune. The constants are the majors a current build server image carries, a set that belongs to the image rather than to this framework. To name a version outside them — a minor such as `27.1`, or a major shipped since this release — write a plain `codename1.arg.ios.xcode_version=<version>` line in `codenameone_settings.properties`. Leaving this attribute at [IosXcodeVersion#DEFAULT] writes nothing, so the two don't conflict. Read only by the build service; a local build uses the Xcode `xcode-select` points at and ignores this.
`ios.zbar_flash`	boolean	`true`	*(none)*	
`javascript.allowBrowserTranslation`	boolean	`false`	*(none)*	true/false (defaults to `false`). By default the page opts out of browser machine translation (`<meta name="google" content="notranslate">` and `translate="no"`), because a translator rewriting the page under the running app, or loading it through a translation proxy, breaks it. Set to `true` to let the browser offer translation.

Name	Type	Default	Annotation	Description
`javascript.background_color`	string	*(none)*	*(none)*	Legacy alias for the PWA background color. `javascript.manifest.background_color` takes precedence.
`javascript.darkreaderLock`	boolean	`true`	*(none)*	true/false (defaults to `true`). Emits `<meta name="darkreader-lock">` so the Dark Reader extension leaves the app's own colors alone. Dark Reader honours the lock in its default Dynamic mode only; its Filter, Filter+ and Static modes ignore it. Set to `false` to omit the tag.
`javascript.desktopTheme`	string	`auto`	*(none)*	The native theme a desktop browser gets. `auto` (default) picks Windows Fluent, macOS Aqua or GNOME Adwaita from the browser's operating system when `nativeTheme=native`; phones and tablets keep the iOS and Android themes. `fluent`, `aqua` or `adwaita` pins one theme for every desktop browser, so the bundle carries only that one. `none` keeps the mobile themes on the desktop too.
`javascript.includeVideoJS`	boolean	`false`	*(none)*	
`javascript.inject.afterHead`	string	*(none)*	*(none)*	Content to be injected into the index.html file at the end of the `<head>` tag.
`javascript.inject.beforeHead`	string	*(none)*	*(none)*	Content to be injected into the index.html file at the beginning of the `<head>` tag.
`javascript.inject_proxy`	boolean	`true`	*(none)*	true/false (defaults to `true`). The ParparVM builder generates a same-origin proxy bundle and configures the app to use it. Setting this to `false` disables both proxy generation and proxy URL injection.
`javascript.minifying`	boolean	*(none)*	*(none)*	true/false (defaults to `true`). By default the JavaScript code is minified to reduce file size. You may optionally disable minification by setting `javascript.minifying` to `false`.

Name	Type	Default	Annotation	Description
`javascript.native.theme`	string	*(none)*	*(none)*	An explicit native theme resource, such as `/WindowsFluentTheme.res`, used in every browser instead of the one the theme hints and the browser would pick.
`javascript.orientation`	string	*(none)*	*(none)*	Legacy alias for the PWA screen orientation. `javascript.manifest.orientation` takes precedence. Omitted by default so the browser can use any orientation.
`javascript.port`	string	*(none)*	*(none)*	`parparvm` (default) or `teavm`. Selects the public JavaScript compiler for cloud builds. `teavm` retains the original builder as a compatibility fallback.
`javascript.portSources`	string	*(none)*	*(none)*	
`javascript.proxy.allowedTargets`	string	*(none)*	*(none)*	Comma-separated target origins, host names, or wildcard subdomains that a generated proxy may access, for example `https://api.example.com,*.services.example.org`. If omitted, the proxy accepts any HTTP or HTTPS target and the build emits a warning.
`javascript.proxy.target`	string	`jakarta-servlet`	*(none)*	The generated ParparVM proxy deployment platform. Supported values are `jakarta-servlet` (default), `javax-servlet`, `node`, `php`, `aws-lambda`, `google-cloud-functions`, `cloudflare-workers`, and `none`.
`javascript.proxy.url`	string	*(none)*	*(none)*	The URL of an existing proxy to use for network requests. Setting it suppresses generated proxy packaging unless `javascript.proxy.target` is also set. If `javascript.inject_proxy` is `false`, this build hint is ignored.
`javascript.pruneThemes`	boolean	`true`	*(none)*	true/false (defaults to `true`). The build ships only the native themes the application can reach from its theme hints, plus any theme its code names as a string. Set to `false` for an application that loads a native theme by a name it computes or reads from configuration, which no build can see.

Name	Type	Default	Annotation	Description
`javascript.short_name`	string	*(none)*	*(none)*	Legacy alias for the PWA short name. `javascript.manifest.short_name` takes precedence.
`javascript.sourceFilesCopied`	boolean	*(none)*	*(none)*	true/false (defaults to `false`). Setting this flag to `true` will cause available java source files to be included in the resulting .zip and .war files. These may be used by Chrome during debugging.
`javascript.splash.accentColor`	string	`#0072ff`	*(none)*	The loading screen's progress bar color in light appearance, as a hex color (`#rgb`, `#rrggbb`, with optional alpha) or a CSS color name. Applied from the first frame the page paints until the first form shows.
`javascript.splash.appearance`	`auto`, `light`, `dark`	*(none)*	*(none)*	Which colors the loading screen uses. Defaults to `auto` when any `javascript.splash.dark*` color is set and to `light` otherwise, so an app that never asked for a dark loading screen doesn't get one. `auto` follows the browser's light/dark preference, or the choice the app remembered with `Display.setProperty("platformHint.javascript.splashAppearance", "dark")`. `light` and `dark` always use that set, for apps with one appearance.
`javascript.splash.background`	string	`#ffffff`	*(none)*	The loading screen's background in light appearance, as a hex color (`#rgb`, `#rrggbb`, with optional alpha) or a CSS color name. Applied from the first frame the page paints until the first form shows.
`javascript.splash.darkAccentColor`	string	`#4da3ff`	*(none)*	The loading screen's progress bar color in dark appearance, as a hex color (`#rgb`, `#rrggbb`, with optional alpha) or a CSS color name. Applied from the first frame the page paints until the first form shows.
`javascript.splash.darkBackground`	string	`#121212`	*(none)*	The loading screen's background in dark appearance, as a hex color (`#rgb`, `#rrggbb`, with optional alpha) or a CSS color name. Applied from the first frame the page paints until the first form shows.

Name	Type	Default	Annotation	Description
`javascript.splash.darkTextColor`	string	`#b3b3b3`	*(none)*	The loading screen's text color in dark appearance, as a hex color (`#rgb`, `#rrggbb`, with optional alpha) or a CSS color name. Applied from the first frame the page paints until the first form shows.
`javascript.splash.logo`	string	*(none)*	*(none)*	The image the loading screen shows above the progress bar, as a path relative to the bundle's `index.html` (letters, digits, `/`, `.`, `-` and `_`). Defaults to the app icon; `none` shows no image.
`javascript.splash.textColor`	string	`#666666`	*(none)*	The loading screen's text color in light appearance, as a hex color (`#rgb`, `#rrggbb`, with optional alpha) or a CSS color name. Applied from the first frame the page paints until the first form shows.
`javascript.stopOnErrors`	boolean	*(none)*	*(none)*	true/false (defaults to `true`). Causes a TeaVM JavaScript build to fail when the compiler reports warnings. Setting this to `false` may allow the fallback builder to complete, but can turn compiler diagnostics into runtime failures that are more difficult to debug.
`javascript.teavm.version`	string	*(none)*	*(none)*	(Optional) The version of TeaVM to use for the build. **Use caution**, only use this property if you know what you're doing!
`javascript.textSelection`	boolean	`false`	*(none)*	true/false (defaults to `false`). Makes read-only text — labels, span labels and non-editable text areas — selectable and copyable in every form, using the framework's own text selection. A mouse selects by dragging; a touch screen selects with a long press, so a swipe still scrolls.
`javascript.theme_color`	string	*(none)*	*(none)*	Legacy alias for the PWA theme color. `javascript.manifest.theme_color` takes precedence.

Name	Type	Default	Annotation	Description
javascript.titleBar	string	toolbar	*(none)*	How a desktop native theme presents the form title and commands in a browser. toolbar (default) keeps the Toolbar in the app, styled by the desktop theme. html shows the title in an HTML title bar and the commands in an HTML menu bar above the app, the way the native desktop ports use the window title and the system menu bar.
linux.arch	string	*(none)*	*(none)*	
linux.cc	string	*(none)*	*(none)*	
linux.debug	boolean	false	*(none)*	
linux.embedded	boolean	false	*(none)*	Builds for an embedded Linux device: the application owns the screen through DRM/KMS or the framebuffer, with no window system and no GTK, and reads touch, mouse, keyboard and rotary input straight from evdev.
linux.embedded.board	string	generic-arm64	*(none)*	Board profile for linux.embedded, which sets the architecture and display defaults: rpi5, rpi4, rpi3, rpi-zero2, rpi-armv7, rpi-touch7, imx8, imx6, rk3588, jetson, beagleplay, visionfive2, generic-arm64, generic-armv7, generic-x64 or generic-riscv64.
linux.embedded.display	string	auto	*(none)*	Default display backend for linux.embedded: auto (KMS, then the framebuffer), kms, fbdev, memory or headless. CN1_DISPLAY on the device overrides it.
linux.embedded.dpi	int	0	*(none)*	Panel density for linux.embedded when the display doesn't report its physical size; 0 uses what the panel reports.
linux.embedded.renderer	string	*(none)*	*(none)*	Renderer for linux.embedded: gpu draws with OpenGL ES 2 on a GBM surface over KMS, software with the CPU. Defaults to the board profile's choice, gpu for boards with a reliable Mesa driver. A gpu build links libgbm, libEGL and libGLESv2 and still falls back to software on a device where they find no GPU.

Name	Type	Default	Annotation	Description
`linux.embedded.rotation`	int	`0`	*(none)*	Clockwise panel rotation for `linux.embedded`: 0, 90, 180 or 270.
`linux.libc`	string	`glibc`	*(none)*	
`linux.musl`	boolean	`false`	*(none)*	
`linux.muslNativeCc`	boolean	`false`	*(none)*	
`linux.nativeVerify`	string	*(none)*	*(none)*	`nativeVerify` for the native Linux translation alone.
`linux.pgo`	boolean	`false`	*(none)*	Cloud builds only, Pro plan and above. true/false. Profile-guided optimization for the native Linux build: an instrumented binary runs unattended on the build host for `pgo.trainingSeconds`, and the profile it records drives the optimizer for the binary that ships. The `linux.arch` being built has to be one the build host can run. See Profile-guided optimization [# _profile_guided_optimization].
`linux.sysroot`	string	*(none)*	*(none)*	Target sysroot (a Yocto SDK, Buildroot staging directory or a mounted device image) whose headers and libraries a cross build compiles and links against.
`linux.toolchain`	string	*(none)*	*(none)*	
`steam.appId`	string	*(none)*	*(none)*	The Steamworks app id. Required by the `steam` build target: it goes into the generated SteamPipe build scripts and into `launch.sh`, which hands it to the application so Steamworks connects even when the game is started outside Steam.
`steam.branch`	string	*(none)*	*(none)*	A beta branch to set the uploaded build live on, such as `beta`. Empty (default) uploads without setting it live. Valve doesn’t allow setting the default branch live from an upload: do that in the Steamworks partner site.
`steam.buildDescription`	string	*(none)*	*(none)*	The description shown for the build in the Steamworks build list. Defaults to the application version.

Name	Type	Default	Annotation	Description
steam.depotId	string	*(none)*	*(none)*	The Linux depot to upload the build into. Defaults to steam.appId + 1, which is the depot Steamworks creates with a new app.
steam.fullscreen	boolean	true	*(none)*	true/false (defaults to true). Starts the game fullscreen, as Steam Deck and Steam Machine players expect.
steam.package	boolean	false	*(none)*	true/false (defaults to false). Lays a native Linux build out as a Steam depot with its SteamPipe scripts. cn1:buildSteam and cn1:buildSteamLocal set it.
steam.sdkPath	string	*(none)*	*(none)*	Local builds only: the unzipped Steamworks SDK, whose redistributable libsteam_api.so is packaged with the game. Also read from the STEAMWORKS_SDK environment variable; the cloud build supplies it itself. Without it the game is packaged without Steamworks, and GameServices reports unavailable.
desktop.mac.cef	boolean	*(none)*	*(none)*	Whetherto use CEF for media or BrowserComponent instead of JavaFX in Mac desktop builds. true/false. Default value is false (Jan 2021), but this will be changed to true in a future version.
macNative.appCategory	string	*(none)*	*(none)*	Mac Native builds only. LSApplicationCategoryType in the generated Info.plist. Default public.app-category.utilities.
macNative.bundleId	string	*(none)*	*(none)*	Mac Native builds only. Used only when macNative.deriveBundleId=false. Default: <packageName>.mac.
macNative.copyright	string	*(none)*	*(none)*	Mac Native builds only. NSHumanReadableCopyright in the Info.plist. Defaults to Copyright (c) <year> <vendor>.

Name	Type	Default	Annotation	Description
macNative.deriveBundleId	boolean	true	*(none)*	Mac Native builds only. true (default) maps to Xcode's DERIVE_MACCATALYST_PRODUCT_BUNDLE_IDENTIFIER=YES (Xcode appends .maccatalyst to the iOS bundle ID). Set to false to take the bundle ID verbatim from macNative.bundleId.
macNative.distribution	string	appStore	*(none)*	Mac Native builds only. appStore (default), developerID, or both. Selects which entitlements + ExportOptions plist + signing certificate to emit. both emits parallel **-AppStore.entitlements** /-DeveloperID.entitlements and matching ExportOptions-*-Mac.plist files so a single project can be archived to either channel.
macNative.enabled	boolean	false	*(none)*	
macNative.entitlements.allowJit	string	*(none)*	*(none)*	Mac Native builds only. true enables com.apple.security.cs.allow-jit for hardened runtime. ParparVM is AOT-compiled so this is false by default; flip when bundling a JIT-using cn1lib.
macNative.entitlements.appSandbox	string	*(none)*	*(none)*	Mac Native builds only. true enables com.apple.security.app-sandbox. Default is true for the appStore channel (Mac App Store requires the sandbox), false for developerID.
macNative.entitlements.device.camera	boolean	*(none)*	*(none)*	Sandboxed Mac Native builds only. Toggles com.apple.security.device.camera. Defaults to whether the app sets ios.NSCameraUsageDescription, so an app that asks for the camera gets the entitlement without naming it twice.
macNative.entitlements.device.microphone	boolean	*(none)*	*(none)*	Sandboxed Mac Native builds only. Toggles com.apple.security.device.microphone. Defaults to whether the app sets ios.NSMicrophoneUsageDescription.

Name	Type	Default	Annotation	Description
`macNative.entitlements.extra`	string	*(none)*	*(none)*	Mac Native builds only. Free-form XML inserted verbatim inside the `<dict>⋯</dict>` of the generated entitlements plist. Use for entitlements Codename One doesn't expose individually.
`macNative.entitlements.files.userSelected`	string	`readwrite`	*(none)*	Mac Native builds only. `readwrite` (default), `readonly`, or `none`. Sets the matching `com.apple.security.files.user-selected.*` entitlement.
`macNative.entitlements.hardenedRuntime`	string	*(none)*	*(none)*	Mac Native builds only. `true` enables hardened runtime restrictions. Default is `true` for `developerID` (notarization requires it), `false` for `appStore`.
`macNative.entitlements.network.client`	string	*(none)*	*(none)*	Mac Native builds only. Toggles `com.apple.security.network.client`. Default `true`.
`macNative.entitlements.network.server`	string	*(none)*	*(none)*	Mac Native builds only. Toggles `com.apple.security.network.server`. Default `false`.
`macNative.entitlements.personalInformation.calendars`	boolean	*(none)*	*(none)*	Sandboxed Mac Native builds only. Toggles `com.apple.security.personal-information.calendars`, which gates all EventKit access. Defaults to whether the app sets any calendar or reminder usage description, including the write-only and reminders-only ones.
`macNative.fixedWindowSize`	string	*(none)*	*(none)*	Mac Native builds only. Opt-in. Format `<width>x<height>` — for example `1024x685`. When set, the Catalyst window's `UISceneSession.sizeRestrictions` minimum and maximum are pinned to the requested size so every launch produces a byte-identical window. Default unset, in which case the window is resizable. The CI screenshot pipeline turns this on to keep the strict-pixel golden comparison stable; production apps should leave it off.

Name	Type	Default	Annotation	Description
macNative.iosMinDeploymentTarget	version	13.1	*(none)*	Mac Native builds only. iOS deployment-target floor for the Catalyst slice (IPHONEOS_DEPLOYMENT_TARGET). Default 13.1. The plugin coerces the iOS slice's minimum upward when set.
macNative.minDeploymentTarget	version	10.15	*(none)*	Mac Native builds only. Minimum macOS version (MACOSX_DEPLOYMENT_TARGET). Default 10.15 — earlier versions don't support Mac Catalyst.
macNative.multiWindow	boolean	false	*(none)*	Mac Native builds only. Declares that the app uses com.codename1.ui.Window, which needs multiple UIScenes and exists only on the Mac Catalyst slice. Writes UIApplicationSupportsMultipleScenes and a scene configuration into the Mac slice's own Info.plist; getWindowManager() reads that key back out of the bundle, so without it windows are reported unsupported and constructing one throws. Off by default: multi-window support relayouts the app into a resizable window, a change an app that never asked for windows has no reason to take on.
macNative.notarize	boolean	false	*(none)*	
macNative.notarize.appleId	string	*(none)*	*(none)*	
macNative.notarize.keychainProfile	string	*(none)*	*(none)*	
macNative.notarize.password	secret	*(none)*	*(none)*	
macNative.notarize.teamId	string	*(none)*	*(none)*	
macNative.provisioningProfile.*	string	*(none)*	*(properties file only)*	Per-profile provisioning data for a native macOS build, keyed by profile name.
macNative.provisioningProfile.appStore	string	*(none)*	*(none)*	Mac Native builds only. Provisioning profile name for App Store distribution — used only when macNative.signing.style=manual.

Name	Type	Default	Annotation	Description
`macNative.provisioningProfile.developerID`	string	*(none)*	*(none)*	Mac Native builds only. Provisioning profile name for Developer ID distribution — used only when `macNative.signing.style=manual`.
`macNative.signing.style`	string	`automatic`	*(none)*	Mac Native builds only. `automatic` (default) lets Xcode pick the signing certificate; `manual` forces the certificate identity hints below to be respected verbatim.
`macNative.signingIdentity.appStore`	string	`Apple Distribution`	*(none)*	Mac Native builds only. Signing certificate identity for the App Store channel. Default `Apple Distribution`.
`macNative.signingIdentity.developerID`	string	`Developer ID Application`	*(none)*	Mac Native builds only. Signing certificate identity for the Developer ID channel. Default `Developer ID Application`.
`macNative.teamId`	string	*(none)*	*(none)*	Mac Native builds only. Apple Developer Team ID (alphanumeric). Falls back to `ios.release.teamId` → `ios.teamId` → `ios.debug.teamId` since most apps share a single Apple Developer Team for iOS and Mac.
`macos.add_libs`	list (; delimited)	*(set by the build)*	`@Mac(addLibs)`	macOS builds. Frameworks to link in addition to the ones the build detects for itself, separated by a semicolon, a comma or a colon — for example `Speech.framework;CoreMIDI.framework`. `ios.add_libs` is read when this is unset, so a project migrated from the Mac Catalyst build keeps linking what its native sources need.
`macos.appCategory`	string	*(set by the build)*	`@Mac(appCategory)`	macOS builds. `LSApplicationCategoryType` in the generated Info.plist. Default `public.app-category.utilities`. See Apple's category list [https://developer.apple.com/documentation/bundleresources/information_property_list/lsapplicationcategorytype].

Name	Type	Default	Annotation	Description
`macos.arch`	string	*(set by the build)*	`@Mac(arch)`	macOS builds. The architectures to compile, as an `ARCHS` value. Default `arm64 x86_64`, which is what a Mac application is expected to be: a single-architecture build is the kind of thing nobody notices until an Intel user reports it.
`macos.bundleId`	string	*(set by the build)*	`@Mac(bundleId)`	macOS builds. Used only when `macos.deriveBundleId=false`. Default: `<packageName>.mac`.
`macos.bundleVersion`	string	*(set by the build)*	`@Mac(bundleVersion)`	macOS builds. `CFBundleVersion` in the Info.plist. `ios.bundleVersion` is read when this is unset, and the project's version when neither is set.
`macos.configuration`	string	*(set by the build)*	`@Mac(configuration)`	macOS builds. The Xcode configuration to archive, as passed to `xcodebuild -configuration`. Default `Release`.
`macos.copyright`	string	*(set by the build)*	`@Mac(copyright)`	macOS builds. `NSHumanReadableCopyright` in the Info.plist. Defaults to `Copyright (c) <year> <vendor>`.
`macos.crypto.gcm`	boolean	*(set by the build)*	`@Mac(cryptoGcm)`	macOS builds. Whether AES-GCM is compiled into the bundled crypto library. On by default wherever the crypto API is on, matching what an iOS build of the same application gets; set `false` to leave it out and keep the symbol set smaller. `ios.crypto.gcm` is read when this is unset.
`macos.deriveBundleId`	boolean	*(set by the build)*	`@Mac(deriveBundleId)`	macOS builds. `false` (default) gives the app its own bundle identifier, `<packageName>.mac`, because a macOS app and an iOS app are separate products in App Store Connect. `true` reuses the iOS identifier. On the legacy Mac Catalyst target this maps instead to Xcode's `DERIVE_MACCATALYST_PRODUCT_BUNDLE_IDENTIFIER`, which appends `.maccatalyst`.

Name	Type	Default	Annotation	Description
macos.distribution	string	*(set by the build)*	@Mac(distribution)	macOS builds. Every macos. hint below is also accepted spelled macNative., which is what the legacy Mac Catalyst target reads, so an existing Catalyst project keeps building unchanged. developerID (default), appStore, or both. Selects the signing certificate, the entitlements and the default packaging. both is genuinely two builds: the channels differ in the certificate and in the entitlements the signature carries — the App Store one has to be sandboxed — so one binary can't be relabelled into the other channel afterwards. It produces <App>-appstore.app and <App>-developerid.app, each with its own container.
macos.entitlements.allowJit	boolean	*(set by the build)*	@Mac(entitlementsAllowJit)	macOS builds. true enables com.apple.security.cs.allow-jit for hardened runtime. ParparVM is AOT-compiled so this is false by default; flip when bundling a JIT-using cn1lib.
macos.entitlements.appSandbox	boolean	*(set by the build)*	@Mac(entitlementsAppSandbox)	macOS builds. true enables com.apple.security.app-sandbox. Default is true for the appStore channel, false for developerID. The App Store channel is always sandboxed whatever this says — the Mac App Store requires it, and a package built without the sandbox gets rejected at submission rather than at build time. The refusal is reported in the build log.
macos.entitlements.extra	string	*(set by the build)*	@Mac(entitlementsExtra)	macOS builds. Free-form XML inserted verbatim inside the <dict>⋯</dict> of the generated entitlements plist. Use for entitlements Codename One doesn't expose individually.

Name	Type	Default	Annotation	Description
`macos.entitlements.files.downloads`	boolean	*(set by the build)*	`@Mac(entitlementsFilesDownloads)`	macOS builds. `true` adds `com.apple.security.files.downloads.read-write`, which is access to the Downloads folder without a panel. Default `false`, and separate from `macos.entitlements.files.userSelected` above because it's a wider grant than picking a file.
`macos.entitlements.files.userSelected`	`readwrite`, `readonly`, `none`	*(set by the build)*	`@Mac(entitlementsFilesUserSelected)`	macOS builds. `readwrite` (default), `readonly`, or `none`. Sets the matching `com.apple.security.files.user-selected.*` entitlement — the files the user picks in an open or save panel, and nothing else.
`macos.entitlements.hardenedRuntime`	boolean	*(set by the build)*	`@Mac(entitlementsHardenedRuntime)`	macOS builds. `true` writes `com.apple.security.cs.allow-jit` and `com.apple.security.cs.allow-unsigned-executable-memory` into the entitlements as explicit denials; `false` leaves them out. It doesn't switch the hardened runtime on or off — that's `macos.hardenedRuntime` above. Default is `true` for `developerID`, `false` for `appStore`.
`macos.entitlements.network.client`	boolean	*(set by the build)*	`@Mac(entitlementsNetworkClient)`	macOS builds. Toggles `com.apple.security.network.client`. Default `true`.
`macos.entitlements.network.server`	boolean	*(set by the build)*	`@Mac(entitlementsNetworkServer)`	macOS builds. Toggles `com.apple.security.network.server`. Default `false`.
`macos.fixedWindowSize`	string	*(set by the build)*	`@Mac(fixedWindowSize)`	macOS builds. Opt-in. Format `<width>x<height>` — for example `1024x685`. When set, the window's minimum and maximum size are pinned to the requested size so every launch produces a byte-identical window. Default unset, in which case the window is resizable. The CI screenshot pipeline turns this on to keep the strict-pixel golden comparison stable; production apps should leave it off.

Name	Type	Default	Annotation	Description
macos.hardenedRuntime	boolean	*(set by the build)*	@Mac(hardenedRuntime)	macOS builds. Sets Xcode's ENABLE_HARDENED_RUNTIME. Default true, because notarization requires it. This is the build setting; the entitlement hint below is a different thing despite the similar name.
macos.loadsExternalCode	boolean	*(set by the build)*	@Mac(loadsExternalCode)	macOS builds. true grants the hardened-runtime exception for loading unsigned libraries. A Codename One application doesn't load code that way, but a cn1lib shipping a dylib needs this, or the load is refused at runtime with nothing in the application's own logs.
macos.minDeploymentTarget	string	*(set by the build)*	@Mac(minDeploymentTarget)	macOS builds. Minimum macOS version (MACOSX_DEPLOYMENT_TARGET). Default 11.0 on the native macOS build, which is the floor for a universal Apple silicon binary. The legacy Mac Catalyst target defaults to 10.15.
macos.packaging	string	*(set by the build)*	@Mac(packaging)	macOS builds. app, dmg, pkg or both. Unset, each channel takes its own default — pkg for appStore, because productbuild's output is what you upload, and dmg for developerID. Set explicitly, the value applies to every channel. A cloud build always ships a file, so app there means the bundle zipped with ditto rather than the raw .app directory.
macos.pgo	boolean	*(set by the build)*	@Mac(pgo)	macOS cloud builds only, Pro plan and above. Profile-guided optimization: an instrumented application runs unattended on the build host for pgo.trainingSeconds, and the profile it records drives the optimizer for the binary that ships. Needs the optimized Release configuration. See Profile-guided optimization in the developer guide.

Name	Type	Default	Annotation	Description
`macos.plistInject`	string	*(set by the build)*	`@Mac(plistInject)`	macOS builds. Raw XML members added to the generated `Info.plist`, the same form `ios.plistInject` takes — for example `<key>NSAppTransportSecurity</key><dict/>`. A key that the build also generates is replaced by the injected one, and the build log names it. `ios.plistInject` is read when this is unset, so a project migrated from the Mac Catalyst build keeps its injections.
`macos.provisioningProfile.appStore`	string	*(set by the build)*	`@Mac(provisioningProfileAppStore)`	macOS builds. Provisioning profile name for App Store distribution — used only when `macNative.signing.style=manual`.
`macos.provisioningProfile.developerID`	string	*(set by the build)*	`@Mac(provisioningProfileDeveloperID)`	macOS builds. Provisioning profile name for Developer ID distribution — used only when `macNative.signing.style=manual`.
`macos.signing.style`	string	*(set by the build)*	`@Mac(signingStyle)`	macOS builds. `manual` (default) signs with the certificate identity hints below, verbatim. `automatic` lets Xcode resolve the certificate from the team and provisioning profile instead. Manual is the default because a build server has an installed certificate and no Xcode account session, and automatic signing there stops to ask you to sign in; use automatic when building on your own machine.

Name	Type	Default	Annotation	Description
`macos.signingIdentity.appStore`	string	*(set by the build)*	`@Mac(signingIdentityAppStore)`	macOS builds. Signing certificate identity for the App Store channel. Default `Apple Distribution`. Unlike the Developer ID channel, this one rejects `none`. An unsigned application still gets packaged into a signed `.pkg`, so the build reports success and App Store Connect rejects the upload hours later for an application with no signature and none of the sandbox entitlements it has to carry. The build fails immediately instead, naming this hint. Build only the `developerID` channel to get an unsigned application. An empty value reads as unset and takes the default, which is why the Developer ID channel spells the escape hatch `none` rather than "".
`macos.signingIdentity.developerID`	string	*(set by the build)*	`@Mac(signingIdentityDeveloperID)`	macOS builds. Signing certificate identity for the Developer ID channel. Default `Developer ID Application`. Set it to `none` to build unsigned.
`macos.signingIdentity.installer`	string	*(set by the build)*	`@Mac(signingIdentityInstaller)`	macOS builds. The certificate `productbuild` signs a `.pkg` with — `3rd Party Mac Developer Installer` for the App Store, `Developer ID Installer` for direct distribution. This is a different certificate from `macos.signingIdentity.appStore`, which signs the application, so it has a hint of its own rather than being derived from that one. Required whenever a package is produced, which includes the App Store default: the build fails with an explanatory error rather than writing an unsigned package, because App Store Connect refuses one and Gatekeeper won’t accept it as Developer ID distribution however well the enclosed application is signed.

Name	Type	Default	Annotation	Description
`macos.signingIdentity.installer.appStore`	string	*(set by the build)*	`@Mac(signingIdentityInstallerAppStore)`	macOS builds. The installer certificate for the App Store channel specifically, when `macos.distribution=both` produces a package on each side. They're different certificates, so one shared value signs both packages with the same one and leaves one of them unusable. Unset, the shared `macos.signingIdentity.installer` applies.
`macos.signingIdentity.installer.developerID`	string	*(set by the build)*	`@Mac(signingIdentityInstallerDeveloperID)`	macOS builds. The installer certificate for the Developer ID channel specifically. Unset, the shared `macos.signingIdentity.installer` applies.
`macos.sourceOnly`	boolean	*(set by the build)*	`@Mac(sourceOnly)`	macOS builds. `true` stops after generating the Xcode project, which is what the `mac-source` target delivers. Set by that target rather than by hand.
`macos.teamId`	string	*(set by the build)*	`@Mac(teamId)`	macOS builds. Apple Developer Team ID (alphanumeric). Falls back to `ios.release.teamId` → `ios.teamId` → `ios.debug.teamId` since most apps share a single Apple Developer Team for iOS and Mac.

Name	Type	Default	Annotation	Description
macos.themeMode	string	*(set by the build)*	@Mac(themeMode)	macOS builds. Which native theme the application installs: modern (equivalently liquid or material) or ios7 (equivalently flat). Defaults to modern, which is where this target parts company with iOS — iOS keeps the legacy theme by default so that applications already shipped, and their screenshot baselines, keep rendering as before. There is no such history here, and the legacy theme defines no dark styles at all, so an application on it renders light however it asks for dark. The cross-platform nativeTheme hint is honoured when this is unset, with legacy mapping to ios7. custom packages and installs no native theme at all, for an application whose own theme is the only one.
macos.urlSchemes	string	*(set by the build)*	@Mac(urlSchemes)	macOS builds. Custom URL schemes to register, comma separated. ios.urlSchemes and then ios.urlScheme are read when this is unset, so a project migrated from the Mac Catalyst build keeps its deep links.
tvNative.bundleId	string	*(none)*	*(none)*	Bundle identifier of the tvOS app. Defaults to <packageName>.tvos.
tvNative.displayName	string	*(none)*	*(none)*	The tvOS app name shown on Apple TV. Defaults to the app's display name.
tvNative.enabled	boolean	false	*(none)*	true/false (defaults to false). Adds an Apple TV (tvOS) application target to the iOS build. The tvOS app is a separate appletvos target built from the same Java/Kotlin sources through ParparVM (UIKit + Metal). Enabling it doesn't change the iOS app. Also turned on implicitly by codename1.tvMain.
tvNative.mainClass	string	*(none)*	*(none)*	
tvNative.minDeploymentTarget	version	13.0	*(none)*	TVOS_DEPLOYMENT_TARGET for the tvOS target. Defaults to 13.0.

Name	Type	Default	Annotation	Description
`tvNative.teamId`	string	*(none)*	*(none)*	Apple Developer Team ID used to sign the tvOS target. Falls back to the iOS team id (`ios.release.teamId` / `ios.teamId` / `ios.debug.teamId`).
`watchNative.enabled`	boolean	`false`	*(none)*	
`watchNative.health`	string	*(none)*	*(none)*	
`watchNative.health.workoutProcessing`	boolean	`false`	*(none)*	
`watchNative.mainClass`	string	*(none)*	*(none)*	
`watchNative.surfaces.deploymentTarget`	string	`10.0`	*(none)*	Deployment target of the WidgetKit extension that carries the watch complication. This is the WATCH APP's floor rather than the extension's own: WidgetKit reaches back to watchOS 9, but the extension is embedded in the watch app, so advertising a version the app itself refuses to install on claims support the user never gets.
`win.desktop-vm`	string	*(none)*	*(none)*	The JVM that should be bundled in the Windows desktop build. Windows desktop builds only. Supported values: zulu8, zuluFx8, zulu8-32bit, zuluFx8-32bit, zulu11, zuluFx11, zulu11-32bit, zuluFx11-32bit
`win.installDirName`	string	*(none)*	*(none)*	Windows desktop builds only. Overrides the default installation folder name suggested by the installer (under `Program Files`). Defaults to the application's main class name for backward compatibility. Use this build hint to set a user-friendly installation folder name (for example, `win.installDirName=My Application`). The application ID used by Windows for upgrade detection is unaffected, so existing installations continue to upgrade.

Name	Type	Default	Annotation	Description
win.shortcutName	string	*(none)*	*(none)*	Windows desktop builds only. Overrides the name used for the Start Menu shortcut, the Desktop shortcut and (when win.launchOnStart=true) the autostart shortcut. Defaults to the application's main class name for backward compatibility. Use this build hint to set a user-friendly shortcut label (for example, win.shortcutName=My Application).
win.vm32bit	boolean	*(none)*	*(none)*	true/false (defaults to false). Forces windows desktop builds to use the Win32 JVM instead of the 64 bit VM making them compatible with older Windows Machines. This is off by default at the moment because of a bug in JDK 8 update 112 that might cause this to fail for some cases
windows.arch	string	*(none)*	*(none)*	Native Windows port only (the windows-native build target — not the JVM win.* desktop hints above). Target CPU architecture for the standalone .exe: x64 (the default) or arm64. Accepts the usual synonyms (x86_64/amd64, aarch64). clang-cl cross-compiles to the chosen architecture from either host. See the Working with the native Windows port chapter [# _working_with_the_native_windows_port].
windows.calendar.restrictedCapability	boolean	false	*(none)*	
windows.debug	boolean	false	*(none)*	Native Windows port only. true/false (defaults to false). When false the .exe is built optimized and **stripped** — no PDB, dead-stripped unreferenced code (/OPT:REF) and folded identical functions (/OPT:ICF) — which is the shipping default. Set true to keep debug symbols (a .pdb next to the exe, via RelWithDebInfo / clang-cl /Zi + linker /DEBUG) so a native crash address can be symbolized during development. Optimizations stay on in both cases.

Name	Type	Default	Annotation	Description
windows.embedded	boolean	false	*(none)*	Native Windows port only. Builds the kiosk target for a Windows IoT Enterprise device: one borderless, topmost window covering a whole monitor, the Windows key and the shell's task switching shortcuts filtered, and text edited through an on-screen keyboard. cn1:deploy-device installs it as the device's shell through Shell Launcher. Can't be combined with windows.xbox.
windows.embedded.board	string	generic-x64	*(none)*	Board profile for windows.embedded, which sets the architecture and the cursor and density defaults: generic-x64, generic-x64-mouse, generic-arm64, imx8 or qualcomm-iot.
windows.embedded.cursor	boolean	*(none)*	*(none)*	Whether windows.embedded shows the mouse cursor. Defaults to the board profile's choice: hidden on touch panels. CN1_CURSOR on the device overrides it.
windows.embedded.dpi	int	0	*(none)*	Panel density for windows.embedded when the panel misreports its size; 0 uses what Windows reports. CN1_DPI on the device overrides it.
windows.embedded.monitor	int	0	*(none)*	Which monitor windows.embedded covers, in Windows' enumeration order; 0, or a monitor that doesn't exist, is the primary. CN1_MONITOR on the device overrides it.
windows.embedded.rotation	int	0	*(none)*	Clockwise rotation windows.embedded applies to its monitor while it runs: 0, 90, 180 or 270. Windows restores the panel's own orientation when the application exits. CN1_ROTATION on the device overrides it.
windows.extensions	string	*(none)*	*(none)*	Historical build hint for the discontinued UWP target. It's retained here only for legacy reference and isn't used by current supported build targets.
windows.msix	boolean	false	*(none)*	

Name	Type	Default	Annotation	Description
windows.msix.identityName	string	*(none)*	*(none)*	
windows.msix.password	secret	*(none)*	*(none)*	
windows.msix.pfx	string	*(none)*	*(none)*	
windows.msix.publisher	string	*(none)*	*(none)*	
windows.msix.version	string	*(none)*	*(none)*	
windows.nativeVerify	string	*(none)*	*(none)*	`nativeVerify` for the native Windows translation alone.
windows.sdkRoot	string	*(none)*	*(none)*	Native Windows port only; used when building on a **non-Windows** host (for example a Linux build server). Path to a Windows SDK laid out by `xwin splat` [https://github.com/Jake-Shadle/xwin] (a directory containing `crt/include` and `sdk/include/um`), used to cross-compile the `.exe` with clang-cl + lld-link instead of a Visual Studio environment. If unset, the `CN1_XWIN_SYSROOT` environment variable is used. Ignored on Windows hosts, which build through Visual Studio. The same SDK serves both `windows.arch` targets (its `x86_64` / `aarch64` lib subdirs).
windows.signing	boolean	`true`	*(none)*	Native Windows port only. `true`/`false` (default `true`). Set `false` to force an unsigned build even when a certificate is available.
windows.signing.digest	string	`sha256`	*(none)*	Native Windows port only. Signature digest algorithm. Default `sha256`.
windows.signing.name	string	*(none)*	*(none)*	
windows.signing.password	secret	*(none)*	*(none)*	
windows.signing.pkcs12	string	*(none)*	*(none)*	
windows.signing.timestampUrl	string	`http://timestamp.digicert.com`	*(none)*	Native Windows port only. RFC 3161 timestamp server used when signing, so the signature stays valid after the certificate expires. Default `http://timestamp.digicert.com`; set empty to disable timestamping.

Name	Type	Default	Annotation	Description
`windows.signing.url`	string	*(none)*	*(none)*	
`windows.xbox`	boolean	`false`	*(none)*	Native Windows port only, experimental. true/false (defaults to false). Builds a UWP app for Xbox Developer Mode instead of a desktop `.exe`: the app runs in the app container on a CoreWindow, the gamepad drives navigation, and the result is an `.msix` to install through the console's Device Portal. Without a signing certificate a self-signed development one is generated and shipped beside the package as `<main class>-dev.cer`. Desktop-only features (secondary windows, menus, native widgets, file dialogs, printing, the camera) report unsupported. Cannot be combined with `windows.msix`.

Chapter 111. Signing, certificates & provisioning

In this section you try to explain how to acquire certificates for the various platforms and how to set them up.

The good news is that this is a "one time issue" and once it’s done the work becomes easier (except for the case of iOS where a provisioning profile should be maintained).

111.1. Common terms in signing & distribution

This section uses some terms that you might not be familiar with if you haven’t used cryptography or built mobile apps before. Here is a quick "FAQ" covering some common terms/concepts in this section.

111.1.1. What’s a certificate

Certificates use cryptographic principals to "sign" data (for example, an application). Think of them as you would think of a company stamp, you use them to sign an app so users know who it’s from.

111.1.2. What’s provisioning

Provisioning provides the hints/guidelines for the application install. For example, if an application needs some service from the OS such as push it can request that with provisioning.

In iOS provisioning is separate from the app and you need to also define the devices supported by the app during development.

111.1.3. What’s a signing authority

Certificates are issued by a signing authority which is a body that certifies that you’re who you say you are. Apple issues certificates for iOS and is in effect a signing authority.

Android uses self-signed certificates which don’t use a signing authority so anyone can ship an Android app.

The logic with the Android approach is that a signature indicates that you’re the same person who earlier shipped the app. Hence an app will be updated with the exact same certificate.

111.1.4. What’s UDID

The UDID is the Universal Device Identifier. It identifies mobile devices uniquely, notice that some operating systems for example, iOS block access to this value due to privacy concerns.

You need the iOS device UDID value during development to add the device into the list of allowed devices.

Don’t use an app to get the UDID!
Most return the wrong value. Use the Finder device summary on macOS, or Apple Configurator.

111.1.5. Should you reuse the same certificate for all apps

For iOS yes. It’s designed to work in that way.

You would recommend it for all platforms for simplicity but some developers prefer creating per-application certificates for Android. The advantage here is that you can transfer ownership of the application later on without giving away what’s effectively "your house keys."

111.2. Certificate Wizard

Codename One features a standalone Certificate Wizard to manage signing assets for Apple, Android and desktop targets. It replaces the old certificate wizard inside `CodenameOneSettings` and is launched as a Maven tool bound to the current project.

Run the wizard from a Codename One Maven project:

```
mvn cn1:certificatewizard
```

The Maven goal resolves the wizard artifact and its runtime dependencies from Maven, then launches it with the current project’s settings path. The wizard uses the Codename One cloud signing API for Apple assets and local `keytool` for Android keystores. On a first run the overview shows that the App Store Connect API key isn’t configured and links to the API key page. This is an Apple credential that allows the cloud service to create and manage certificates, bundle IDs, devices, provisioning profiles, APNs keys and Mac signing assets for your Apple Developer Program team.

111.2.1. Creating the App Store Connect API key

Open App Store Connect > Users and Access > Integrations > App Store Connect API [https://appstoreconnect.apple.com/access/integrations/api]. If this is the first time your team uses the API, App Store Connect asks you to request API access first. Click **Request Access**, accept the terms, and submit the request.

Once access is enabled, go to **Team Keys** and click **Generate API Key**. Give the key a recognizable name, such as `Codename One Signing`, and choose **Admin** access.

Use **Admin** access for the Certificate Wizard. The wizard needs to create and list signing certificates, bundle IDs, devices, and provisioning profiles. App Manager or Developer access may not be sufficient for these operations.

After creating the key, App Store Connect shows the **Issuer ID** above the table and the **Key ID** in the key row. Copy both values into the wizard. Download the API key file. Apple only allows the `.p8` file to be downloaded once, so store a backup in a secure location.

In the Codename One Certificate Wizard, fill these fields:

- **Key ID**: The value shown in the generated key row in App Store Connect. This isn't your Apple ID.
- **Issuer ID**: The UUID shown above the Team Keys table on the App Store Connect API page.
- **Private key .p8**: Click **Import .p8 file** to select the downloaded file with the native file chooser, or paste the full file contents, including the `BEGIN PRIVATE KEY` and `END PRIVATE KEY` lines.

The `.p8` private key is sent to the Codename One cloud signing service and isn't returned by the API later. If you delete the key from App Store Connect or lose the local `.p8` backup, generate and store a new API key.

When you download a generated `.p12` certificate from the wizard, the **P12 password** field is a new password that you choose for that downloaded file. It's not the App Store Connect Issuer ID, and it doesn't come from Apple.

111.2.2. Recommended fast path: Auto Setup

After the API key is stored, the top toolbar shows **Auto Setup** next to the API key status. This is the recommended path for a normal Codename One project. It creates the common Apple signing assets for the current project and installs the downloaded files into `codenameone_settings.properties`.

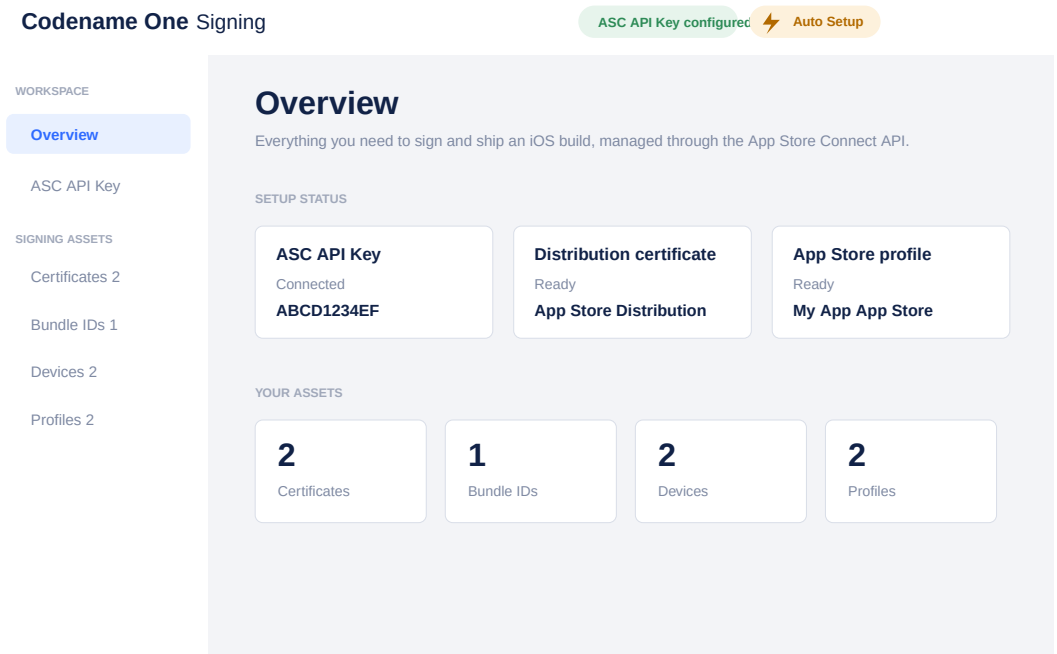

Figure 391. Certificate wizard overview with mocked signing assets

Click **Auto Setup**. The wizard reads the current project's `codenameone_settings.properties`, uses `codename1.packageName` as the bundle ID, uses `codename1.displayName` or `codename1.mainName` as the app name, enables push notifications for the bundle ID, and then creates or reuses the signing assets it needs.

The fast path creates the common Apple signing setup:

- A Bundle ID for the current project, if it doesn't already exist.

- An iOS Development certificate, if no compatible active certificate exists.
- An iOS Development provisioning profile, if at least one development device is registered.
- An iOS Distribution certificate, if no compatible active certificate exists.
- An App Store provisioning profile.
- Debug signing settings for the development certificate/profile pair.
- Release signing settings for the App Store certificate/profile pair.
- Mac App Store or Developer ID assets when you use the Mac Signing page.
- App extension assets for each extension the project generates. Apple signs an app extension against its own App ID, so a project using External Surfaces or the Document Provider also gets an App Group, a separate App ID for the extension, and an App Store and a development profile for it, all installed into the project settings.

Development provisioning requires at least one registered device. If no devices are registered, the wizard defers development profile creation and continues with the App Store signing assets. Register the device in the **Devices** section and run **Auto Setup** again to fill in the debug signing settings.

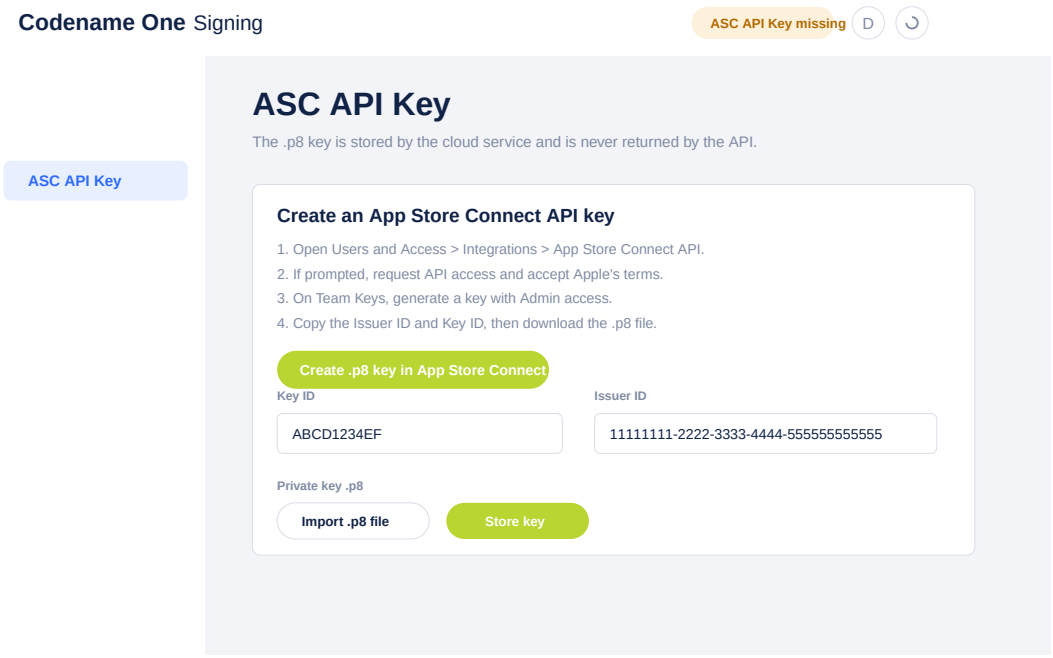

Figure 392. Certificate wizard API key screen with mocked values

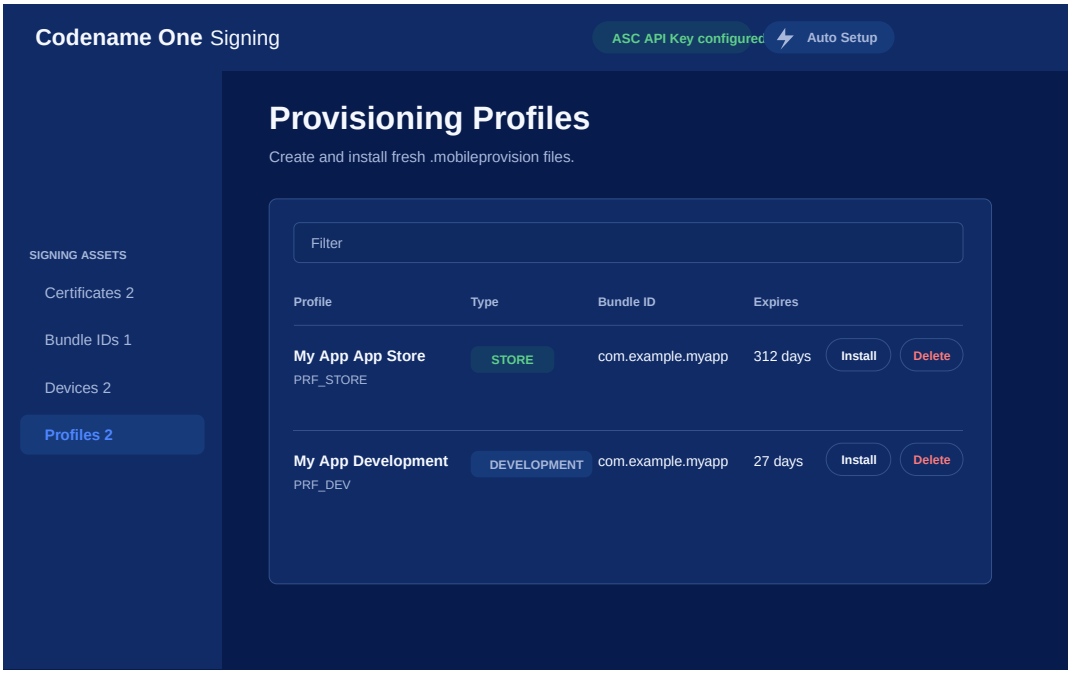

Figure 393. Certificate wizard profiles screen with mocked values

The wizard writes downloaded Apple `.p12`, `.mobileprovision` and Mac `.provisionprofile` files into the current project signing configuration. For a development iOS profile it updates the iOS debug settings. For an App Store iOS profile it updates the iOS release settings. For Mac profiles it updates `codename1.mac.certificate`, `codename1.mac.certificatePassword`, `codename1.mac.provision` and the relevant `macNative.*` hints.

111.2.3. Mac signing and notarization

The **Mac** section uses the same App Store Connect API key and the unified Apple signing API. It supports Mac App Store certificates/profiles and Developer ID certificates for direct distribution. Developer ID builds can use notarization credentials derived from the stored App Store Connect key when the build server performs notarization.

Mac native signing uses the project settings documented in the Mac native chapter:

- `codename1.mac.certificate`: The generated or imported Mac `.p12`.
- `codename1.mac.certificatePassword`: The password for that `.p12`.
- `codename1.mac.provision`: The Mac `.provisionprofile`.
- `codename1.arg.macNative.enabled=true`: Enables the Mac native signing path.
- `codename1.arg.macNative.distribution=appStore` or `developerID`: Chooses the signing channel.

111.2.4. Android signing

The **Android** section generates a local self-signed Android keystore using the JDK `keytool` executable. It stores the file under `androidCerts/KeyChain.ks` in the project by default and writes:

- `codename1.android.keystore`
- `codename1.android.keystoreAlias`

- `codename1.android.keystorePassword`

Back up the generated keystore and password. Android apps already published with one certificate can't be updated with a different certificate.

111.2.5. Windows signing

The **Windows** section doesn't issue certificates. Windows Authenticode certificates must come from a code-signing certificate authority or a managed signing service such as Azure Trusted Signing, DigiCert KeyLocker, GlobalSign GCC, Sectigo, or another OV/EV provider. Once you have a `.pfx` or `.p12`, configure:

- `codename1.windows.signing.certificate`
- `codename1.windows.signing.password`
- `codename1.windows.signing.timestamp`

111.2.6. Clearing cached signing data

The **Clear Signing Data** section is a privacy tool, not a recommended part of normal signing setup or troubleshooting. Use it only when you need to delete cached signing data owned by the current Codename One account from the cloud signing service.

It clears stored Apple API credentials, generated certificate private keys, provisioning profile metadata, APNs keys and notarization data. It doesn't delete assets from Apple, but future cloud builds will need signing data to be regenerated or re-imported.

111.2.7. Manual asset management

Use the individual wizard sections when you need to inspect assets, register a device, sync certificates with Apple, create an ad-hoc or Mac profile, install a specific certificate/profile pair, generate an Android keystore, or delete/revoke an obsolete asset.

The asset tables are live-filterable and sortable. Click a row to show the values returned by the signing API. Existing Apple assets can't currently be edited through this API; for changes, create a new asset or delete/revoke the old one where Apple permits it. Destructive actions such as deleting a profile, deleting an APNs key, deleting the stored API key, or revoking a certificate prompt for confirmation.

111.2.8. Selecting devices

Development and ad-hoc provisioning profiles can only include devices that are registered on your Apple Developer account. In the standalone wizard, open the **Devices** section to register a device by name and UDID before creating a development or ad-hoc provisioning profile.

Figure 394. Devices form

Select the ones that you want to include in your provisioning profile and click next.

Apple allows up to 100 devices per device type (iPhone, iPad, Apple Watch, Apple TV, and Apple Vision) for testing purposes in each membership year. Make sure every device you intend to install builds on is registered here before you generate a new provisioning profile.

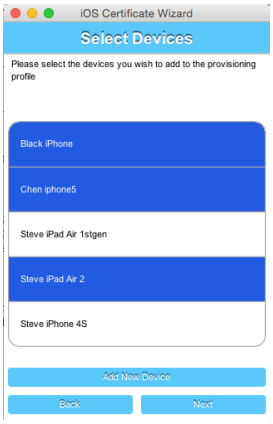

Figure 395. After selecting devices

If you don't have any devices registered yet, you can click the "Add New Device" button, which will prompt you to enter the UDID for your device.

111.2.9. Decisions & edge cases

If you already have iOS P12 development/distribution certificates you should reuse them for all your apps from that account and you shouldn't regenerate them

After you click `Next` on the device form, the wizard checks to see if you already have a valid certificate. If your project already has a valid certificate and it matches the one that's active in your Apple developer account, then it will use the same certificate. If the certificate doesn't match the currently active one, or you haven't provided a certificate, you will be prompted to overwrite the old certificate with a new one.

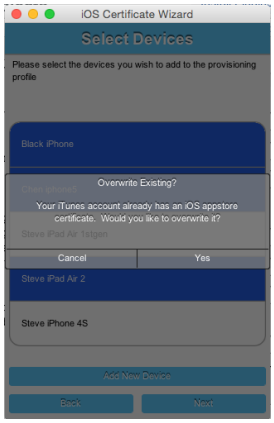

Figure 396. Prompt to overwrite existing certificate

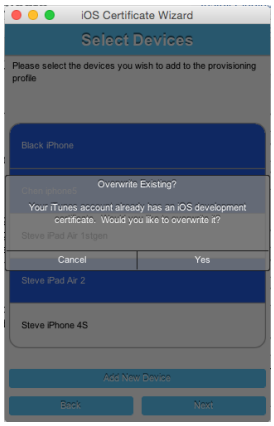

Figure 397. Prompt to overwrite other certificate

The same decision need to be made twice: Once for the development certificate, and once for the App Store distribution certificate.

Each Apple Developer account can have three active iOS Development certificates and three active iOS Distribution certificates at a time. Reuse existing certificates whenever possible to avoid hitting this limit.

You can revoke a certificate when you have an application in the store shipping with said certificate!
This won't affect the shipping app see this [https://stackoverflow.com/questions/6320255/if-i-revoke-an-existing-distribution-certificate-will-it-mess-up-anything-with].

Why Two Certificates?

A typical iOS app has at least two certificates:

- Development - this is used during development and can't be shipped to 3rd parties. An application signed with this certificate can only be installed on one of the up to 100 devices listed above.
- Distribution - this is used when you're ready to upload your app to App Store Connect whether for final shipping or beta testing. Notice that you can't install a distribution build on your own device. You need to upload it to App Store Connect.
- Two push certificates exist, separate from the signing certificates. Don't confuse them!

They're used to authenticate with Apple when sending push messages.

111.2.10. App IDs and provisioning profiles

The next form in the wizard asks for your app's bundle ID. This should have been pre-filled, but you can change the app ID to a wildcard ID if you prefer.

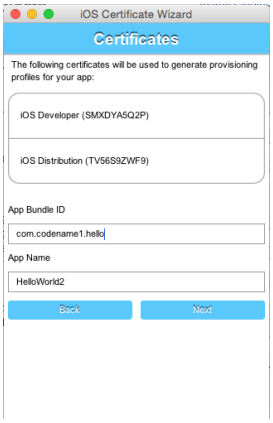

Figure 398. Enter the app bundle ID

Wildcard Card Provisioning

Wildcard IDs such as `com.mycompany.` or `even` allow one generic development profile to cover multiple applications. The standalone Certificate Wizard can reuse an existing wildcard profile, but wildcard apps can't use capabilities such as push notifications and aren't suitable for App Store distribution.

111.2.11. Installing files locally

Once the wizard is finished generating your provisioning profiles, you should click `Install Locally`, which will open a file dialog for you to navigate to a folder in which to store the generated files.

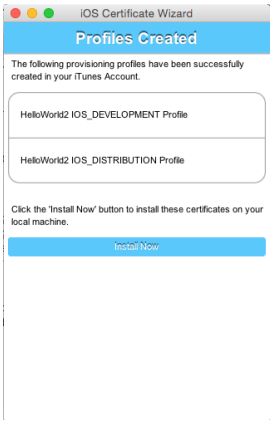

Figure 399. Install files locally

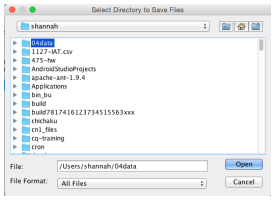

Figure 400. Select directory to save files in

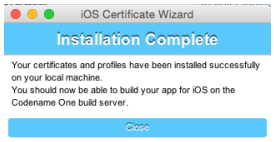

Figure 401. Final Done Message

You can see the password for the P12 files in the `codenameone_settings.properties` file. You can use the values defined there when creating a new application

111.2.12. Building your app

After selecting your local install location, and closing the wizard, you should see the fields of the "iOS Signing" properties panel filled in. You should now be able to send iOS debug or App Store builds without the usual hassles.

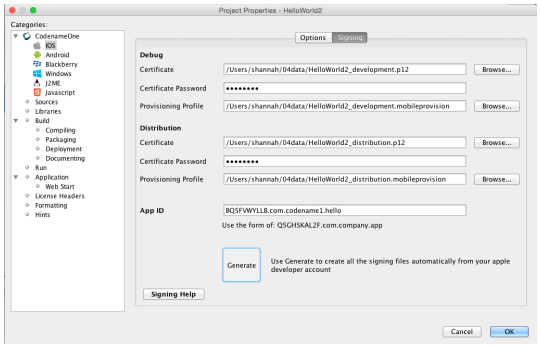

Figure 402. Filled in signing panel after wizard complete

111.3. Advanced iOS signing

You should use the Certificate Wizard, if you don't have a Mac. This section is here for reference and edge cases that don't work with the Certificate Wizard

iOS signing has two distinct modes: App Store signing which is valid for distribution via App Store Connect (you won't be able to run the resulting application without submitting it to Apple) and development mode signing.

You've two major files to keep track of:

1. **Certificate** - your signature
2. **Provisioning Profile** - details about the application and who is allowed to execute it

You need two versions of each file (4 total files) one pair is for development and the other pair is for uploading to App Store Connect.

You need to use a Mac to create a certificate file for iOS

The first step you need to do is signing up as a developer to Apple's iOS development program [https://developer.apple.com/], even for testing on a device this is required!
This step requires that you pay Apple on an annual basis.

The Apple website will guide you through the process of applying for a certificate at the end of this process you should have a distribution and development certificate pair. After that point you can log in to the iOS provisioning portal [https://developer.apple.com/ios/manage/overview/index.action] where there are plenty of videos and tutorials to guide you through the process. Within the iOS provisioning portal you need to create an application ID and register your development devices.

You can then create a provisioning profile which comes in two flavors:

- Distribution - for building the release version of your application
- Development - the development provisioning profile needs to contain the devices on which you want to test.

You can then configure the 4 files in the IDE and start sending builds to the Codename One cloud.

111.3.1. Preparing the certificates and profiles

The layout of Apple's portal changes, so what follows are the constraints that hold whatever the current screens look like, rather than a tour of them.

The application ID you register has to match your project's package identifier exactly. Nothing checks this while you're filling the forms in: the mismatch surfaces later, as a build that can't match a profile to the application.

The development profile has to name every device you intend to install on. A device registered after the profile was generated isn't covered by it, so the profile has to be regenerated and downloaded again. An `Ad Hoc` distribution profile works the same way. The profiles that name no devices are the ones where you aren't the one doing the installing: App Store, and enterprise in-house.

Apple issues certificates as `.cer` files, and the build servers need `.p12` files. On a Mac, double-clicking a `.cer` imports it into Keychain Access, and you export the development and distribution certificates from there as `.p12`, choosing a password for each. Those are the passwords the next section asks for.

111.3.2. Configuring `codenameone_settings.properties` for manual signing

The Codename One build servers read signing assets from `codenameone_settings.properties`. When you bypass the Certificate Wizard, populate the following keys manually so the packaging process can locate your certificates, provisioning profiles, and keystores:

iOS

- `codename1.ios.debug.certificate` / `codename1.ios.debug.certificatePassword` / `codename1.ios.debug.provision`: Development P12 and provisioning profile for device/debug builds.
- `codename1.ios.release.certificate` / `codename1.ios.release.certificatePassword` / `codename1.ios.release.provision`: Distribution P12 and provisioning profile for App Store/TestFlight builds.
- `codename1.ios.certificate`, `codename1.ios.certificatePassword`, and `codename1.ios.provision`: Legacy/global defaults. The IDE uses these as fallbacks when the debug/release-specific properties are blank, so keep them aligned with your preferred certificates.
- `codename1.ios.appext.<Name>.provision`: Provisioning profile for an embedded app extension (for example the generated `CN1Widgets` widget extension), used for both build types. Add `codename1.ios.debug.appext.<Name>.provision` / `codename1.ios.release.appext.<Name>.provision` to use the development profile for device/debug builds and the distribution profile for release builds; the variant matching the build target wins and the unqualified key is the fallback.

Paths may be absolute or relative to the project directory. The passwords must match the values you used when exporting the P12 files from Keychain Access.

Android

- `codename1.android.keystore`: Path to the Android keystore (`.ks` or `.keystore`).
- `codename1.android.keystorePassword`: Password protecting the keystore and key entry.
- `codename1.android.keystoreAlias`: Alias of the keypair used to sign the APK/AAB.

If the keystore fields are empty the Maven and Ant builders will create a default keystore, but production apps should commit the real paths and credentials so reproducible builds use your long-lived signing key.

111.3.3. iOS code signing failure checklist

Below is a list of common issues when singing and a set of suggestions for things to check. Notice that some of these signing failures will sometimes manifest themselves during build and sometimes will manifest during the installation of the application.

Most of these issues aren't applicable when using the wizard for example, a Mac isn't required for the Certificate Wizard as it uses the Codename One cloud

- **You must use a Mac to generate P12 certificates manually**. The workaround you found is the Certificate Wizard!

Notice that this is something you need to do once a year (generate P12), you will also need a Mac to upload your final app to the store now.

- When exporting the P12 certificate **make sure that you selected BOTH the public and the private keys** as illustrated here. If you see one entry (no private key) then you created the CSR (singing request) on a different machine than the one where you imported the resulting CER file.

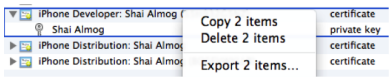

Figure 403. p12 export

- Launch Codename One Settings with `mvn cn1:settings` and make sure the **Package Name** in **Basic** matches the App ID used by the provisioning profile.
- Make sure the App ID prefix in the provisioning profile matches the prefix assigned by Apple. The standalone Certificate Wizard handles this automatically for profiles it creates.
- Make sure your provisioning profile's app ID matches your package name or is a * provisioning profile. Both are sampled in the pictures below, notice that you would need an actual package name for push/in-app purchase support as well as for app store distribution.

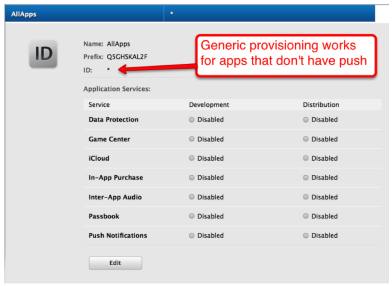

Figure 404. The star (*) Provisioning Profile

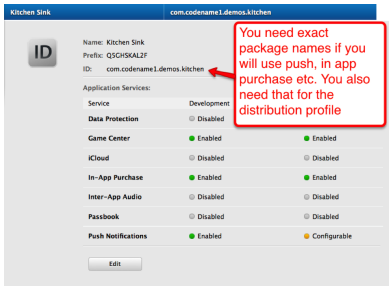

Figure 405. Provisioning Profile with app ID

- Make sure the certificate and provisioning profile are from the same source (if you work with multiple accounts), notice that provisioning profiles and certificates expire so you will need to regenerate provisioning when your certificate expires or is revoked.
- If you declare push in the provisioning profile then `ios.includePush` (in the build arguments) MUST be set to true, otherwise it **MUST** be set to false (see pictures below). Notice that this should be configured via the UI in the iOS section. The build server automatically enables the notification entitlement when your project uses `LocalNotification`, even if `ios.includePush` is false, so don't try to disable the entitlement manually to "fix" warning messages from App Store Connect.

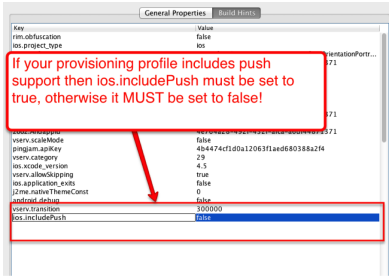

Figure 406. Include push build hint

111.4. Android

Signing Android applications is trivial when compared to the pain of iOS signing.

The Certificate Wizard generates a keystore for you. One keystore can sign every application you ship, though some developers prefer one per application, so that an application can be handed over to someone else later without also handing over the key to all the others.

111.4.1. Generating an Android certificate manually

You need the JDK's keytool executable (it should be under the JDK's bin directory) and execute the following command:

```
keytool -genkey -keystore Keystore.ks -alias [alias_name] -keyalg RSA -keysize 2048 -validity 15000 -dname "CN=[full name], OU=[ou], O=[comp], L=[City], S=[State], C=[Country Code]" -storepass [password] -keypass [password]
```

The elements in the brackets should be filled up based on this:

```
Alias: [alias_name] (just use your name/company name without spaces)
Full name: [full name]
Organizational Unit: [ou]
Company: [comp]
City: [City]
State: [State]
CountryCode: [Country Code]
Password: [password] (we expect both passwords to be identical)
```

Executing the command produces a `Keystore.ks` file in that directory. Keep it safe: if you lose it, you can no longer publish upgrades signed with the same identity. Enter its path, alias, and passwords in `common/codenameone_settings.properties`, or use the **Android** page in the standalone Certificate Wizard (`mvn cn1:certificatewizard`) to generate and install a keystore.

For more details see https://developer.android.com/studio/publish/app-signing

Chapter 112. App Store Submission and Deployment

Once a build is signed you still have to get it in front of users: upload the binary, fill in the release notes, set the store listing, and send it for review — on every store where your users are. Codename One automates that last mile as a one-stop shop. From the build console you can submit a finished build to the **App Store**, the **Mac App Store**, **Google Play**, and **Huawei AppGallery** with one click, manage the store **listing itself** — title, description, keywords, what's-new, screenshots — as code in your project, and produce per-store Android packages so you can reach the large Android audience that isn't on Google Play.

Reaching those audiences doesn't depend on, and can't be restricted by, any single store. Google Play always receives the standard, unmodified Android App Bundle, so your Play listing follows Google's rules exactly; the additional channels (AppGallery and other Android markets) are separate artifacts delivered to separate stores.

This chapter covers the end-to-end flow, credentials, the metadata-as-code workflow, and multi-store Android distribution. It builds on Signing: submission reuses the same App Store Connect API key the certificate wizard configures.

112.1. What it does, and what it doesn't

Automated submission delivers the binary and applies your release metadata to an **existing** app on the store. It doesn't create the app for you.

> You must create the app once, by hand, in App Store Connect [https://appstoreconnect.apple.com] and/or the Google Play Console [https://play.google.com/console] before you can submit to it. Neither store's API can register a brand-new app, set up pricing, in-app purchases, the privacy questionnaire, or the content-rating questionnaire — those remain one-time manual steps in the store consoles. After that, every release's binary and listing can be shipped automatically.

Three things are worth separating, because they happen at different times:

- **The app record** — the listing shell in the store. Created once, manually, and exists before any build.
- **The binary** — produced by your build, delivered when you **submit**.
- **The metadata** — description, what's-new, screenshots. Managed as code and applied when you submit. Metadata attaches to the app record and the new version, not to the binary, so there's no chicken-and-egg problem: the app already exists on the store by the time you build.

112.2. Prerequisites

112.2.1. Store credentials

Apple. Submission uses the App Store Connect API key described under the certificate wizard. If you have already run `mvn cn1:certificatewizard` and stored the key, you are ready — the same key that creates certificates and profiles also uploads builds and manages listings.

Google. Create a Google Play service account with the **Android Publisher** role in the Google Play Console (API access > Service accounts), download its JSON key, and add it to the build console's submission credentials page. The console shows which stores are connected.

Huawei. In AppGallery Connect, create an API client under **Users and permissions** > **API client** and note its **Client ID** and **Client Secret**, then add them on the same submission credentials page. The app must already exist in AppGallery Connect (submission binds to the app resolved from your package name).

The Submissions page shows a connect card for each store you haven't configured yet; fill one in and save to enable one-click submission to that store.

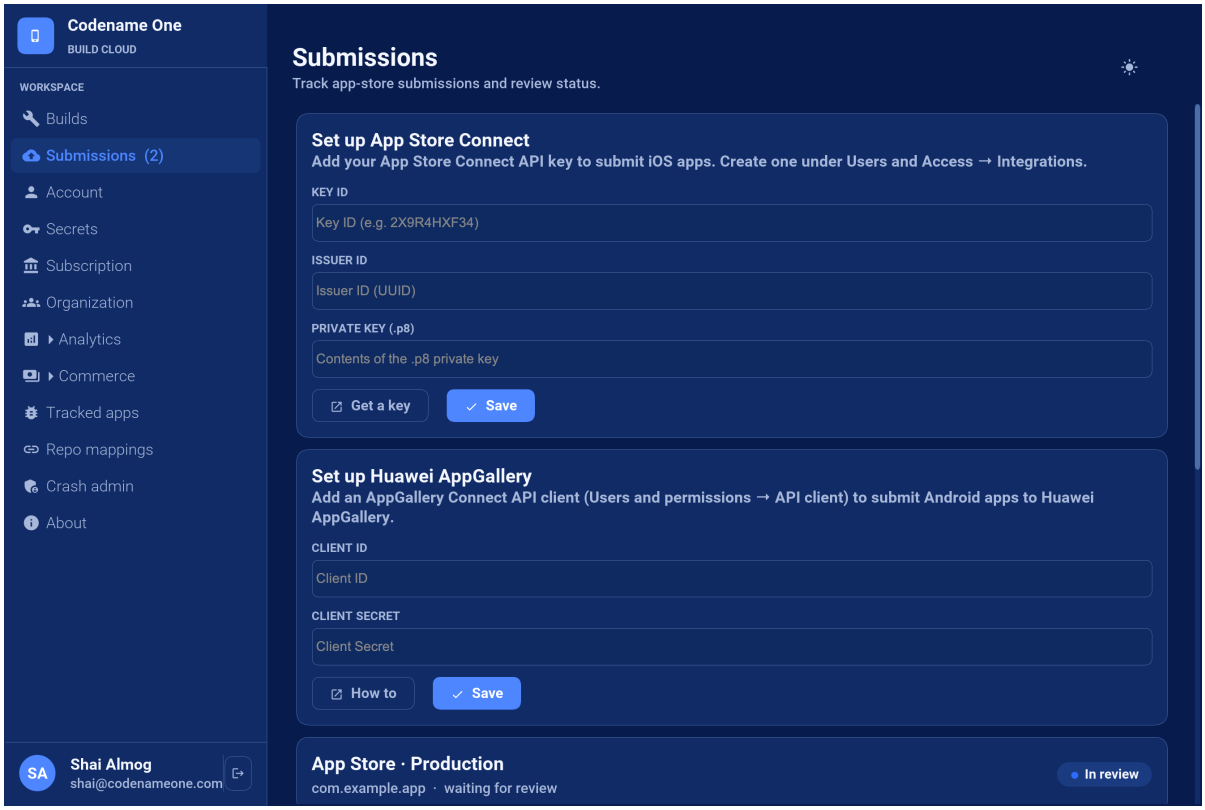

Figure 407. The submission credentials cards in the build console

112.2.2. Beta vs production

When you submit you choose a destination. **Beta** means TestFlight (Apple) or the internal-testing track (Google). **Production** means App Store review (Apple) or the production track (Google).

112.3. Submitting a build from the console

On any successful build the console shows a **Submit** action for each store the build can go to:

- **Submit to App Store** — when the build produced an iOS `.ipa`.

- **Submit to Mac App Store** — when the build produced a native macOS `.pkg` (see the **Working with macOS** chapter). An iOS build that also produced a `.pkg` offers both.
- **Submit to Google Play** — for an Android build.
- **Submit to AppGallery** — for an Android build, to Huawei AppGallery. Production sends the build for review; the beta destination uploads it and leaves it as a draft for you to promote or open-test.

The submit dialog lets you pick the destination (Beta or Production) and add release notes for this submission, then delivers the binary. For an Apple **production** submission the console then tracks the App Store review state (processing → in review → approved/rejected) and can email you when the state changes. Google submissions and TestFlight deliveries complete as soon as the binary is delivered.

Submitting to **Production** on Apple opens an App Store review submission automatically. Submitting to **Beta** delivers to TestFlight without opening a review.

112.4. Metadata as code

Release metadata — the store listing text and screenshots — can live in your project as a folder of plain text and image files, versioned in git alongside your code, and pushed to the stores with a single command. This makes your listing reproducible and CI-drivable: generate release notes from your changelog, push, and the next submission applies it to both stores. It's the alternative to typing the same fields into two different web consoles by hand for every release.

112.4.1. The metadata folder

By default the goal reads a `cn1-metadata` folder next to your `codenameone_settings.properties`. It's organized by store, then locale, with one plain text file per listing field:

```
cn1-metadata/
  apple/
    primary_locale.txt          (optional; defaults to the first locale)
    primary_category.txt        (optional; an App Store Connect category id)
    secondary_category.txt      (optional)
    en-US/
      name.txt                  (app name, max 30 chars)
      subtitle.txt              (max 30 chars)
      description.txt           (max 4000 chars)
      keywords.txt              (comma separated, max 100 chars)
      promotional_text.txt      (max 170 chars)
      whats_new.txt             (release notes for this version)
      marketing_url.txt
      support_url.txt
      privacy_url.txt
      screenshots/
        APP_IPHONE_67/1.png 2.png ...
        APP_IPAD_PRO_129/1.png ...
```

```
  google/
    en-US/
      name.txt                  (listing title, max 30 chars)
      subtitle.txt              (short description, max 80 chars)
      description.txt           (full description, max 4000 chars)
      whats_new.txt             (release notes, max 500 chars)
      support_url.txt
      screenshots/
        phoneScreenshots/1.png 2.png ...
        tenInchScreenshots/1.png ...
```

Every file is optional; a field you don't include keeps whatever value the store already has. The same neutral file names map to each store's fields (for example `subtitle.txt` becomes the App Store **subtitle** and the Google Play **short description**). Fields a store doesn't have (Apple `keywords` /`promotional_text`) are simply ignored for the other store.

The `screenshots/<dir>` sub-folders are named with each store's own type identifiers: App Store `screenshotDisplayType` values (for example `APP_IPHONE_67`) for Apple, and listing `imageType` values (for example `phoneScreenshots`) for Google. Images are uploaded in filename order.

You don't have to create the folder by hand. Run `mvn cn1:metadata-init` to scaffold `cn1-metadata` with an empty template of the field files, a screenshots folder, and a `README`, ready to fill in:

+

```
mvn cn1:metadata-init                        # apple + google, en-US
mvn cn1:metadata-init -Dstore=apple -Dlocale=fr-FR
```

+ It only creates what's missing, so it's safe to re-run (for example to add a new locale) — it never overwrites files you've already filled in.

112.4.2. Pushing the metadata

Run the goal from your project; it authenticates with the same Codename One account your builds use (run `mvn cn1:certificatewizard` once to sign in, or pass `-Dtoken=`):

```
# push both stores from cn1-metadata/
mvn cn1:metadata-push

# or a single store
mvn cn1:metadata-push -Dstore=apple

# override the folder or the package id if needed
mvn cn1:metadata-push -DmetadataDir=path/to/metadata -Dpackage=com.example.app
```

The package id defaults to `codename1.packageName` from `codenameone_settings.properties`. The goal

validates every field against the store's limits before storing it, so an over-long name or a malformed URL fails fast with a clear message. Wire it into CI to keep the stored listing in sync with your repo.

`metadata-push` uploads the descriptor and screenshots to Codename One; it does **not** submit. The stored metadata is applied to the store the next time you **submit** a build for that package.

112.4.3. When and how it's applied

At submission time the stored descriptor is applied to the store automatically:

- **Apple** — applied to the **production** App Store version (App Store review), while the version is still editable. TestFlight has no store listing, so beta Apple submissions don't apply listing metadata.
- **Google** — applied to the listing on the edit that publishes the binary, on any track.

Applying metadata is **best-effort**: the binary is delivered first, so a rejected field (say a name that's too long, or a locale the app hasn't enabled) never blocks the submission — it's recorded as a warning you can see in the console, and the rest of the listing still applies. You can always fix a field by hand in the store console afterward.

112.4.4. Screenshots aren't stored long-term

Screenshots are a transient pass-through: `metadata-push` uploads them, the next submission delivers them to the store, and they're then deleted from Codename One's servers. Keep the canonical images in your repo (that's the point of managing them as code) and re-push when they change. Text descriptors are retained until you delete them, your account is deleted, or they go unused for about a year.

Per-image limits: up to 10 MB, PNG or JPEG, and at most 10 screenshots per locale and display type (the stores' own limit).

112.5. Reaching Android users beyond Google Play

A large share of Android users — most of the market in China, and many devices elsewhere — can't install from Google Play. Reaching them means shipping to other Android stores: Huawei AppGallery, and the many app markets run by device makers and carriers (Xiaomi, OPPO, VIVO, Tencent MyApp, Baidu, 360 and others). Codename One makes your app available on those stores without changing how you build or locking you to any of them.

Huawei AppGallery is a first-class submission target, exactly like the App Store or Google Play (see Submitting a build above). For the remaining Android markets, Codename One produces **distribution-channel packages**.

112.5.1. Distribution-channel packages

Most of these stores accept a plain, self-signed APK rather than an App Bundle, and they attribute

each download and its revenue to the store it came from. A distribution-channel package is your signed release APK stamped with a store identifier — one APK per store, all built from the same release.

You choose the stores; the build produces one package per store, each carrying its channel id. Your app reads that id at runtime with `Display.getInstance().getProperty("DistributionChannel", "")` — an empty string for a normal Google Play build — so you can report the install source (to your own analytics or the store's) **without adding any third-party channel SDK**. Codename One writes the id and reads it back for you.

Google Play is never a channel package. Play always receives the standard, unmodified Android App Bundle, so nothing about this feature affects your Play listing or its compliance — the channel packages are separate APKs for separate stores.

Sensible defaults keep this simple: enable it and you get packages for the major Android markets out of the box, and you can narrow or extend the channel list to match the stores you actually publish to. Each package is signed with your app's release key, so every store receives a signed, installable APK.

112.6. Benefits over editing the stores by hand

Managing submission and metadata through Codename One pays off most for teams, frequent releases, many locales, or many apps:

- **Automated release notes.** Generate what's-new from your changelog and ship it to both stores on every release — the one field that always changes.
- **One source, two stores.** A single descriptor fans out to App Store Connect and Google Play, which have different fields and limits.
- **Reproducible and reviewable.** The listing lives in git, versioned and code-reviewed like everything else. Console edits have no history.
- **Localization at scale.** Localized listings are just files, and can be generated or translated in a pipeline.
- **Fewer console logins.** Team members who ship releases don't each need App Store Connect or Play Console access; they ship through the build pipeline instead.

For a single app with infrequent updates, editing the store console by hand is fine — the payoff scales with how often you release and how many listings you maintain.

Platform guides

Chapter 113. Working with iOS

113.1. Troubleshooting iOS debug build installs

If you've access to a Mac, connect the device, open Xcode, and use the device explorer console to inspect messages that may explain what went wrong. If not, check the following:

- Make sure the build is the debug version and not the App Store version. The App Store version won't install on the device and can be distributed through Apple's store or TestFlight.
- Check that the UDID is correct. If you got the UDID from an app, it's probably wrong because apps no longer have access to the device UDID. Get it from the iOS Settings app or iTunes.
- Make sure the device isn't locked for installing third-party apps. This can happen on devices configured with parental controls.
- Check that you own the package name. For example, if you earlier installed an app with the same package name but a different certificate, a new install will fail. This is true for Android too. If you installed the kitchen sink from the store and then built your own app with the same package name, the installation will collide.
- This can be a problem if you use a generic package name that someone else already claimed, so use your own domain.
- Make sure the device has a recent enough version of iOS for the dependencies. Codename One builds target iOS 14 unless you say otherwise, and never drop below iOS 13 whatever is asked for. Raise the floor with the `ios.deployment_target` build hint when a library needs a newer version.
- Verify that you're using Safari when installing on the device. If you used a cable, that isn't a problem. Some developers had issues with Firefox not launching the install process.
- Check that the `ios.includePush` build hint matches your iOS provisioning. It must be false if your provisioning profile doesn't include push.

113.2. Launch screen best practices

Every iOS build declares a launch screen. Apps linked with the iOS 27 SDK or later are rejected unless the bundle declares one of `UILaunchStoryboardName`, `UILaunchStoryboards`, `UILaunchScreen` or `UILaunchScreens`, and `UIRequiresFullScreen` isn't a substitute for any of them. The build checks the finished `Info.plist` and fails if none of the four is there, so an `ios.plistInject` that removes the generated key stops the build rather than producing an archive the App Store refuses.

What the build declares by default is `UILaunchScreen`: the system background color, which follows light and dark mode on its own, with `Launch.Foreground.png` centered on it. That's deliberate rather than a simplification. Every Codename One app runs on the UIScene lifecycle, and SplashBoard doesn't render a launch **storyboard** for a scene-based app — it animates from a black frame instead. Since iOS prefers the storyboard whenever both keys are present, declaring one would mean a black launch.

You can still take the storyboard, and the build still ships `LaunchScreen.storyboard` for you to point

at. Declare the key yourself, which overrides the generated one:

```
codename1.arg.ios.plistInject=<key>UILaunchStoryboardName</key><string>LaunchScreen</string>
```

Do that only if you've verified the result on the devices you ship to. The same applies to `UILaunchStoryboards` and `UILaunchScreens`: declare either one through `ios.plistInject` and the build leaves your launch experience alone.

The `ios.generateSplashScreens`, `ios.uiscene` and `ios.launchStoryboardName` build hints have been removed, and a build that still sets one fails with a message explaining what replaced it. The first named the pre-storyboard `Default*.png` generator, which iOS stopped using long ago; the second selected the legacy `UIApplicationDelegate` lifecycle, which Apple no longer permits; the third named the storyboard for a key only that legacy lifecycle emitted.

113.2.1. Key files

The build provides the default launch screen automatically. Customize it by adding either of the following files under your project's `ios/src/main/resources` directory:

1. `Launch.Foreground.png` - Shown in the center of the screen instead of your app icon. Used by the default `UILaunchScreen`.
2. `Launch.Background.png` - Drawn behind the content to provide a color or illustration. Read by `LaunchScreen.storyboard`, so it only applies if you opt into the storyboard as shown above.

You can also replace `LaunchScreen.storyboard` itself with a custom storyboard created in Xcode.

113.2.2. Designing a flexible Layout

Keep the launch storyboard simple and static. The layout is rendered before your app code runs, so avoid views that depend on live data or animation. Follow these guidelines when editing `LaunchScreen.storyboard` in Xcode:

- Use Auto Layout constraints and safe-area guides so the design scales to every device, including split view on iPad.
- Prefer system colors or vector/PDF assets for logos so the result stays crisp on high-density screens and supports Dark Mode.
- Reserve text for short taglines or status messages that don't need localization at launch. Dynamic localization isn't available.
- Avoid referencing application delegate outlets or custom classes. Only design-time UIKit elements are supported.

113.2.3. Asset reference

The default storyboard expects PNG assets with the following characteristics. All sizes are specified in points (pt). Supply @2x and @3x variants for Retina displays when possible.

Table 17. Launch Screen Asset Reference

Asset	Purpose	Suggested 1x dimensions	Notes
`Launch.Foreground.png`	Brand mark centered on screen	152×152	Provide optional `Launch.Foreground@2x.png` (304×304) and `Launch.Foreground@3x.png` (456×456) for sharper output. Use transparency to let the background show through.
`Launch.Background.png`	Full-screen backdrop, storyboard only	1024×1024	Supply complementary `Launch.Background@2x.png` (2048×2048) and `Launch.Background@3x.png` (3072×3072) if you rely on artwork instead of a flat color. Keep file sizes small (<2 MB) to avoid slowing startup.
`LaunchScreen.storyboard`	Complete custom layout	N/A	Only used if you declare `UILaunchStoryboardName` through `ios.plistInject`. Enable Auto Layout and include constraints for every view. Avoid timers or code connections.

113.2.4. Testing changes

Changes to the launch screen don't take effect until the device has been restarted. If you install your app on a device, then change the launch screen and update the app, the launch screen won't change until the device is restarted.

When iterating locally with a Mac, open the generated Xcode project and run it on a device or simulator to verify that the layout adapts. On Windows or Linux, submit a TestFlight or Ad-Hoc build and check on hardware before shipping.

113.3. Local notifications on iOS and Android

Local notifications are like push notifications, except that they're initiated locally by the app, rather than remotely. They're useful for communicating information to the user while the app is running in the background, since they manifest themselves as pop-up notifications on supported devices.

To set the notification icon on Android place a 24×24 icon named `ic_stat_notify.png` under `android/src/main/resources`. The icon can be white with transparency areas

113.3.1. Sending notifications

The process for sending a notification is:

1. Create a LocalNotification [https://www.codenameone.com/javadoc/com/codename1/notifications/LocalNotification.html] object with the information you want to send in the notification.
2. Pass the object to `Display.scheduleLocalNotification()`.

Notifications can either be set up as one-time or as repeating.

Example sending notification

On iOS, scheduling a local notification with an `id` that already exists now replaces the earlier scheduled notification with that same `id` instead of keeping duplicates.

The resulting notification will look like

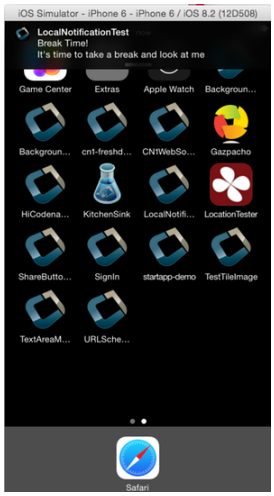

Figure 408. Resulting notification in iOS

113.3.2. Receiving notifications

The API for receiving/handling local notifications is also like push. Your application's main lifecycle class needs to implement the `com.codename1.notifications.LocalNotificationCallback` interface which includes a single method:

```
public void localNotificationReceived(String notificationId) {
}
```

The `notificationId` parameter will match the `id` value of the notification as set using `LocalNotification.setId()`.

Example receiving notification

`localNotificationReceived()` is called when the user responds to the notification by tapping on the alert. If the user doesn't click on the notification, then this event handler will never be fired.

113.3.3. Canceling notifications

Repeating notifications will continue until they're canceled by the app. You can cancel a single notification by calling:

```
Display.getInstance().cancelLocalNotification(notificationId);
```

Where `notificationId` is the string id that was set for the notification using `LocalNotification.setId()`.

113.4. iOS beta testing (testflight)

Apple provides the ability to distribute beta versions of your application to beta testers using testflight. This allows you to recruit up to 1000 beta testers without the typical UDID limits a typical Apple account has.

This is supported for pro users as part of the crash protection feature.

To take advantage of that capability use the build hint `ios.testFlight=true` and then submit the app to the store for beta testing. Make sure to use a release build target.

113.5. Metal renderer

iOS builds render through Metal. The pipeline drives a `CAMetalLayer`; there is no second renderer to choose between, and nothing to configure to get it.

113.6. Choosing a color space for the Metal renderer

The `CAMetalLayer` is configured with the sRGB color space. CG-rasterized images and gradients, which are tagged `DeviceRGB` in their `CGBitmapContext`, are displayed with the brightness their tag implies.

For most apps the default is the right choice. Apps that need a different color profile — for example, wide-gamut artwork that should be displayed in Display P3, or a strictly device-RGB pipeline that matches a custom rendering toolchain — can override the choice with the `ios.metal.colorSpace` build hint:

Value	Effect
sRGB (default)	Sets metalLayer.colorspace to kCGColorSpaceSRGB. Use this unless you have a specific reason not to.
displayP3	Sets metalLayer.colorspace to kCGColorSpaceDisplayP3. Use for wide-gamut content on devices with a P3 display.
deviceRGB	Calls CGColorSpaceCreateDeviceRGB(). Skips sRGB gamma encoding — raw bytes are written to the layer.
linearSRGB	Sets metalLayer.colorspace to kCGColorSpaceLinearSRGB for linear (non-gamma-encoded) sRGB output.
extendedSRGB	Sets metalLayer.colorspace to kCGColorSpaceExtendedSRGB (extended-range sRGB, allows values outside [0,1]).
extendedLinearSRGB	Sets metalLayer.colorspace to kCGColorSpaceExtendedLinearSRGB.
none	Leaves metalLayer.colorspace unset, so Metal uses the system default for the device.

113.7. Accessing insecure URLs

Due to security exploits Apple blocked some access to insecure URLs which means that http code that worked before could stop working for you on iOS 9+. This is a good move, you should use https and avoid http as much as possible but that's sometimes impractical when working with an internal or debug environment.

You can disable the strict URL checks from Apple by using the venerable ios.plistInject build hint and setting it to:

```
<key>NSAppTransportSecurity</key><dict><key>NSAllowsArbitraryLoads</key><true/></dict>
```

For example, it seems that Apple will reject your app if you include that and don't have a good reason.

113.8. Using Cocoapods

CocoaPods remains fully supported, but it's no longer the only supported iOS dependency path. Swift Package Manager (SPM) is also supported. The current guidance is documented in this section.

CocoaPods [https://cocoapods.org/] is a dependency manager for Swift and Objective-C Cocoa projects. It has over eighteen thousand libraries and can help you scale your projects. Cocoapods can be used in your Codename One project to include native iOS libraries without having to go through the hassle of bundling the actual library into your project. Rather than bundling .h and .a files in your ios/src/main/resources directory, you can specify which "pods" your app uses through the ios.pods build hint. (Other build hints also exist if you need more advanced features.)

Examples

Include the AFNetworking [https://github.com/AFNetworking/AFNetworking] library in your app:

```
ios.pods=AFNetworking
```

Include the AFNetworking [https://github.com/AFNetworking/AFNetworking] version 3.0.x library in your app:

```
ios.pods=AFNetworking ~> 3.0
```

For full versioning syntax specifying pods see the Podfile spec for the "pod" directive [https://guides.cocoapods.org/syntax/podfile.html#pod].

113.8.1. Including multiple pods

Multiple pods can be separated by either commas or semi-colons in the value of the `ios.pods` build hint. For example: To include GoogleMaps and AFNetworking, you could:

```
ios.pods=GoogleMaps,AFNetworking
```

Or specifying versions:

```
ios.pods=AFNetworking ~> 3.0,GoogleMaps
```

113.8.2. Other pod related build hints

`ios.pods.platform` : The least platform to target. Sometimes, Cocoapods require functionality that isn't in older version of iOS. For example, the GoogleMaps pod requires iOS 7.0 or higher, so you would need to add the `ios.pods.platform=7.0` build hint.

`ios.pods.sources` : Some pods require that you specify a URL of the source of the pod spec. This may be optional if the spec is hosted in the central CocoaPods source (`https://github.com/CocoaPods/Specs.git`).

113.8.3. Converting PodFile to build hints

Most documentation for Cocoapods "pods" provide instructions on what you need to add to your Xcode project's PodFile. Here is an example from the GoogleMaps cocoapod to show you how a PodFile can be converted into equivalent build hints in a Codename One project.

The GoogleMaps cocoapod directs you to add the following to your PodFile:

```
source 'https://github.com/CocoaPods/Specs.git'
platform :ios, '7.0'
```

```
pod 'GoogleMaps'
```

This would translate to the following build hints in your Codename One project:

```
ios.pods.sources=https://github.com/CocoaPods/Specs.git
ios.pods.platform=7.0
ios.pods=GoogleMaps
```

(Note that the `ios.pods.sources` directive is optional).

113.9. Using Swift package manager

Swift Package Manager can be used as an alternative to CocoaPods for remote Swift package dependencies on iOS. Select the dependency path with `ios.dependencyManager`. Supported values are `auto`, `CocoaPods`, `spm`, and `both`.

For an SPM-only configuration, declare the packages in `ios.spm.packages` using the format `<identity>|<url>|<requirement>` and then declare the products to link using `ios.spm.products.<identity>`.

```
ios.dependencyManager=spm
ios.spm.packages=swift-collections|https://github.com/apple/swift-collections.git|from:1.1.0
ios.spm.products.swift-collections=Collections
```

Supported need formats are `from:`, `exact:`, `branch:`, `revision:`, and `range:`.

`ios.dependencyManager=auto` preserves backward compatibility. Existing projects with `ios.pods` continue to use CocoaPods. Projects with `ios.spm.*` use SPM. If both hint families are present, both are applied.

Explicit dependency-manager modes are validated rather than dropping dependencies. `ios.dependencyManager=spm` fails when the project or a built-in API requires a CocoaPod; use `auto` or `both`. Likewise, `ios.dependencyManager=none` fails while pod or SPM hints are present; remove the dependency hints only if suppression is intentional, or switch to `auto`. This is a migration-visible change for older projects that used `spm` or `none` to ignore declared native dependencies.

113.10. Including dynamic frameworks

If you need to use a dynamic framework (for example: SomeThirdPartySDK.framework), and it isn't available through CocoaPods, then you can add it to your project by zipping up the framework and copying it to `ios/src/main/resources`.

For example: `ios/src/main/resources/SomeThirdPartySDK.framework.zip`

No build hints necessary for this approach. The build server will automatically detect the framework and link it into your app.

Chapter 114. Working with JavaScript

This section covers the Codename One JavaScript port, which allows you to compile your app as native JavaScript and run it inside a browser. This is different from the BrowserComponent [https://www.codenameone.com/javadoc/com/codename1/ui/BrowserComponent.html] and other methods of displaying HTML/JavaScript inside a Codename One app.

114.1. Choosing the JavaScript compiler

JavaScript builds use the ParparVM-based JavaScript port by default. The same builder is available to all Codename One accounts and is also used by the local `local-javascript` Maven target.

Cloud builds retain the original TeaVM port as a public fallback. Select the compiler with the `javascript.port` build hint:

Value	Behavior
`parparvm`	Use the current ParparVM/JavaScriptPort builder. This is the default.
`teavm`	Use the legacy TeaVM builder.

For example, add `javascript.port=teavm` to `codenameone_settings.properties` to diagnose a ParparVM-specific regression. An unknown value fails the build instead of selecting a different compiler.

114.2. Troubleshooting build errors

If your JavaScript build fails, download the error log and inspect the first compiler error. The following error applies specifically to the fallback TeaVM builder:

"Method XXX wasn't found"

TeaVM uses its own Java runtime library. It's complete, but you may occasionally run into methods that haven't been implemented. If you run into errors saying that certain classes or methods weren't found, please post them to the Codename One issue tracker [https://github.com/codenameone/CodenameOne/issues]. You can also work around these by changing your own code to not use such functions. If this missing method doesn't fall on a critical path on your app, you can also force the app to still build despite this error by adding the `javascript.stopOnErrors=false` build hint.

114.3. ZIP, WAR, or preview: What's the difference

The default ParparVM builder produces a static browser ZIP and, unless proxy packaging is disabled or an external proxy is configured, a deployable proxy bundle. The deployable bundle is a Jakarta Servlet WAR by default. Use `javascript.proxy.target` to select another deployment platform as described in Section 114.4, "Setting up a proxy for network requests".

The legacy TeaVM builder can result in up to three different bundles:

1. YourApp-1.0.war

2. YourApp-1.0.zip
3. YourApp-1.0-Preview.html

YourApp-1.0.war is the legacy TeaVM self-contained application bundle. It can be installed in a Java EE servlet container and includes the old `javax.servlet` proxy implementation. New ParparVM builds use the current proxy profiles below and default to Jakarta Servlet.

As an example, the `PropertyCross.war` file contains the following files:

```
$ jar tvf PropertyCross-1.0.war
     0 Thu Apr 30 15:57:38 PDT 2015 META-INF/
   132 Thu Apr 30 15:57:36 PDT 2015 META-INF/MANIFEST.MF
     0 Thu Apr 30 15:57:36 PDT 2015 assets/
     0 Thu Apr 30 15:57:36 PDT 2015 assets/META-INF/
     0 Thu Apr 30 15:57:36 PDT 2015 js/
     0 Thu Apr 30 15:57:36 PDT 2015 teavm/
     0 Thu Apr 30 15:57:36 PDT 2015 WEB-INF/
     0 Thu Apr 30 15:57:36 PDT 2015 WEB-INF/classes/
     0 Thu Apr 30 15:57:36 PDT 2015 WEB-INF/classes/com/
     0 Thu Apr 30 15:57:36 PDT 2015 WEB-INF/classes/com/codename1/
     0 Thu Apr 30 15:57:36 PDT 2015 WEB-INF/classes/com/codename1/corsproxy/
     0 Thu Apr 30 15:57:36 PDT 2015 WEB-INF/lib/
 27568 Thu Apr 30 15:57:12 PDT 2015 assets/CN1Resource.res
306312 Thu Apr 30 15:57:12 PDT 2015 assets/iOS7Theme.res
427737 Thu Apr 30 15:57:12 PDT 2015 assets/iPhoneTheme.res
   350 Thu Apr 30 15:57:12 PDT 2015 assets/META-INF/MANIFEST.MF
 92671 Thu Apr 30 15:57:12 PDT 2015 assets/theme.res
 23549 Thu Apr 30 15:57:14 PDT 2015 icon.png
  2976 Thu Apr 30 15:57:14 PDT 2015 index.html

   903 Thu Apr 30 15:57:12 PDT 2015 WEB-INF/web.xml
  9458 Thu Apr 30 15:57:14 PDT 2015 META-INF/maven/com.propertycross/PropertyCross/pom.xml
   113 Thu Apr 30 15:57:36 PDT 2015 META-INF/maven/com.propertycross/PropertyCross/pom.properties
```

Some things to note in this file listing:

1. The **index.html** file is the entry point to the application.
2. `CORSProxy.class` is the proxy servlet for making network requests to other domains.
3. The **assets** directory contains all your application's **jar** resources. All resource files in your app

will end up in this directory.

4. The `teavm` directory contains all the generated JavaScript for your application. Notice that there are some debugging files generated (**classes.js.map** and **classes.js.teavmdbg**). These aren't loaded by the browser when your app is run, but they can be used by Chrome when you're doing debugging.
5. The **jar** files in the **WEB-INF/lib** directory are dependencies of the proxy servlet. They aren't required for your app to run - unless you're using the proxy.

YourApp-1.0.zip is appropriate for deploying the application on any web server. It contains all the same files as the `.war` file, excluding the WEB-INF directory (that is, it doesn't include any servlets, class files, or Java libraries - it contains purely client-side JavaScript files and HTML).

As an example, this is a listing of the files in the zip distribution of the PropertyCross demo:

```
$ unzip -vl PropertyCross-1.0.zip
Archive:  /path/to/PropertyCross-1.0.zip
 Length   Method    Size  Ratio   Date   Time   CRC-32    Name

```

You'll notice that it has many of the same files as the `.war` distribution. It's missing the proxy servlet and dependencies.

YourApp-1.0-Preview.html is a single-page HTML file with all the application's resources embedded into a single page. This is generated for convenience so that you can preview your application on the build server directly. While you could use this file in production, you're probably better to use the ZIP or WAR distribution instead as some mobile devices have file size limitations that may cause problems for the "one large single file" approach. If you do decide to use this file for your production app (that is, copy the file to your own web server), you will need to change the proxy settings, as it's configured to use the proxy on the Codename One build server - which won't be available when the app is hosted on a different server.

114.4. Setting up a proxy for network requests

The Codename One API includes a network layer (the NetworkManager [https://www.codenameone.com/javadoc/com/codename1/io/NetworkManager.html] and ConnectionRequest [https://www.codenameone.com/javadoc/com/codename1/io/ConnectionRequest.html] classes) that allows you to make HTTP requests to arbitrary destinations. When an application is running inside a browser as a JavaScript app, it's constrained by the same origin policy. You can make network requests to the same host that served the app originally.

For example, If your application is hosted at http://example.com/myapp/index.html, then your app will be able to perform network requests to retrieve other resources under the **example.com** domain, but it won't be able to retrieve resources from **example2.com**, **foo.net**, etc.

The HTTP standard does support cross-origin requests in the browser via the `Access-Control-Allow-Origin` HTTP header. Some web services supply this header when serving resources, but not all. The way to be make network requests to arbitrary resources is to do it through a proxy.

In the browser a request runs as one synchronous `XMLHttpRequest`, which reports no progress until it ends. The connection and read timeouts of a `ConnectionRequest` therefore bound the whole request: their sum is a deadline, not an idle limit, so a long download needs a timeout that covers the whole transfer.

A ParparVM JavaScript build generates a same-origin proxy wrapper by default and configures the application to use `/cn1-cors-proxy?_target=`. Select its platform with the `javascript.proxy.target` build hint:

Value	Generated deployment bundle
`jakarta-servlet`	A Jakarta Servlet WAR for current containers such as Tomcat 10.1 or newer. This is the default.
`javax-servlet`	A Servlet 4 WAR for older containers such as Tomcat 9.
`node`	A Node.js 20 application ZIP that serves both the static app and the proxy.
`php`	A PHP 8 application ZIP containing the static app, proxy endpoint, and Apache rewrite configuration.
`aws-lambda`	An AWS SAM/Node.js 20 proxy ZIP. Static assets are included under `public/` for deployment to your static host.
`google-cloud-functions`	A Google Cloud Functions/Node.js 20 proxy ZIP. Static assets are included under `public/`.
`cloudflare-workers`	A Cloudflare Worker ZIP with a static-assets binding.
`none`	Don't generate a proxy deployment bundle.

Restrict a generated proxy before deploying it publicly. Set `javascript.proxy.allowedTargets` to a comma-separated list of allowed origins, host names, or wildcard subdomains. For example:

```
javascript.proxy.allowedTargets=https://api.example.com,*.services.example.org
```

If this hint is omitted, the generated proxy accepts any HTTP or HTTPS target and the build emits a warning.

Proxy hint precedence is explicit:

1. `javascript.inject_proxy=false` disables proxy generation and URL injection.
2. `javascript.proxy.url` configures an existing external proxy and suppresses generated proxy packaging unless `javascript.proxy.target` is also set.
3. `javascript.proxy.target=none` disables generated proxy packaging.
4. Otherwise, `javascript.proxy.target` selects the bundle, defaulting to `jakarta-servlet`.

114.4.1. Step 1: Setting up a proxy

You can skip this step when deploying one of the generated ParparVM wrappers. Use it when you host only the static ZIP or want to operate the proxy independently.

For a ParparVM build, select the matching generated wrapper with `javascript.proxy.target`. The old cors-proxy [https://github.com/shannah/cors-proxy] project remains relevant only to legacy TeaVM WARs and older Java EE deployments.

If you don't want to install the `.war` file, but would rather copy the proxy servlet into an existing web project, you can do that also. See the cors-proxy wiki for more information about this [https://github.com/shannah/cors-proxy/wiki/Embedding-Servlet-into-Existing-Project].

114.4.2. Step 2: Configuring your application to use the proxy

There are three ways to configure your application to use your proxy.

1. Using the **javascript.proxy.url** build hint.

   E.g.:

   ```
   javascript.proxy.url=http://example.com/myapp/cn1-cors-proxy?_target=
   ```

2. By modifying your app's **index.html** file after the build.

   E.g.:

   ```
   <script type="text/javascript">
       window.cn1CORSProxyURL='http://example.com/myapp/cn1-cors-proxy?_target=';
   </script>
   ```

3. By setting the `javascript.proxy.url` property in your Java source. You would do this inside your `init()` method, but it has to be executed before you make a network request that requires the proxy.

```
Display.getInstance().setProperty(
        "javascript.proxy.url",
        "http://example.com/myapp/cn1-cors-proxy?_target="
);
```

The method you choose will depend on the workflow that you prefer. Options #1 and #3 will almost always result in fewer changes than #2 because you've to set them up once, and the builds will retain the settings each time you build your project.

114.5. Using the CORS proxy for same origin requests

By default, the CORS proxy is used for HTTP requests to URLS at a different domain than the one that the app is running in. Some circumstances where you may want to **even** use the proxy for same domain requests. You can do this by setting the `javascript.useProxyForSameDomain` display property to `true`. For example:

```
Display.getInstance().setProperty("javascript.useProxyForSameDomain", "true");
```

Why would you want to do this?

The browser shields some HTTP headers (for example, "Set-Cookie") from JavaScript so that your app can't access them. Going through the proxy works around this limitation by copying and encoding such headers in a format that the browser will allow, and then decoding them client-side to make them available to your app seamlessly.

114.5.1. Using apache as a proxy

If you're hosting your application on an Apache 2 web server with mod_proxy installed, and you need to make CORS requests to a single domain (or a limited set of domains), you can use Apache to serve as your proxy. One sample configuration (which you would place either in your `VirtualHost` definition or your `.htaccess` file is as follows:

```
SSLProxyEngine on
ProxyPass /app https://www.myexternaldomain.com
ProxyPassReverse /app https://www.myexternaldomain.com
```

This tells Apache to proxy all requests for '/app' to the domain https://www.myexternaldomain.com. You would then need to set your CORS proxy URL in your CN1 app to `/app/`.

The syntax is the same if you've multiple domains, but keep attention to the order of the lines to make the proxy working. For example:

```
SSLProxyEngine on
ProxyPass /app https://www.myexternaldomain1.com
ProxyPassReverse /app https://www.myexternaldomain1.com
ProxyPass /storage https://www.myexternaldomain2.com
ProxyPassReverse /storage https://www.myexternaldomain2.com
```

This tells Apache to proxy all requests for '/app' to the domain https://www.myexternaldomain1.com and all requests for '/storage' to the domain https://www.myexternaldomain2.com

114.6. Customizing the splash screen

While the application downloads and starts, the page shows a loading screen: the app icon, an animated progress bar and a "Loading" label. It stays up until the first form is shown.

Build hints set its look, so the settings survive every build instead of being edited into each generated bundle:

Build hint	Default	Meaning
`javascript.splash.appearance`	`auto` once any dark color is set, otherwise `light`	`auto` follows the browser's light/dark preference. `light` or `dark` always uses that set of colors, for an app with a single appearance. An app that sets none of these hints keeps a light loading screen, so a light app never opens dark.
`javascript.splash.background`, `javascript.splash.textColor`, `javascript.splash.accentColor`	`#ffffff`, `#666666`, `#0072ff`	The page background, the label and the progress bar in the light appearance.
`javascript.splash.darkBackground`, `javascript.splash.darkTextColor`, `javascript.splash.darkAccentColor`	`#121212`, `#b3b3b3`, `#4da3ff`	The same three in the dark appearance.
`javascript.splash.logo`	The app icon	A different image, as a path relative to the bundle's `index.html`, or `none` for no image.

Colors are hex values (`#rgb`, `#rrggbb`, with optional alpha) or CSS color names. The page applies them before it paints anything, and keeps the background until the first form is shown, so a dark app no longer opens on a white page.

An app that lets the user choose its own appearance can have the next launch's loading screen match that choice, even when it differs from the browser's preference:

```
CN.setProperty("platformHint.javascript.splashAppearance", "dark"); // or "light"
```

```
CN.setProperty("platformHint.javascript.splashAppearance", null);   // follow the browser again
```

The choice is kept in the browser's local storage and applies only in `auto` mode.

For anything the hints don't cover, the markup is the `cn1-splash` `div` in the generated `index.html`; edit it there if you host the bundle yourself.

114.7. Blocking code and performance

The browser has one thread per page, so Codename One runs your threads as green threads inside a web worker. A Java method that can wait — `Object.wait()`, `Thread.sleep()`, `invokeAndBlock()`, a modal `Dialog`, or a call that waits for the browser to answer — is compiled to a JavaScript generator, which can pause and resume. Every method that can reach such a method is compiled to a generator too, through any direct call, and through any interface or virtual call whose target could be one. Code you never meant to block pays the cost: a call to a generator is several times slower than a call to a plain function.

The build writes `*-js-suspension-report.txt` beside the bundle. It lists every method compiled as a generator, with the reason, and the called methods that make the most of them.

The `@JavaScriptDetached` annotation in `com.codename1.annotations` stops that spread at a method boundary. Every other platform ignores it.

Put it on a `void` method whose callers don't wait for the work it starts. On the web the method runs as a plain function until it would block; the rest of it then continues on its own green thread, and the caller returns. `Display.callSerially` carries it, so a component that schedules work on the EDT is no longer a generator because of it.

It changes nothing a caller observes on any other platform. On the web, use it only where the method's contract already says the caller doesn't wait for the result.

114.8. Debugging

If you run into problems with your app that occur in the JavaScript version, you may need to do a little bit of debugging. Many debugging tools for JavaScript, but the preferred tool for debugging Codename One apps is Chrome's debugger.

If your application crashes and you don't have a clue where to begin, follow these steps:

1. Load your application in Chrome.
2. Open the Chrome debugger.
3. Enable the "Pause on Exceptions" feature, then click the "Refresh" button to reload your app.
4. Step through each exception until you reach the one you're interested in. Chrome will then show you a stack trace that includes the name of the Java source file and line numbers.

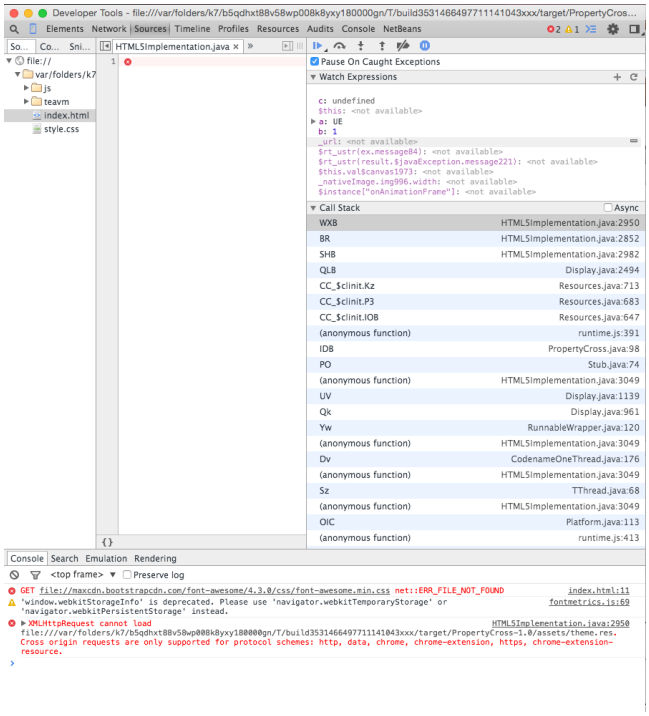

Figure 409. Debugging using Chrome tools

114.9. Profiling

Chrome's profiler samples the call stack while your app runs, so it doesn't change the code it measures:

1. Open the app in Chrome, open DevTools and select the **Performance** tab.
2. Set **CPU** to a 4x slowdown to get closer to a phone, then press **Record**.
3. Do the slow thing in the app, then stop the recording.
4. Open **Bottom-Up** and sort by **Self Time**. The functions at the top are where the time goes.

To record one section only, wrap it in `console.profile("name")` and `console.profileEnd("name")` from a native interface.

The build shortens every translated function name to keep the bundle small, so the profile shows names like `$Mbqx`. It writes the mapping to a file that ends in `-js-symbols.txt`, never into the website itself. A local Maven or Gradle build copies it into the build directory as `MyAppJavaScriptMain-js-symbols.txt`, named after your main class, and a cloud build delivers it as `symbols.txt` in the separate build artifacts zip. Each line holds a short name, a tab, and the full name, which spells out the Java package, class, method and signature: `cn1_com_mycompany_Board_copyBoard_int`.

To restore the names, save the profile from the **Performance** tab (the download button) and run `deobfuscate-javascript-profile.py` [https://github.com/codenameone/CodenameOne/blob/master/scripts/deobfuscate-javascript-profile.py] over it:

```
python3 deobfuscate-javascript-profile.py MyAppJavaScriptMain-js-symbols.txt Trace.json > Trace-named.json
```

Load `Trace-named.json` back into the **Performance** tab. A few functions keep their full names in

every build, such as constructors and static initializers, so a profile shows both forms. The same command works on a stack trace pasted into a text file. Use the map from the build you profiled: every build assigns the short names again, and the script warns when a name isn't in the map.

114.10. Including Third-Party JavaScript libraries

Codename One allows you to interact directly with JavaScript using native interfaces. Native interfaces are placed inside your project's `native/JavaScript` directory using a prescribed naming convention. If you want to, include third-party JavaScript libraries in your application you should also place these libraries inside the `native/JavaScript` directory but you must specify which files should be treated as "libraries" and which files are treated as "resources." You can do this by adding a file with extension `.cn1mf.json` file either the root of your `native/JavaScript` directory or the root level of the project's `src` directory.

114.10.1. Libraries vs resources

A **resource** is a file whose contents can be loaded by your application at runtime using `Display.getInstance().getResourceAsStream()`. In a typical Java environment, resources would be stored on the application's classpath (usually inside a Jar file). On iOS, resources are packaged inside the application bundle. In the JavaScript port, resources are stored inside the `APP_ROOT/assets` directory. Historically, JavaScript files have always been treated as resources in Codename One, and many apps include HTML and JavaScript files for use inside the BrowserComponent [https://www.codenameone.com/javadoc/com/codename1/ui/BrowserComponent.html].

With the JavaScript port, it isn't quite so clear whether a JavaScript file is meant to be a resource or a library that the application itself uses. Most of the time you probably want JavaScript files to be used as libraries, but you might also have JavaScript files in your app that are meant to be loaded at runtime and displayed inside a Web View - these would be considered resources.

114.10.2. The JavaScript manifest file

To differentiate libraries from resources, you should provide a **cn1mf.json** file inside your `native/JavaScript` directory that specifies any files or directories that should be treated as libraries. This file can be named anything you like, as long as its name ends with `cn1mf.json`. Any files or directories that you list in this manifest file will be packaged inside your app's `includes` directory instead of the `assets` directory. It adds appropriate `<script>` tags to include your libraries as part of the `index.html` page of your app.

If you include the `cn1mf.json` file in your project's `src` directory it could be used to add configuration parameters to platform's other than JavaScript (although no other platforms use this feature). If you place it inside your `native/JavaScript` directory, then the JavaScript port will use the configuration contained therein.

A simple manifest file might contain the following JSON:

```
{
    "javascript" : {
        "libs" : [
```

```
            "mylib1.js"
        ]
    }
}
```

That is, It contains an object with key **libs** whose value is a list of files that should be treated as libraries. In the above example, you're declaring that the file `native/JavaScript/mylib1.js` should be treated as a library. This will result in the following `<script>` tag being added to the `index.html` file:

```
<script src="includes/mylib1.js"></script>
```

This also caused the `mylib1.js` file to be packaged inside the `includes` directory instead of the `assets` directory.

A project may contain more than one manifest file. This allows you to include manifest files with your cn1libs also. You need to make sure that each manifest file has a different name.

How to NOT generate the `script` tag

Sometimes you may want a JavaScript file to be treated as a library (that is, packaged in the `includes` directory) but not automatically included in the `index.html` page. Rather than specifying the name of the file in the `libs` list, you can provide a structure with multiple options about the file. For example,

```
{
    "JavaScript" : {
        "libs" : [
            "mylib1.js",
            {
                "file" : "mylib2.js",
                "include" : false
            }
        ]
    }
}
```

In the above example, the `mylib2.js` file will be packaged inside the `includes` directory, but the build server won't insert its `<script>` tag in the `index.html` page.

Library directories

You can also specify directories in the manifest file. In this case, the entire directory will be packaged inside the `includes` directory of your app.

If you're including JavaScript files in your app that are contained inside a

> directory hierarchy, you should specify the root directory of the hierarchy in your manifest file and use the sub "includes" property of the directory entry to specify which files should be included with `<script>` tags. Specifying the file directly inside the "libs" list will result in the file being packed directly in the your app's `includes` directory. This may or may not be what you want.

For example,

```
{
    "javascript" : {
        "libs" : [
            "mylib1.js",
            {
                "file" : "mylib2.js",
                "include" : false
            },
            {
                "file" : "mydir1",
                "includes" : ["subfile1.js", "subfile2.js"]
            }
        ]
    }
}
```

In this example the entire `mydir1` directory would be packed inside the app's `includes` directory, and the following `script` tags would be inserted into the `index.html` file:

```
<script src="includes/mydir1/subfile1.js"></script>
<script src="includes/mydir1/subfile2.js"></script>
```

> Libraries included from a directory hierarchy may not work with the single file preview that the build server generates. For that version, it will embed the contents of each included JavaScript file inside the `index.html` file, but the rest of the directory contents will be omitted. If your the library depends on the directory hierarchy and supporting files and you require the single-file preview to work, then you may consider hosting the library on a separate server, and including the library directly from there, rather than embedding it inside your project's "native/JavaScript" directory.

Including remote libraries

The examples so far have demonstrated the inclusion of libraries that are part of the app bundle. But, you can also include libraries over the network by specifying the URL to the library directly. This is handy for including common libraries that are hosted by a CDN.

For example, The Google Maps library requires the Google Maps API to be included. This is accomplished with the following manifest file contents:

```
{
    "javascript" : {
        "libs" : [
            "//maps.googleapis.com/maps/api/js?v=3.exp"
        ]
    }
}
```

This example uses the "//" prefix for the URL instead of specifying the protocol directly. This allow the library to work for both http and https hosting. You could but specify the protocol as well:

+

```
{
    "javascript" : {
        "libs" : [
            "https://maps.googleapis.com/maps/api/js?v=3.exp"
        ]
    }
}
```

Including CSS files

CSS files can be included using the same mechanism as is used for JavaScript files. If the file name ends with `.css`, then it will be treated as a CSS file (and included with a `<link>` tag instead of a `<script>` tag. For example,

```
{
    "JavaScript" : {
        "libs" : [
            "mystyles.css"
        ]
    }
}
```

or

```
{
    "JavaScript" : {
        "libs" : [
            "https://example.com/mystyles.css"
        ]
    }
}
```

Embedding variables in URLs

Sometimes the URL of a library may depend on the values of some build hints in the project. For example, in the Google Maps cn1lib, the API key must be appended to the URL of the API as a GET parameter. For example, `https://maps.googleapis.com/maps/api/js?v=3.exp&key=SOME_API_KEY`, but the developer of the library doesn't want to put his own API key in the manifest file for the library. It would be better for the API key to be supplied by the developer of the actual app that uses the library and not the library itself.

The solution for this is to add a **variable** into the URL as follows:

```
{
    "JavaScript" : {
        "libs" : [
            "//maps.googleapis.com/maps/api/js?v=3.exp&key={{javascript.googlemaps.key}}"
        ]
    }
}
```

The `{{javascript.googlemaps.key}}` variable will be replaced with the value of the `javascript.googlemaps.key` build hint by the build server, so the resulting include you see in the index.html page will be something like:

```
<script src="//maps.googleapis.com/maps/api/js?v=3.exp&key=XYZ"></script>
```

114.11. Browser environment variables

Native interfaces allow you to interact with the JavaScript environment in unlimited ways, but Codename One provides a simpler method of obtaining some common environment information from the browser via the `Display.getInstance().getProperty()` method. The following environment variables are currently available:

Table 18. Property hints for the JavaScript port

Name	Description
`browser.window.location.href`	A String, representing the entire URL of the page, including the protocol (like http://)
`browser.window.location.search`	A String, representing the querystring part of a URL, including the question mark (?)
`browser.window.location.host`	A String, representing the domain name and port number, or the IP address of a URL
`browser.window.location.hash`	A String, representing the anchor part of the URL, including the hash sign (#)

Name	Description
`browser.window.location.origin`	A String, representing the protocol (including ://), the domain name (or IP address) and port number (including the colon sign (:) of the URL. For URLs using the "file:" protocol, the return value differs between browsers
`browser.window.location.pathname`	A String, representing the pathname
`browser.window.location.protocol`	A String, representing the protocol of the current URL, including the colon (:)
`browser.window.location.port`	A String, representing the port number of a URL. + Note: If the port number isn't specified or if it's the scheme's default port (like 80 or 443), an empty string is returned
`browser.window.location.hostname`	A String, representing the domain name, or the IP address of a URL
`User-Agent`	The User-agent string identifying the browser, version etc.
`browser.language`	The language code that the browser is currently set to. (for example, en-US)
`browser.name`	the name of the browser as a string.
`Platform`	a string that must be an empty string or a string representing the platform on which the browser is executing. + For example: `MacIntel`, `Win32`, `FreeBSD i386`, "WebTV OS"
`browser.codeName`	the internal name of the browser
`browser.version`	the version number of the browser
`javascript.deployment.type`	Specifies the deployment type of the app. This will be "file" for the single-file preview, "directory" for the zip distribution, and "war" for the war distribution.

114.12. Changing the native theme

The JavaScript port picks a native theme from the build hints and the browser it runs in. The shared `nativeTheme` hint, and the per-platform `ios.themeMode` and `and.themeMode` hints, apply here as they do on a device:

- Unset, an Android browser gets the Holo Light theme and every other browser the iOS 7 theme.
- `nativeTheme=modern` gives iOS and Mac browsers the Liquid Glass theme and every other browser Material 3.
- `nativeTheme=native` does the same on phones and tablets, and gives a desktop browser the desktop theme of its operating system: Windows 11 Fluent, macOS Aqua, or GNOME Adwaita for

Linux and everything else. An iPad counts as a tablet even though it reports a Mac browser.

Two JavaScript hints refine that:

Hint	Values	Description

`javascript.desktopTheme`	`auto` (default)
	`fluent` / `aqua` / `adwaita`
	`none`
		`auto` follows the operating system as described above. Naming a theme gives every desktop browser that theme, whatever it runs on. `none` keeps the mobile themes on the desktop too.

`javascript.native.theme`	a resource path, such as `/WindowsFluentTheme.res`	Loads this theme in every browser, instead of the one the hints and the browser would pick. Place JavaScript-only themes in `javascript/src/main/resources` so they aren't bundled into other platforms.

The build ships only the themes the application can reach. Pinning a desktop theme, or leaving the desktop themes out, keeps the others out of the bundle. A theme your own code opens by name, such as `Resources.open("/GnomeAdwaitaTheme.res")`, is always kept. If your code builds the name at runtime, for example from its configuration, set `javascript.pruneThemes=false` to ship every theme.

114.12.1. Title bar and menu bar on the desktop

A desktop native theme expects the operating system to own the window title and the menu bar. The native desktop ports hide the Toolbar and hand the form title to the window and the commands to the system menu bar. A web page has neither, so the `javascript.titleBar` build hint decides what stands in for them:

- `toolbar` (default) keeps the Toolbar inside the app, styled by the desktop theme, with its hamburger side menu and overflow menu.
- `html` draws a title bar and a menu bar in the page, above the app. The title bar shows the current form's title, and the menu bar lists every Toolbar command, grouped into menus by `Command.setDesktopMenu()` exactly as the native Windows menu bar groups them. A command with no menu hint goes into a **Commands** menu. The bars follow the operating system's look and the browser's light or dark preference. There are no minimize, maximize or close buttons, because a page can't do any of those to the browser window.

The browser tab title is the application's display name in both modes.

114.13. Page settings

The generated `index.html` sets up the page for the application:

- The page title is the application's display name, `codename1.displayName`.
- A `viewport` meta tag gives mobile browsers the device's width, so the app starts at the phone's own scale rather than as a shrunken desktop page. The tag doesn't forbid scaling, so browser and accessibility zoom still work, but touch gestures over the app go to the app, including two-finger ones, so the page itself doesn't pinch-zoom.

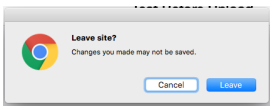
- Browser translation is off: the page carries `<meta name="google" content="notranslate">` and `translate="no"`. The app draws its own text, and a browser translating the page under it, or loading it through a translation site, breaks it. Set `javascript.allowBrowserTranslation=true` to let the browser offer translation.
- The page carries `<meta name="darkreader-lock">`, which asks the Dark Reader extension to leave the app's own colors alone. Dark Reader honors it in its default Dynamic mode only; its Filter, Filter+ and Static modes ignore it. Set `javascript.darkreaderLock=false` to omit it.

114.14. Selecting and copying text

The app's text is present in the page, so find-in-page matches it and assistive technology reads it. Selecting it with the mouse isn't available by default, because the app itself receives every press and drag.

Set the `javascript.textSelection=true` build hint to enable browser-native selection for labels, span labels and text areas. Eligible text areas use a persistent native input or textarea, including before focus, so the first drag or right click works. Use the browser's word/paragraph selection gestures, context menu and copy shortcut; on touch screens, long-press to select or swipe to scroll. Buttons, custom `Label` subclasses (including sliders), draggable components, password fields, text inside a lead component such as a `MultiButton`, and components with application pointer or action listeners retain their existing interaction.

The hint also calls `TextSelection.setDefaultSelectable(true)` and enables `Form.getTextSelection()` for canvas text that can't use the DOM layer. An individual read-only component still decides for itself with `setTextSelectionEnabled()`. Editable native controls retain their normal browser editing selection.



Customize the highlight in the generated application's CSS with the stable `.cn1-native-selection::selection` selector, or override its color variables:

```
<style>
:root {
    --cn1-selection-color: #ffffff;
    --cn1-selection-background: #1967d2;
}
</style>
```

Choose contrasting foreground and background colors. The browser owns selection handles and native context-menu appearance.

114.15. Disabling the 'OnBeforeUnload' handler

By default, apps will display warning/confirm dialog when the user attempts to leave the page.

You can explicitly enable or disable this behaviour by setting the "platformHint.javascript.beforeUnloadMessage" display property. Setting the property to `null` will disable this behaviour, so that users won't be harassed by this dialog when they navigate away from the app. Setting it to a string value, like "leaving so soon?," will re-enable this behaviour.

Some browsers don't allow you to specify the message that's displayed in this dialog. In those browsers, this property can be viewed as boolean: A null value will result in no prompt being shown, and a non-null value will result in a prompt being shown.

114.15.1. Example: Toggling the BeforeUnload prompt On/Off

```
Form f = new Form("Test Before Unload", BoxLayout.y());
CheckBox enableBeforeUnload = new CheckBox("Enable Before Unload");
enableBeforeUnload.setSelected(true);
enableBeforeUnload.addActionListener(e->{
    if (enableBeforeUnload.isSelected()) {
        CN.setProperty("platformHint.javascript.beforeUnloadMessage", "Are you sure you want to leave this page?  It
might be bad");
    } else {
        CN.setProperty("platformHint.javascript.beforeUnloadMessage", null);
    }
});
f.add(enableBeforeUnload);
f.show();
```

114.16. Deploying as a progressive web app

JavaScript application builds include the files needed for progressive web app (PWA) installation. Users can open the app in a browser and install it on browsers that support installation. The default manifest requests a standalone window without browser navigation controls. Offline launch becomes available after the service worker finishes caching the application files; network-dependent features still require a connection.

Below is a screenshot from Chrome for Android where the browser is prompting the user to add the app to their home screen.

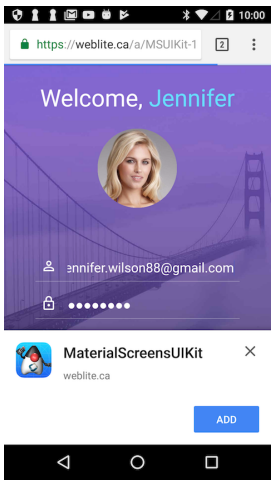


Figure 410. Add app to homescreen banner

If the app is available as a native app, in the Play store, you can indicate this using the `javascript.manifest.related_applications` and `javascript.manifest.prefer_related_applications` build hints. Then, instead of prompting the user to add the web app to their home screen, they'll be prompted to install the native app from the Play store, as shown below.

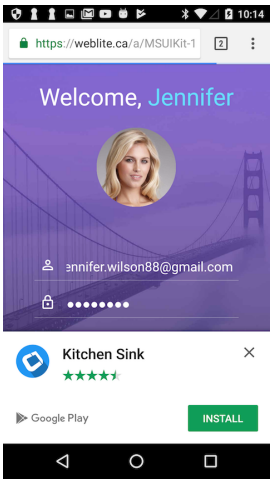

Figure 411. Add native app banner

Host the app over HTTPS. For local testing, browsers also allow service workers on `localhost`. In Chrome DevTools, use the `Application` panel to inspect the manifest, icons, service-worker status and cache contents, then test an offline reload.

For more information about Progressive Web Apps see Google's introduction to the subject [https://developers.google.com/web/progressive-web-apps/].

114.16.1. Customizing the app manifest file

At the heart of a progressive web app is the web app manifest [https://developer.mozilla.org/en-US/docs/Web/Manifest]. It specifies things like the app's name, icons, description, preferred orientation, display mode (for example, whether to display browser navigation or to open with the full screen like a native app), associated native apps, etc. The Codename One build server will automatically generate a manifest file for your app but you can (and should) customize this file via build hints.

Build hints of the form `javascript.manifest.XXX` will be injected into the app manifest. For example, To set the app's description, you could add the build hint:

```
javascript.manifest.description=An app for doing cool stuff
```

You can find a full list of available manifest keys here [https://developer.mozilla.org/en-US/docs/Web/Manifest]. The build server will automatically generate all the icons so you don't need to worry about those. The "name" and "short_name" properties will default to the app's display name, but they can be overridden via the `javascript.manifest.name` and `javascript.manifest.short_name` build hints respectively.

The `javascript.manifest.related_applications` build hint expects a JSON formatted list, like in the raw manifest file.

114.16.2. Offline use and updates

ParparVM JavaScript application builds generate `manifest.json`, home-screen icons, and `sw.js` automatically. No PWA enablement hint is required. Deploy the complete bundle over HTTPS (or localhost for testing), including its subdirectories. Relative manifest and asset URLs allow deployment under a path such as `/cn1test/`.

The service worker caches the generated application files, including the runtime, translated JavaScript chunks, themes and bundled resources. Wait for its first installation to finish while online before testing offline launch. API responses, proxy requests and external resources aren't included; application features that need those services still require a connection.

A content change creates a new cache even when the application version is unchanged. An update waits until the previous app's tabs/windows close before activating, so a running app doesn't mix runtime and resource versions. Each deployment path has its own cache. Allow browsers to revalidate `sw.js` and deploy the files together.

114.16.3. Related applications

One nice feature (discussed above) of progressive web apps, is the ability to specify related applications in the app manifest. Browsers that support the PWA standard use some heuristics to "offer" the user to install the associated native app when it's clear that the user is using the app on a regular basis. Use the `javascript.manifest.related_applications` build hint to specify the location of the native version of your app. For example, `javascript.manifest.related_applications=[{"platform":"play", "id":"my.app.id"}]`

You can declare that the native app is the preferred way to use the app by setting the `javascript.manifest.prefer_related_applications` build hint to "true."

According to the app manifest documentation [https://developer.mozilla.org/en-US/docs/Web/Manifest], this should be used if the related native apps do offer something that the web application can't do.

114.16.4. Device/Browser support for PWAs

Installation controls vary by browser. Chrome on Android and Chromium browsers on desktop can install a web app from its manifest. On iOS and iPadOS, use Safari's Share menu and choose `Add to Home Screen`. Home Screen web apps support offline service workers; Web Push is available starting with iOS and iPadOS 16.4 [https://webkit.org/blog/13878/web-push-for-web-apps-on-ios-and-ipados/]. Browser support doesn't by itself configure an application's push provider or permissions.

On the desktop, Chrome provides an analogous feature to "add to your homescreen": `Add to shelf`. If it looks like the user is using the app on a regular basis, and it isn't yet installed, it will show a banner at the top of the page asking the user if they want to add to their shelf.

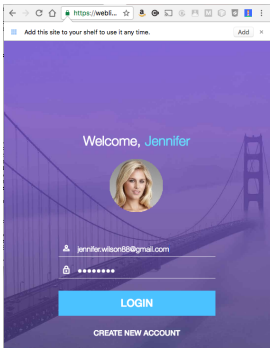

Figure 412. Add to shelf banner

Clicking the "Add button" prompts the user for the name they wish the app to appear as:

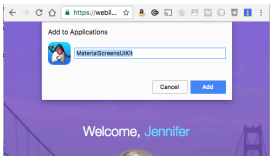

Figure 413. Add to shelf prompt

Upon submission, Chrome will generate a real application (on Mac, it will be a `.app`, on Windows, an "exe," etc.) which the user can double-click to open the app directly in the Chrome. And, importantly, the app will still work when the user is offline.

The app will also appear in their "Shelf" which you can always access at `chrome://apps`, or by opening the "Chrome App Launcher" app (on OS X this is located in "~/Applications/Chrome Apps/Application Launcher").

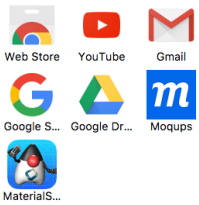

Figure 414. Chrome App Launcher

The Chrome App Launcher lists apps installed both via the Chrome Web Store and via the "Add to Shelf" feature discussed here. The features described in this article are orthogonal to the Chrome Web Store and won't be affected by its closure.

114.17. Playing media and opening links

People don't like it when the browser automatically starts playing sounds, or opening links without their permission. For this reason, modern browsers restrict your ability to programmatically do these things, unless they're in response to a user action, like a mouse click.

If your app needs to play media (for example, `Media.play()`) without the user actually interacting physically (for example, key press or pointer press), then it will display a popup dialog confirming that the user actually wants to perform this action. Opening a link (for example, `Display.execute("…")`) used to do the same, but now defaults to navigating the current page instead

of prompting — see Opening links below.

Sometimes this dialog may affect the utility of the app. For example, suppose you want to play a video in response to a voice command. Having to press an "OK" button after the command, may be annoying. For such cases, you can use the `platformHint.javascript.backsideHooksInterval` property to **poll** for media play requests on an authorized event.

For example:

```
CN.setProperty("platformHint.javascript.backsideHooksInterval", "1000");

// Now your app will process media.play() and Display.execute(null) calls
// once per second (1000ms). If play() or execute() has been called anytime
// in that second (since the last poll), it will seamlessly process the
// request.

// To disable polling, just set it to an interval 0 or lower.
// for example, CN.setProperty("platformHint.javascript.backsideHooksInterval", "0");
```

Don’t abuse this feature. You should enable this polling when necessary. For example, If your app enables the user to listen for voice commands, enable polling for the period of time that it’s listening. When the user wants to stop listening, you should also stop the polling by setting the interval to "0."

114.17.1. Choosing where a link opens

Opening a link deserves its own note, because the restriction above bites almost every app that calls `Display.execute()`. Codename One dispatches events on its own EDT, so by the time your action listener runs, the browser no longer sees the tap as an ongoing user gesture and refuses to open a new window. Navigating the page the app already runs in has no such restriction: it always works, at the cost of unloading the app.

The port picks between those two with the `javascript.execute.target` property:

Value	Behavior
`auto`	The default. Opens a new tab while the page still has user activation, and navigates the current page when it doesn’t. No confirmation sheet is ever shown.
`_blank`	Only ever opens a new tab. When the browser blocks that, the port shows a confirmation sheet whose OK button supplies the gesture the browser wanted. This was the behavior before the property existed.
`_self`	Always navigates the page the app runs in.

```
// The default. Opens a new tab while the browser still considers a
// user gesture to be in progress, and navigates the page the app runs
```

```
// in when it doesn't. Never shows a confirmation sheet.
CN.setProperty("javascript.execute.target", "auto");

// Always navigate the page the app runs in. Never blocked and never
// prompts, but it unloads the app.
CN.setProperty("javascript.execute.target", "_self");

// Only ever open a new tab. When the browser blocks that, the port
// shows a confirmation sheet whose OK button supplies the gesture the
// browser wanted. This was the behavior before the property existed.
CN.setProperty("javascript.execute.target", "_blank");

CN.execute("https://www.codenameone.com/");
```

Under `auto` and `_self` the app is unloaded whenever the current page navigates away, so persist anything you need before you call `execute()`. Pick `_blank` when keeping the app alive matters more than avoiding the sheet.

The property applies to any URL the browser can hand off, which means anything carrying a URI scheme. Custom deep links such as `imdb:///find?q=godfather` count, and so do protocol-relative `//host/path` URLs. The exceptions keep their existing meaning: a `javascript:` URL still evaluates on the page, and a `data:` URL, a `file:` URL or a path into local storage still becomes a download.

114.18. BrowserComponent lifecycle

On the JavaScript port, `BrowserComponent` uses an iframe that's added to the DOM when the component is initialized. Understanding the lifecycle is important when showing `Dialog`s over forms that contain `BrowserComponent` instances.

114.18.1. Dialogs and BrowserComponent

When a `Dialog` is shown, the parent `Form` is deinitialized. This causes any `BrowserComponent` instances on that form to also be deinitialized, which removes their iframes from the DOM. When the `Dialog` is dismissed and the parent form is re-shown, the `BrowserComponent` is reinitialized with a **new iframe**, losing all JavaScript state.

This affects:

- **Stateful embedded editors** - content and cursor position lost
- **WebRTC** connections - broken when removed from DOM
- **Interactive visualizations** - charts, maps, diagrams with JavaScript state
- **Any JavaScript state** - event listeners, variables, etc.

114.18.2. Preserving BrowserComponent state

To preserve the iframe and its JavaScript state across deinitialization cycles, set the `HTML5Peer.removeOnDeinitialize` client property to `Boolean.FALSE`:

```
BrowserComponent browser = new BrowserComponent();
browser.putClientProperty("HTML5Peer.removeOnDeinitialize", Boolean.FALSE);
```

This keeps the iframe in the DOM even when the component is deinitialized, preserving all JavaScript state.

114.18.3. Lifecycle example

Without the property set:

1. `Dialog.show()` is called
2. Parent `Form`'s `deinitialize()` is called
3. `BrowserComponent` is deinitialized, iframe removed from DOM
4. Dialog is dismissed
5. Parent `Form`'s `initComponent()` is called
6. `BrowserComponent` creates a **new iframe** - JavaScript state is lost

With `removeOnDeinitialize=false`:

1. `Dialog.show()` is called
2. Parent `Form`'s `deinitialize()` is called
3. `BrowserComponent` is deinitialized, but iframe **stays in DOM**
4. Dialog is dismissed
5. Parent `Form`'s `initComponent()` is called
6. `BrowserComponent` reconnects to the existing iframe - JavaScript state preserved

Chapter 115. Running Android applications

A classic Android application — activities, XML layouts, `res/values`, drawables and the framework widgets — can build and run as a Codename One application without changes to its Java code or its resources. The Android sources go into the Codename One project, the build compiles them against a Codename One implementation of the `android.*` API, and the result runs on every Codename One target: iOS, Android, the JavaScript port, the desktop ports and the simulator.

There is no Android runtime involved. Views are Codename One components, layouts follow Android's measure and layout rules, text fields are the platform's native text fields, and resources are compiled into a compact table at build time.

115.1. Quick start

Create a Codename One application project (for example from the initializr [https://start.codenameone.com]), then import the Android Studio project into it:

```
mvn cn1:import-android-project -Dcn1.android.import=/path/to/MyAndroidApp
```

The goal copies the module's `src/main` (the `app` module unless `-Dcn1.android.module` names another) into `common/src/main/android`, makes the Codename One main class start the Android application, and lists the module's Gradle dependencies the compatibility runtime covers and the ones it doesn't cover. After that, run and build as usual:

```
mvn cn1:run
mvn cn1:build -Dcodename1.platform=ios
```

You can also copy the files by hand. The directory mirrors an Android Studio module's `src/main`:

```
common/src/main/android/
    AndroidManifest.xml
    res/          layouts, values, drawables, menus, fonts...
    assets/
    java/         the Android application's Java (and Kotlin) sources
    kotlin/       Kotlin sources, if the module keeps them apart
```

Kotlin sources compile with the application's Kotlin support, which the import goal switches on when the module has any.

When the manifest declares no `package` (an Android Gradle plugin `namespace` replaces it), add `package="…"` to the manifest or set the `cn1.android.namespace` Maven property; the import goal does this for you.

115.2. How the build works

Three steps run as part of the normal build of the `common` module:

1. **`compile-android-res`** (in `generate-sources`) compiles the manifest and `res/` tree. It writes the `R` class for the application package, a generated class with `new` for every activity in the manifest and every view class the layouts use, and a binary resource table with every value, style and compiled XML file. Images, fonts and assets are copied next to it.
2. The Java compiler builds the application against the `codenameone-android-compat` artifact, which provides the `android.*` API. This is why the sources need no changes.
3. **`remap-android`** (in `process-classes`) moves the compiled `android.*` references and the runtime classes under `com.codename1.androidcompat`, so nothing in the application uses a name the real Android framework owns. The application therefore also builds for Android without conflicts. This step also generates the dispatcher for `android:onClick` attributes from the methods that exist in the compiled classes.

Nothing is created by reflection: layouts are inflated from the compiled table by calling constructors the build generated, which is what lets the same code run on iOS.

The `codenameone-android-compat` dependency is added to the `common` module by the project's `android-compat` profile, which activates when `src/main/android` exists. Gradle projects get the same tasks (`compileAndroidRes`) and the dependency automatically.

115.3. The entry point

If the project has no main class of its own, the build generates one that starts the activity the manifest marks as the launcher. To customize startup, write the class yourself; it needs one line:

```
public class MyApp extends com.codename1.androidcompat.runtime.AndroidLifecycle {
    public MyApp() {
        super(new com.codename1.generated.android.AndroidAppImpl());
    }
}
```

115.4. Resources

Resources resolve the way they do on Android:

- Every value type: strings (with formatting arguments and Android's quoting and escaping rules), plurals, string and integer arrays, colors, color state lists, dimensions in every unit, integers, booleans, fractions and ids.
- Styles and themes, including parent inheritance through `parent=` and dotted names, theme attributes (`?attr/colorPrimary`), `style=` on views, default widget styles from the theme and text appearances.
- Configuration qualifiers: locale and region, layout direction, smallest width, width and height,

orientation, night mode, density buckets and API level. The best match for the device is chosen with Android's precedence rules and is re-evaluated when the device rotates or switches to dark mode.

- Drawables: PNG and JPEG images scaled from their density bucket, nine-patches, vector drawables (`<vector>` with groups, clip paths and theme tints), `<shape>`, `<selector>`, `<layer-list>`, `<inset>`, `<ripple>`, `<bitmap>` and `<color>`.
- Fonts in `res/font` and files in `res/raw` and `assets/`.

The framework's own resources — the Material themes, `android.R.id`, `android.R.color` and the widget styles — are part of the runtime.

Problems are reported against the resource file and line with a stable code, for example `src/main/android/res/layout/main.xml:12: <CalendarView> is not a view class the Codename One Android runtime implements (android2cn1:E0201)`.

115.5. What's supported

- Activities with the complete lifecycle, explicit intents with extras, `startActivityForResult`, the back stack and `finish()`, implicit intents for web pages, phone numbers, mail, text messages and sharing, and configuration changes: an activity that doesn't declare `android:configChanges` is recreated with its saved state, as on Android.
- The action bar with the options menu and its overflow, `PopupMenu`, `PopupWindow` and `ListPopupWindow`.
- Fragments: `Fragment`, `FragmentManager` and transactions with the back stack, `ListFragment`, `DialogFragment`, `<fragment>` in layouts, child fragment managers and fragments' option menus. `ListActivity` is supported too.
- Layout inflation with `<include>`, `<merge>`, `<ViewStub>`, custom views (constructed with their `AttributeSet`), `android:theme` on views and `android:onClick`.
- Views drawn and measured as on Android: `View`, `ViewGroup`, `TextView`, `Button`, `EditText`, `AutoCompleteTextView`, `ImageView`, `ImageButton`, `LinearLayout`, `RelativeLayout`, `FrameLayout`, `TableLayout`, `GridLayout`, `ScrollView`, `HorizontalScrollView`, `Space`, `CheckBox`, `RadioButton` and `RadioGroup`, `Switch`, `ToggleButton`, `ProgressBar`, `SeekBar`, `RatingBar`, `NumberPicker`, `DatePicker`, `TimePicker`, `WebView`, and custom views that override `onMeasure`, `onLayout` and `onDraw` with `Canvas`, `Paint`, `Path` and `Matrix`.
- Lists and adapters: `ListView`, `GridView` and `Spinner` with view recycling, `ArrayAdapter`, `BaseAdapter`, `SimpleAdapter`, `CursorAdapter` and `SimpleCursorAdapter`.
- Touch input dispatched down the view tree, so `onInterceptTouchEvent`, `onTouchEvent` and touch listeners behave as written, and the back key.
- Dialogs: `AlertDialog`, `DatePickerDialog`, `TimePickerDialog`, `ProgressDialog` and `Toast`.
- Data and files: `SQLiteOpenHelper`, `SQLiteDatabase`, cursors and `ContentValues` over the platform's SQLite, `SharedPreferences`, the application's private directories (`getFilesDir()`, `getCacheDir()`, `openFileOutput()`), and `java.io.File` with the file streams, readers and writers.
- `Handler` and `Looper`, `Bundle`, `Uri`, `AssetManager` and `BitmapFactory`.

- Animation: view animations from `res/anim` (`alpha`, `translate`, `scale`, `rotate` and `set`) with `startAnimation`, layout animations, the framework and XML interpolators, `ViewFlipper` and the switchers, and property animation with `view.animate()`, `ValueAnimator`, `ObjectAnimator`, `AnimatorSet` and `res/animator` resources.
- XML: `getResources().getXml()` returns a pull parser over the compiled resource, and `Xml.newPullParser()` and `Xml.newSerializer()` read and write XML text.
- Room: entities, DAOs, type converters, `@Embedded`, `@Upsert`, `@RawQuery`, `LiveData` queries and migrations. The build generates the `_Impl` classes that the Room annotation processor would, so nothing is found by reflection.
- WorkManager: one-time and periodic work, chains whose outputs merge into the next worker's input, unique work, retries with a growing delay and `LiveData` status queries. Pending work is saved and resumes on the next run.
- Location and sensors: `LocationManager` with its listeners, last known and current location, and `SensorManager` with the accelerometer, gyroscope, magnetometer, gravity, rotation vector and orientation, including `getRotationMatrix()` and `getOrientation()`.
- Services declared in the manifest: started and bound services, `IntentService`, and `startForeground()`, which runs as a Codename One `ForegroundService`. Notifications and channels posted through `NotificationManager` and `NotificationCompat` are shown as local notifications.
- Document intents: `ACTION_OPEN_DOCUMENT`, `ACTION_CREATE_DOCUMENT` and `ACTION_GET_CONTENT` for types other than images and video open the platform's Open and Save dialogs, through `startActivityForResult` or the `OpenDocument`, `OpenMultipleDocuments`, `CreateDocument`, `GetContent` and `GetMultipleContents` contracts. See Section 115.9, "Opening and creating documents".
- The `AndroidKeyStore` with AES keys from `KeyGenerator` and `KeyGenParameterSpec`, used through `Cipher` in GCM or CBC mode.

115.6. AndroidX

The runtime includes the AndroidX libraries a classic application most often depends on, so code written against them builds without changes:

- AppCompat: `AppCompatActivity` with `getSupportActionBar()` and `setSupportActionBar()`, the `Toolbar` widget with its navigation button, title, subtitle, logo, action buttons and overflow menu, `AlertDialog`, `SwitchCompat`, and the AppCompat versions of the framework widgets, which an AppCompat activity inflates in place of the framework tags so that `app:srcCompat`, `app:tint`, `app:backgroundTint` and `app:buttonTint` apply. The `Theme.AppCompat` themes, including the `DayNight`, `NoActionBar` and `DarkActionBar` variants and the `ThemeOverlay.AppCompat` overlays, and `AppCompatDelegate.setDefaultNightMode()`.
- `androidx.activity`: `ComponentActivity`, `OnBackPressedDispatcher` and `OnBackPressedCallback`, and the Activity Result API with the `StartActivityForResult`, `RequestPermission`, `RequestMultiplePermissions` and `GetContent` contracts.
- `androidx.core`: `ContextCompat`, `ResourcesCompat`, `ViewCompat`, `WindowCompat`, `WindowInsetsCompat`, `ActivityCompat`, `DrawableCompat`, `TextViewCompat`, `ImageViewCompat` and `HandlerCompat`.
- Fragments: `androidx.fragment.app.Fragment` with its own lifecycle and a separate one for its

view (`getViewLifecycleOwner()`), `FragmentActivity` and `getSupportFragmentManager()`, transactions and the back stack, which the back key pops before the activity handles it, `FragmentContainerView` with `android:name`, `<fragment>` tags, `DialogFragment`, `ListFragment`, fragment results (`setFragmentResult()` and `setFragmentResultListener()`), the Activity Result API from a fragment, and `FragmentFactory`. `AppCompatActivity` is a `FragmentActivity`.

- `androidx.lifecycle`: `Lifecycle`, `LifecycleOwner`, `LifecycleRegistry`, `DefaultLifecycleObserver`, `LifecycleEventObserver` and `ProcessLifecycleOwner`; `ViewModel`, `AndroidViewModel` and `ViewModelProvider`, with view models of an activity or a fragment surviving a configuration change; `LiveData`, `MutableLiveData`, `MediatorLiveData` and `Transformations`; and `SavedStateHandle`.
- `androidx.annotation`.
- ConstraintLayout: `ConstraintLayout` with every `layout_constraint` attribute — edges, baselines, circular positioning, bias, chains (spread, spread inside, packed and weighted), match-constraint sizes with their minimum, maximum and fraction of the parent, dimension ratios and gone margins — `Guideline`, `Barrier`, `Group`, `Placeholder`, `Flow`, `Layer` and `ConstraintSet`. Layouts are solved by ConstraintLayout's own solver, so views land where they do on Android.
- RecyclerView: view recycling with the shared `RecycledViewPool`, the view cache and stable ids; `LinearLayoutManager` (vertical and horizontal, `reverseLayout`, `stackFromEnd`, `scrollToPositionWithOffset()`), `GridLayoutManager` with `SpanSizeLookup`, and `StaggeredGridLayoutManager`, also set through `app:layoutManager`; touch scrolling and flings, `smoothScrollToPosition()` and `LinearSmoothScroller`; every adapter notification, payloads included; `ItemDecoration` and `DividerItemDecoration`; `DefaultItemAnimator`; `DiffUtil`, `ListAdapter` and `AsyncListDiffer`; `ItemTouchHelper` for swipe-to-dismiss and drag-to-reorder; and `LinearSnapHelper` and `PagerSnapHelper`.
- `ViewPager2` with a `RecyclerView.Adapter`, horizontal or vertical, `OnPageChangeCallback`, `setCurrentItem()`, page transformers and `MarginPageTransformer`.
- Material Components: the `Theme.MaterialComponents` and `Theme.Material3` themes (light, dark and `DayNight`, with or without an action bar) with the library's default color roles, type scale and corner shapes, and the `ThemeOverlay` variants. Under either theme a `<Button>` inflates as a `MaterialButton` and a `<CheckBox>`, `<RadioButton>`, `<TextView>` or `<AutoCompleteTextView>` as its Material version, as they do on Android. The widgets are `MaterialButton` (icon, corner radius, stroke, toggling through `MaterialButtonToggleGroup`), `MaterialCardView` and AndroidX `CardView`, `FloatingActionButton` and `ExtendedFloatingActionButton`, `TextInputLayout` with `TextInputEditText` (floating label, helper text, error, counter, filled and outlined boxes, the password toggle and clear-text icons, and the exposed drop-down menu), `Chip` and `ChipGroup`, `BottomNavigationView`, `TabLayout` with `TabLayoutMediator`, `MaterialToolbar` and `AppBarLayout`, `Snackbar`, `MaterialAlertDialogBuilder`, `MaterialSwitch` and `SwitchMaterial`, `MaterialCheckBox` and `MaterialRadioButton`, `Slider`, `LinearProgressIndicator` and `CircularProgressIndicator`, `BottomSheetDialog` with `BottomSheetBehavior`, and `MaterialDivider`.

The libraries' resources — `Theme.AppCompat`, `?attr/colorPrimary`, `app:` attributes, the `androidx.appcompat.R` class — belong to the application's own namespace, as they do in an Android Gradle build: the application refers to them without a package, its `R` class lists them, and a resource it defines under a library resource's name overrides the library's value.

115.7. Side by side with Android

The gallery in `scripts/android-compat-samples/gallery` is an ordinary Android Studio module. Each image below shows one of its screens twice, both captured on the same Android 16 emulator (720 by 1600 pixels at 320 dpi). On the left, the module is built by Android Studio against the real framework and AndroidX libraries. On the right, the same unmodified sources are built as a Codename One application; this is the screen the screenshot tests capture on every port.

A few differences are expected:

- On the left, the black band at the top is the emulator's display cutout; a Codename One application paints its toolbar color under the status bar.
- Codename One's bold face on Android is Roboto Condensed, so bold text sets narrower and wraps later.
- The native build targets API 34, so its window keeps the classic layout the sample was written for. From API 35, Android draws such an application edge-to-edge unless it handles the window insets itself.
- The screenshot test hides the indeterminate progress spinner on the widgets screen, because it never stops moving.

115.8. Limitations

This is a compatibility layer for classic Android application code using the APIs described above. It doesn't promise complete Android framework behavior. Validate the screens and data flows your application uses on its target ports; the gallery and automated tests cover a subset of those behaviors.

- `Parcel` is an in-process value container, not Android's serialization or IPC format. Positions count values rather than bytes. `writeParcelable()` and `readParcelable()` retain and return the same object; they don't invoke `writeToParcel()` or `CREATOR`. Typed `Parcelable` lists also retain their elements. Code that depends on serialization making a snapshot, creator-side validation, or restoring state after process death needs an explicit storage or copy implementation.
- SQLite uses one Codename One database connection. While one thread's transaction is open, another thread's statements wait for it to end, as on Android, and throw `SQLiteDatabaseLockedException` after ten seconds. On the main thread the wait is two seconds, because the UI is frozen while it waits and the other thread may be waiting for the main thread itself. Threads don't read concurrently: one thread's long transaction holds up every other thread's queries.
- Switching only a locale's script, such as `zh-Hans` to `zh-Hant` with the same region, updates resource selection but doesn't notify or recreate existing activities. Already-inflated text and

layouts can retain the old script until the activity is recreated. Automatic handling of this live configuration change is deferred.

- Configuration changes don't call `Application.onConfigurationChanged()`. Refresh shared resource-dependent state from an activity's `onConfigurationChanged()` callback, or from `onResume()` after recreation.
- The application's own code must avoid the JDK classes Codename One doesn't provide; the build's bytecode check reports them. The runtime provides the `java.io` classes Android code uses most (`File`, the file streams, readers and writers, the buffered streams and `PrintWriter`).
- Code that loads classes by name (`Class.forName`, reflection-based libraries) doesn't run on iOS, with or without this runtime.
- `PackageManager.queryIntentActivities()` exposes at most the activity the runtime would launch. It doesn't enumerate every matching handler and uses the default-category restriction even without `MATCH_DEFAULT_ONLY`. Apps that present their own handler chooser need an explicit application registry.
- A stopped activity's attached views can still report `VISIBLE` from `getWindowVisibility()`. Pause rendering and other view work from the activity's `onStop()` callback, then resume it from `onStart()`, rather than waiting for a window-visibility callback.
- `BitmapFactory.Options.inBitmap` isn't used as a decode target. Decoding allocates a new bitmap; applications that depend on bitmap pooling should leave `inBitmap` unset and manage the old bitmap themselves.
- `Canvas.setBitmap(null)` unbinds the target and clears its dimensions and drawing state. Bind a live bitmap or view graphics before calling drawing or state methods on that canvas; unbound drawing isn't supported.
- Give sibling fragments of the same class stable, distinct IDs or tags when using `registerForActivityResult()`. Their launcher keys otherwise collide, and an outstanding result can be lost after activity recreation.
- Register or unregister `SavedStateRegistry` providers outside a provider's `saveState()` callback. Changing the registry during its save pass can abort state collection.
- Locale resources use exact region matches and language-only fallbacks. They don't rank translations from other regions. Ship a language-only directory, such as `values-fr`, for text shared across regions.
- `LayoutInflater.Filter` isn't supported by compiled layout factories. Installing a non-null filter throws `UnsupportedOperationException` before inflation. Applications needing a class restriction must control their compiled layouts and factories.
- `DigitsKeyListener` selects the keyboard input type but doesn't enforce a custom accepted-character set. Use an explicit `InputFilter` and validate submitted text when the application requires a restricted alphabet.
- Gradle recompiles all Java sources in an imported Android project after a source edit, because relocation rewrites the compiler output. Unchanged builds still use Gradle's up-to-date checks.
- Content providers and broadcast intents from the system aren't available; use the corresponding Codename One APIs through native interfaces or directly.
- `AndroidKeyStore` keys aren't hardware backed or non-extractable. Their material is kept in

Codename One's `SecureStorage` without a prompt: the keychain on iOS, and a key of the platform's own keystore on Android. A port without a secure store keeps the material in the application's private storage, which a rooted device or a backup can read. `setUserAuthenticationRequired()` isn't enforced; for a key the user must unlock, use `SecureStorage` with a reason, which prompts for biometrics. GCM supports only 128-bit tags.

- Room rejects `@Relation`, `suspend` DAO methods, `Flow`, RxJava and Paging return types, `@AutoMigration`, `@DatabaseView` and full-text tables at build time, naming the member. `createFromAsset()` fails when the database is built.
- A `ListenableWorker` subclass returns a `java.util.concurrent.Future` rather than Guava's `ListenableFuture`; `Worker` subclasses are unaffected. A network constraint is treated as met, and charging, idle, battery and storage constraints are checked only where Codename One's `BackgroundWork` supports them. Work saved by an earlier run resumes once the application calls `WorkManager.getInstance()`.
- A manifest that asks for location access gets the iOS location usage descriptions, and with `ACCESS_BACKGROUND_LOCATION` or `FOREGROUND_SERVICE_LOCATION` the `location` background mode, added to `codenameone_settings.properties` when the project doesn't set them. Edit the added text to change what the iOS permission prompt says.
- `ViewModelProvider` creates view models without reflection: the build registers every public, concrete `ViewModel` class whose public constructor takes nothing, an `Application`, a `SavedStateHandle`, or an `Application` and a `SavedStateHandle`. A view model with another constructor needs a `ViewModelProvider.Factory` of the application's own, as on Android.
- The Kotlin extensions of the `-ktx` libraries (`by viewModels()`, `lifecycleScope`, the `commit { }` transaction builder) and coroutines aren't provided; use the Java API they wrap.
- An observer added to a `Lifecycle` hears events through `DefaultLifecycleObserver` or `LifecycleEventObserver`; methods annotated with `@OnLifecycleEvent` aren't called, because there's no reflection.
- System insets are always zero: Codename One lays an application out inside the safe area itself, so edge-to-edge drawing has no effect.
- `ListView` and `GridView` don't automatically restore scroll position or checked items after activity recreation. Save the first visible position and checked item keys in the activity state, then restore selection and checks after attaching and populating the adapter. Stable item keys belong to the application; positions alone may change when its data changes.
- `RecyclerView` doesn't defer a saved layout anchor for an empty adapter. `PREVENT` and `PREVENT_WHEN_EMPTY` restoration policies don't gate that restore, so an empty first layout can consume the anchor. If data arrives later, save a stable item key or position in activity state and restore the scroll position after the adapter contains the items.
- Drawable selectors keep the window-focused appearance when a window loses focus. Applications needing a different appearance can update their drawables in `onWindowFocusChanged()`.
- Apply menu icon tint with `setIconTintList()` after assigning the icon, and repeat after replacing it. A tint set before the icon, or on a previous icon, isn't retained for the new drawable.
- `ObjectAnimator` finds a property by name only on the framework's own classes (view transforms, colors, progress, drawable alpha and level), because there is no reflection. Animate a property

of your own class through an `android.util.Property` instead.

- `TimeAnimator` doesn't honor a nonzero start delay. Leave its start delay at zero and schedule the `start()` call when delayed updates are needed.
- An anchored `PopupWindow` keeps its position until `update()` is called. Applications must update or dismiss it when its anchor scrolls or moves. Automatic anchor tracking is deferred.
- Options menus use their last prepared contents. Call `invalidateOptionsMenu()` after changing state that affects menu items; opening the overflow alone doesn't prepare the menu again.
- Overloads that differ only by `Closeable` and `AutoCloseable` can't survive remapping to the Codename One runtime. The build rejects these collisions with the class and method name; rename the overload or use one signature.
- XML `android:onClick` handlers must be declared in application output classes. The dispatcher doesn't discover methods inherited only from dependency JARs. Add a public forwarding method in the application activity, or register an explicit click listener in code. Dependency-wide handler discovery is deferred.
- A subclass of `Animation` or `Animator` that the application wrote must override `clone()` to be copied, for the same reason.
- `MotionLayout` isn't available. A `ConstraintSet` custom attribute sets the standard view and text properties (colors, alpha, rotation, scale, translation, text, text size, visibility and similar); a setter on a class of the application's own isn't called, because it's found by reflection on Android.
- Methods a `WebView` exposes to JavaScript with `addJavascriptInterface` return a JavaScript promise rather than the value, and the object is available once the page has loaded rather than during its inline scripts.
- `RecyclerView` item animations are the simple kind: items that move slide, new items fade in and removed items fade out, but an item that a change moves out of view doesn't slide out, and there are no predictive animations. `ListAdapter` and `AsyncListDiffer` compute the difference when the list is submitted, on the UI thread, and the scroll ends without an overscroll glow or a fast-scroll thumb.
- `CoordinatorLayout` isn't available, so a `layout_behavior` (a scrolling app bar, a button that hides on scroll) has no effect; a `Snackbar` appears at the bottom of the activity's content. `BottomSheetBehavior` drives the sheet of a `BottomSheetDialog` only. Material elevation shadows are drawn by the runtime and are softer than the platform's, a card doesn't clip its children to its rounded corners, and badges, centered toolbar titles and the `prefixText` and `suffixText` of a text field aren't shown; the build's compatibility report lists the ones an application uses.

115.9. Opening and creating documents

An opened document arrives as a `file:` URI that `ContentResolver.openInputStream()` reads; with `EXTRA_ALLOW_MULTIPLE` every chosen document is in the result's `getClipData()`. `takePersistableUriPermission()` has nothing to do, because the application can read the file again later.

Creating a document works in a different order than on Android. The iOS document picker can only export a file that already exists, so `ACTION_CREATE_DOCUMENT` answers at once with a file of the

requested name in the application's storage. The Save dialog opens when the application closes the stream it wrote through `ContentResolver.openOutputStream()`, and places the file where the user chooses. The application has already received `RESULT_OK` by then, so it isn't told when the user cancels the Save dialog, and the document is saved only if the user confirms it. Keep the data until the application no longer needs it rather than relying on the export. Write the document straight away in the result callback, as most applications already do.

115.10. Background execution on iOS

Android lets an application keep running in the background through a foreground service, and schedules deferred work through WorkManager. iOS has neither. An application in the background is suspended within seconds unless it declared one of a few background modes, and deferred work runs when the system chooses. The runtime maps each Android mechanism to the nearest iOS one:

Android	On iOS
`LocationManager` updates in a foreground service (track recording, navigation)	Continue in the background. A manifest with `ACCESS_BACKGROUND_LOCATION` or `FOREGROUND_SERVICE_LOCATION` adds the `location` background mode and the location usage descriptions, and the location stream then keeps the application running while it's in the background. The blue location indicator is shown, and the stream stops if the user force-quits the application.
Other work in a foreground service (`startForeground()`)	Runs in a background execution window that iOS ends after a short time, with the notification shown as a local notification. Long downloads and processing don't survive in the background; the next section shows the alternatives.
WorkManager work while the application runs	Runs at once, in the application process, as on Android.
WorkManager work with charging, idle, battery or storage constraints	Handed to Codename One's `BackgroundWork`, which uses `BGTaskScheduler`. iOS decides when to run it, often overnight while charging, and gives it a limited time.
Periodic work	Runs on its interval while the application runs. In the background it runs only when it has one of the constraints above, at times iOS chooses.
Work left when the application was closed	Saved, and resumed the next time the application calls `WorkManager.getInstance()`.
`PendingIntent` location updates, geofences, boot receivers	Not available. Use `com.codename1.location.LocationManager` `setBackgroundLocationListener()` or geofencing, which iOS can deliver to an application that isn't running.

115.10.1. Porting long-running work

- **Large downloads**: download while the application is open, in pieces the worker can resume from (HTTP range requests). WorkManager saves the request, so a download interrupted by suspension continues from the last piece when the application returns, rather than starting

over.

- **Recording while the screen is off**: keep it tied to the location stream. As long as location updates run, the code they call runs, so write each fix to the database from the location listener rather than from a separate worker thread that waits on a timer.
- **Processing that can wait**: give the WorkManager request a constraint such as `setRequiresCharging(true)` so that it goes to `BGTaskScheduler`, and make the worker able to stop part way and resume.

On Android the same application keeps its foreground services and WorkManager behaviour unchanged.

115.11. Mixing Codename One and Android code

Any Android view can be placed in a Codename One form: its peer is an ordinary Codename One component.

```
android.view.View chart = new MyChartView(androidContext);
form.add(BorderLayout.CENTER, chart.getPeer());
```

Code in the application can also call Codename One APIs directly, which is how features the Android API surface doesn't cover are added during a port.

A Codename One application can also open the screens of an Android module without handing it the whole app. Install the runtime once, without launching it, and start activities from its context:

```
AndroidRuntime rt = AndroidRuntime.getInstance();
if (rt == null) {
    rt = AndroidRuntime.install(new com.codename1.generated.android.AndroidAppImpl());
}
Context app = rt.getApplication();
Intent intent = new Intent(app, SettingsActivity.class);
intent.addFlags(Intent.FLAG_ACTIVITY_NEW_TASK);
app.startActivity(intent);
```

The form that was showing when the first activity started is remembered. When the last activity finishes, through `finish()`, the back button or `ActivityThread.finishAllActivities()`, that form is shown again instead of the application exiting.

Chapter 116. Running Unity 2D games

A Unity 2D project — C# scripts, scenes, prefabs, sprites and project settings — builds and runs as a Codename One application without changes to its scripts or its assets. You copy the project into a Codename One project, the build compiles the C# and translates it to Java bytecode, and the game runs on every Codename One target: iOS, Android, the JavaScript port, the desktop ports and the simulator.

No Unity player and no .NET runtime ship with the application. Scripts become ordinary classes, scenes and prefabs become generated code that creates their objects, and a runtime that implements the `UnityEngine` API draws the game into a Codename One component.

That component is the point. The game sits on a Codename One form, inside a Codename One application, so the same project can put a toolbar and a side menu around it, show a settings screen or a store, and use sign-in, in-app purchase, push, advertising and sharing from one Java codebase on every target. Scripts and Java call each other; Using Codename One from your game shows how.

The scope is 2D games built from sprites, tile maps, 2D physics, animation controllers, particle effects, a canvas interface and scripts. Five open source games run unmodified today, among them the platformer in the image above; see Games that run. Read Scope and porting notes before you plan a port.

116.1. Requirements

Besides what every Codename One project needs, a project with Unity sources needs the .NET SDK [https://dotnet.microsoft.com/download], version 6 or newer, on the machine that runs the build. The build uses its C# compiler and nothing else: no package is downloaded and no Unity installation or Unity license is needed.

The build looks for the `dotnet` command in this order:

1. The `cn1.unity.dotnet` property, which names the command or its directory.
2. The `DOTNET_ROOT` environment variable.
3. The `PATH`.

```
dotnet --list-sdks
mvn package -Dcn1.unity.dotnet=/opt/dotnet/dotnet
```

A project with no Unity sources doesn't need the SDK. An unchanged Unity project isn't compiled again, so only the builds that follow a change to a script or an asset use it.

The Unity project must store its assets as text, which is the default in current Unity versions (**Edit** > **Project Settings** > **Editor** > **Asset Serialization** > **Force Text**). The build reads scenes, prefabs and `.meta` files as the YAML text Unity writes in that mode.

116.2. Quick start

Create a Codename One application project (for example from the initializr [https://start.codenameone.com]), then import the Unity project into it:

```
mvn cn1:import-unity-project -Dsource=/path/to/MyUnityGame
```

Then run and build as usual:

```
mvn cn1:run
mvn cn1:build -Dcodename1.platform=ios
```

The next section walks through the same steps and what each one prints.

116.3. Porting a project, step by step

116.3.1. 1. Import the project

Run `cn1:import-unity-project` from the root of the Codename One project and point `-Dsource` at the directory that holds `Assets` and `ProjectSettings`. The goal does four things:

- Copies `Assets` and `ProjectSettings` into `common/src/main/unity`. It leaves out what the Unity editor derives from them (`Library`, `Temp`, `obj`) and the version control directories.
- Adds the `codenameone-unity-compat` runtime and the `compile-unity` goal to the `common` module's `pom.xml`.
- Rewrites the Codename One main class so that it starts the game. The previous class is kept beside it with a `.pre-unity-import` suffix.
- Prints what it copied, and lists every file the build won't use. A compiled plugin shows up here as `not built: Assets/Plugins/Foo.dll (compiled code: only C# source is translated)`.

The copy mirrors the Unity project. Keep editing the game in Unity and run the import again: it replaces the files it copied, removes the ones the Unity project no longer has, and leaves alone both the files you added by hand and a main class you changed since the last import.

You can also copy the files by hand. The directory mirrors the root of a Unity project:

```
common/src/main/unity/
    Assets/            scripts, scenes, prefabs, sprites and their .meta files
    ProjectSettings/   the input axes, tags, layers and physics settings
```

Keep the `.meta` files. Unity identifies an asset by the identifier in its `.meta` file, and that's how a scene finds the sprite or the script it refers to.

116.3.2. 2. Run the first build

Build the project. This is the step that needs the .NET SDK:

```
mvn package
```

The build compiles the scripts, translates them and compiles the scenes. A project inside the supported surface ends with the line `Compiled the Unity project`. A script that uses an API outside the surface stops the build here with the script file, the line and the name of the missing member, so the list of changes a port needs is in front of you after the first build rather than after the first crash. Troubleshooting shows both forms of that message.

116.3.3. 3. Read the build report

The translator and the scene compiler report everything they left out or approximated. Maven and Gradle print each line in the build output, prefixed `src/main/unity:`:

- A **warning** names something that changes how the game behaves or looks: a component the runtime doesn't have, a perspective camera made orthographic, a sprite a scene refers to that isn't under `Assets`, a script method Unity would call and the runtime doesn't. The build log shows these at warning level, and the last line counts them: `Compiled the Unity project with 2 warning(s): what they name will not behave as it does in Unity`.
- A **note** names something left out that doesn't change the game, or a substitution you might want to know about. Maven shows notes at info level.

A line about a scene names the scene or prefab file, the GameObject and the component's file ID, the number after the `&` in the scene's YAML. A warning about a script names the class, the method, the file and the line. This is the complete report of the Sokoban game from Games that run, seven notes and no warnings, shown without the prefix:

```
Sokoban.unity: the FlareLayer component of GameObject 'Camera with script' (component file ID 1187623029) was left out;
nothing in a 2D scene is drawn through it
Sokoban.unity: the GUILayer component of GameObject 'Camera with script' (component file ID 1187623030) was left out;
nothing in a 2D scene is drawn through it
Sokoban.unity: the StandaloneInputModule of GameObject 'EventSystem' (component file ID 1460168504) was left out; the
event system beside it routes the pointer to the controls itself, and nothing moves between controls by keyboard
Hero.png is a polygon sprite: it was cut to its outline when the project was built, into unity-polygon-Hero.png (256 by
256 pixels), and is drawn as that image
Ball.png is a polygon sprite: it was cut to its outline when the project was built, into unity-polygon-Ball.png (256 by
256 pixels), and is drawn as that image
```

```
Sokoban.unity: the image of GameObject 'RestartButton' (file ID 1532672074) uses Unity's built-in interface sprite 10905,
which is not in the project; a plain rectangle of the image's colour is drawn instead
the input settings define joystick axes; those read as zero, and the keys of the same axes work
```

The full output of each tool is in `common/target/unity`:

```
less common/target/unity/dotnet.log
less common/target/unity/translate.log
less common/target/unity/scene-compiler.log
```

116.3.4. 4. Run in the simulator

`mvn cn1:run` opens the game in the Codename One simulator. It shows the first scene of the Unity build settings in a form that fills the screen. If the build settings list no scene, every scene under `Assets` is compiled in order of path and the first one starts.

The simulator has a keyboard, so a game written for the desktop plays as it is. Keys reach `Input` under Unity's key codes, the arrow keys drive the default `Horizontal` and `Vertical` axes beside WASD, and the pointer is the mouse.

116.3.5. 5. Plan the input for a phone

Touches reach a script two ways. `Input.touchCount`, `Input.touches` and `Input.GetTouch` report every finger on the screen with its phase, so a game written for touch plays as it is. The first finger also reads as mouse button 0, with `Input.mousePosition` at the touch, and canvas buttons respond to it. A game played with the mouse or with canvas buttons therefore needs nothing more on a phone.

A script that shows its touch controls only on a handheld can keep asking `Application.isMobilePlatform`, which is true on iOS and on Android. In a browser, ask `Input.touchSupported` instead: it reports whether the device has a touch screen, which is the question on a phone's browser and a laptop's alike.

A game played with keys needs a way to press them on a device that has none. The game's view accepts key events from Java code: call `keyPressed` and `keyReleased` on it with the character of the key, and the script sees `Input.GetKey` exactly as if a keyboard had sent it. Add Codename One buttons around the game for that, as Using Codename One from your game describes.

116.3.6. 6. Build for a device

Device builds are ordinary Codename One builds. Nothing about them is specific to Unity sources:

```
mvn cn1:build -Dcodename1.platform=android
mvn cn1:build -Dcodename1.platform=ios
mvn cn1:build -Dcodename1.platform=javascript
```

116.3.7. 7. Iterate

After a change to a script, a scene or an asset, build again. The build fingerprints `Assets` and `ProjectSettings` and repeats the C# compile, the translation and the scene compile only when one of those files changed. A change to your Java code alone doesn't run the .NET SDK.

To leave the Unity project out of one build, set `cn1.unity.skip`. The classes an earlier build produced stay in place:

```
mvn package -Dcn1.unity.skip=true
```

116.4. Using Codename One from your game

The game isn't the whole application. It's one component, a `UnityGameView`, on a Codename One form, in an application whose main class is Java. The rest of this guide therefore applies to the same project and reaches every target the game does: the user interface toolkit and its themes, sign-in, in-app purchase, push, advertising, sharing, storage, and networking.

Code travels in three directions, and this section takes them in turn:

- Codename One around the game: forms, a toolbar, a side menu and other screens, written in Java.
- Java calling the game: reading a score, or restarting a level.
- The game calling Codename One: a script that asks to sign in, to share a result or to open a leaderboard.

The samples are one small application. Its Unity project has two scripts besides the game's own, and its Java side is two classes.

116.4.1. The entry point

The import writes a main class that extends `com.codename1.unitycompat.app.UnityApplication`. A project that has no main class of its own gets the same class generated by the build. This is the whole class, for an application whose main class is `com.example.mygame.MyGame`:

```
package com.example.mygame;

public class MyGame extends com.codename1.unitycompat.app.UnityApplication {
    @Override
    protected void installProject() {
        com.codename1.generated.unity.UnityAppImpl.install();
    }
}
```

`installProject` is the one method you must have. It names the class the scene compiler generated, in source, because a device build has no reflection to find it by name. `UnityApplication` gives you

more places to work from, in the order they're called:

- `onProjectInstalled()` runs once the project is installed and before the first scene is built, so before the first `Awake` of any script.
- `createForm(UnityGameView gameView)` returns the form the game is shown in.
- `onStarted(Form gameForm, UnityGameView gameView)` runs once, after the first scene is loaded and the game loop runs.
- `getForm()` and `getView()` return the same two objects later.
- `callInFrame(Runnable)` is static, and runs your code inside the game's frame. Calling the game from Java explains when you need it.

116.4.2. Codename One screens around the game

Override `createForm` to decide what surrounds the game. The default returns a form with a `BorderLayout`, a hidden title area and the view in the center. Return your own form instead; the one rule is that it must contain the view. This main class gives the game a title bar with a leaderboard command, a side menu with a Restart command and a score label under the playfield:

```
public class MyGame extends UnityApplication {
    private final GameServices services = new GameServices(this);
    private final Label scoreLabel = new Label("Score 0");

    @Override
    protected void installProject() {
        UnityAppImpl.install();
    }

    @Override
    protected void onProjectInstalled() {
        // No scene is built yet: every Awake and Start finds this set.
        Platform.Services = services;
    }

    @Override
    protected Form createForm(UnityGameView gameView) {
        Form form = new Form(new BorderLayout());
        Toolbar toolbar = new Toolbar();
        form.setToolbar(toolbar);
        form.setTitle("My Game");
        form.setScrollable(false);
        toolbar.addMaterialCommandToRightBar("", FontImage.MATERIAL_LEADERBOARD,
                e -> callInFrame(() -> services.ShowLeaderboard(score().get_Best())));
        toolbar.addMaterialCommandToSideMenu("Restart", FontImage.MATERIAL_REPLAY,
                e -> callInFrame(() -> score().points = 0));
        form.add(BorderLayout.CENTER, gameView);
        form.add(BorderLayout.SOUTH, scoreLabel);
        return form;
    }
```

```
    @Override
    protected void onStarted(Form gameForm, UnityGameView gameView) {
        // Twice a second: read the score inside the frame, show it on the
        // event dispatch thread.
        UITimer.timer(500, true, gameForm, () -> callInFrame(() -> {
            int points = score().points;
            CN.callSerially(() -> {
                scoreLabel.setText("Score " + points);
                gameForm.revalidate();
            });
        }));
    }

    // Only ever called inside the frame.
    private static Score score() {
        return (Score) GameObject.Find("Ball").GetComponent(Score.class);
    }
}
```

`UnityGameView` is in `com.codename1.unitycompat.unityengine.ui`. It extends the `GameView` of the `com.codename1.gaming` package, so it sizes and lays out like any other component. Here it takes the center of a `BorderLayout`, and the game draws into whatever size the layout gives the view.

Everything around the view is ordinary Codename One user interface. The toolbar, the side menu and the label take their look from the application's theme, so you style them in `theme.css` as Working with CSS themes describes, and Toolbar covers the commands, the search field and the side menu. The theme doesn't reach inside the view: what the game draws is the game's own.

116.4.3. Another form, and back to the game

A settings screen, a store or a leaderboard is a second form. Pause the view before you show it and resume the view when the player returns. A paused view runs no script and advances no game time; it keeps its last frame. Scripts that declare `OnApplicationPause` or `OnApplicationFocus` are told of both:

```
final class GameServices implements IPlatformServices {
    private final UnityApplication app;

    GameServices(UnityApplication app) {
        this.app = app;
    }

    // Scripts call these inside a frame, which isn't always on the event
    // dispatch thread. Each one hands its work to that thread.

    @Override
    public void SignIn() {
        CN.callSerially(() -> {
```

```
            if (Preferences.get("player", null) != null) {
                return;
            }
            GoogleConnect.getInstance().signIn(
                    "YOUR_CLIENT_ID.apps.googleusercontent.com",
                    "com.example.mygame:/oauth2redirect",
                    "openid", "email"
            ).ready(tokens -> Preferences.set("player", tokens.getEmail()));
        });
    }

    @Override
    public void Share(String text) {
        CN.callSerially(() -> CN.share(text, null, null));
    }

    @Override
    public void ShowLeaderboard(int score) {
        CN.callSerially(() -> showLeaderboard(score));
    }

    private void showLeaderboard(int score) {
        app.getView().pause();
        Form board = new Form(BoxLayout.y());
        Toolbar toolbar = new Toolbar();
        board.setToolbar(toolbar);
        board.setTitle("Leaderboard");
        board.add(new Label("Your best: " + score));
        toolbar.setBackCommand("", e -> {
            app.getForm().showBack();
            app.getView().resume();
        });
        board.show();
    }
}
```

`showLeaderboard` at the end of the class is the part that matters here: it pauses the view, shows a form with a back command, and the back command shows the game's form again and resumes.

`UnityApplication` already pauses the game when the application goes to the background and resumes it on return, so no frame is simulated while nobody sees it and `Time.time` doesn't jump. A script that calls `Application.Quit()` exits the application.

116.4.4. Stepping the game by hand

A test that captures a scene, or a tool that renders one, needs the same picture on a fast device and on a slow one. The view normally simulates the time that passed since its last frame, so the picture depends on how fast the frames came. `gameView.holdClock()` takes the clock away from the game: a frame then simulates nothing and draws the scene as it stands. `gameView.advance(90, 1f / 60)` asks for 90 steps of a sixtieth of a second each, and the next frame the view draws runs every one,

however long that frame took. `framesAdvanced()` grows by the number of steps once they've been run and the scene shows the last of them, which is the moment to capture. `releaseClock()` hands the clock back.

A view whose clock is held takes no input: keys and touches that arrive are dropped, so nothing but the steps you ask for moves the scene. Calls queued with `callInFrame` still run.

To show one scene of a project by itself, start the runtime with `UnityRuntime.begin(index)` where `UnityApplication` calls `begin()`. The index is the scene's place in the build settings. `UnityRuntime.reset()` takes everything down again, the objects, the clock and the application's settings, so the next scene starts from nothing. Call `Random.InitState` before `begin` when the scene has particle systems or scripts that ask for random numbers.

116.4.5. On-screen controls

For a game that reads keys, add buttons in `createForm` and forward their press and release to the view. `gameView.keyPressed('a')` followed by `gameView.keyReleased('a')` is one tap of the A key, and the script's `Input.GetKey(KeyCode.A)` is true from one call to the other. Letters, digits and the space character are passed as themselves. For the arrow keys pass the key code of the matching game action, which `Display.getInstance().getKeyCode(Display.GAME_LEFT)` returns. The view queues these calls and hands them to the game at the start of its next frame, so a button's listener makes them directly.

116.4.6. Calling the game from Java

A translated script is an ordinary class, and Java code in the same module calls it by name. A script with no namespace is in the package `global`; a script in a namespace is in the package of that name. This is the script the samples read:

```
public class Score : MonoBehaviour
{
    public int points;

    public int Best { get; private set; }

    public void Add(int amount)
    {
        points += amount;
        if (points > Best)
        {
            Best = points;
        }
    }

    public Vector2 Where()
    {
        return transform.position;
    }
```

```
    private void Start()
    {
        Platform.Services?.SignIn();
    }

    private void OnApplicationPause(bool paused)
    {
        Debug.Log("score paused=" + paused);
    }

    private void Update()
    {
        if (Platform.Services == null)
        {
            return;
        }
        if (Input.GetKeyDown(KeyCode.L))
        {
            Platform.Services.ShowLeaderboard(Best);
        }
        if (Input.GetKeyDown(KeyCode.S))
        {
            Platform.Services.Share("I scored " + Best);
        }
    }
}
```

And this is Java finding it and reading it, in code that runs inside a frame:

```
// Inside a frame: in a Runnable given to callInFrame, or in a
// method a script called.
// By the name of its object, then by the script's class.
Score score = (Score) GameObject.Find("Ball").GetComponent(Score.class);
// Or the first one in the scene, whatever object it is on.
Score first = (Score) com.codename1.unitycompat.unityengine.Object
        .FindObjectOfType(Score.class);

int points = score.points;                    // public int points;
int best = score.get_Best();                  // public int Best { get; }
Vector2 where = score.Where(new Vector2());  // public Vector2 Where()
float height = where.y;
```

The rules a Java author needs:

- **Finding an object.** `GameObject.Find` takes the object's name and returns `null` when the scene has none. `GetComponent` and `FindObjectOfType` take the script's class where C# takes a type argument, and return an `Object` to cast. The engine's classes are in `com.codename1.unitycompat.unityengine`; its own `Object` class shares a name with `java.lang.Object`, so write that one in full.
- **When.** A scene's objects exist once the scene is loaded, so from `onStarted` on. A scene load

replaces them, apart from the ones a script kept with `DontDestroyOnLoad`, so find an object again after one.

- **Fields and methods** keep their C# names, capitals included.
- **Properties** are a pair of methods: `Best` is `get_Best()` and `set_Best(int)`.
- **Types.** `int`, `float` and `bool` are `int`, `float` and `boolean`. A `string` is a `java.lang.String`. An enumeration is an `int`. A C# array of those is the Java array. A `List<T>` is a `com.codename1.unitycompat.system.collections.generic.List_1`, without its type argument.
- **Value types.** `Vector2`, `Vector3`, `Color` and the other `UnityEngine` value types are classes of the Java package `UnityEngine`, with their fields public. A method that returns one takes an extra last argument, the object the result is written into: `Where()` in C# is `Where(new Vector2())` in Java.
- **Access.** The translated members are all public. A member the script declared private isn't part of what the script offers; leave it alone.

One rule covers threads. Scripts run inside the game's frame, on the thread that draws it, and on some ports that isn't the event dispatch thread your listeners run on. So:

- Touch game objects and scripts inside `callInFrame`.
- Touch Codename One components on the event dispatch thread.

`callInFrame(Runnable)` runs the code at the start of the next frame, before any script. It's a static method of `UnityApplication`, and the view has the same method. Calls run in the order they were made, and they run while the view is paused too. The main class above uses it three times. The Restart command sets a field of the script. The leaderboard command reads the best score and hands it on. The timer reads the points inside the frame and then passes the number to `CN.callSerially`, which sets the label on the event dispatch thread.

Code that a script calls is already inside the frame, and may use any script directly.

116.4.7. Calling Codename One from the game

A script compiles against the `UnityEngine` API and the .NET base library, so it can't name a Java class. It can name an interface of its own. Declare, in the Unity project, what the game needs from the application, and a static field to hold the object that provides it:

```
// What the game asks of the application around it. The game compiles
// against this interface alone; the application supplies the object.
public interface IPlatformServices
{
    void SignIn();
    void Share(string text);
    void ShowLeaderboard(int score);
}

public static class Platform
{
    public static IPlatformServices Services;
```

```
}
```

The interface is translated with the scripts and becomes the Java interface `global.IPlatformServices`. Implement it in Java, with the whole Codename One API at hand. `GameServices`, shown earlier, is that implementation: `SignIn` uses `GoogleConnect`, `Share` opens the platform's share sheet through `CN.share` and `ShowLeaderboard` shows a form.

Three things make the bridge work:

- **Register it before the first scene loads.** The main class assigns `Platform.Services` in `onProjectInstalled`. Every `Awake` and `Start` then finds it set; `Score` calls `SignIn()` from its `Start`.
- **Hand the work to the event dispatch thread.** A script calls the interface from inside a frame. Each method wraps what it does in `CN.callSerially`, and returns at once so the frame isn't held up.
- **Keep the interface to simple types.** `int`, `float`, `bool` and `string` cross unchanged. A method that returns a value answers on the game's thread: return something the application already holds, and don't touch a component there.

The script side stays plain C#. `Platform.Services?.Share("I scored " + Best)` does nothing when no object is registered, so the scripts don't depend on the application being there.

From the Java side of that interface the whole platform is in reach:

- **Sign-in** with Google, Apple, Facebook, Microsoft or any OpenID Connect provider: Authentication and Identity.
- **In-app purchase and subscriptions** through `Purchase`: In-app purchase.
- **Advertising**, including rewarded and interstitial formats between levels: Advertising.
- **Push notifications**: Push notifications.
- **Sharing** a score or a screenshot: `CN.share`, or the ShareButton component.
- **Storage and networking** for saved games and online scores: `Preferences`, Storage and `ConnectionRequest`.
- **Anything a platform SDK offers** that Codename One doesn't wrap: native interfaces.

`PlayerPrefs` needs no bridge. The runtime keeps it in Codename One's `Preferences` storage, so a high score outlives the application on every target.

116.5. How the build works

A single step runs as part of the normal build of the `common` module: **`compile-unity`**, in `generate-sources`. It does three things:

1. The .NET SDK compiles every `.cs` file under `Assets` to one assembly, with the language level set to C# 9. It leaves out the scripts in an `Editor` directory, as Unity leaves them out of a player build. The scripts compile against a `UnityEngine` assembly that ships with the runtime, so a script that uses a `UnityEngine` member the runtime doesn't have fails here, with the C# compiler's own file and line.

2. The translator reads the assembly and writes Java class files, one class for each C# type. A type in a namespace lands in the package of the same name. A type with no namespace, which is what most Unity scripts are, lands in the package `global`, because a Java class in the default package can't be imported. The translator also checks every call into the .NET base library against the runtime and lists the members the runtime lacks.
3. The scene compiler turns every scene and prefab into Java source: a generated class, `com.codename1.generated.unity.UnityAppImpl`, that creates the objects with `new`, assigns the values the Inspector stored and connects the references. It copies the sprites, sounds and text assets next to it.

Nothing is created by reflection and no scene file is parsed on the device. That's what lets the same code run on iOS and in the browser, where the translated application keeps only the code something refers to. Three things Unity resolves by name at run time are resolved by the build instead:

- `Invoke("Fire", 1f)` and `InvokeRepeating` call a dispatcher the translator writes into each script, which maps the method names of that script to calls.
- A button's persistent `onClick` calls, the ones set up in the Inspector, become direct calls in the generated scene code.
- `Resources.Load("level1")` is a lookup the scene compiler writes from the files it found under the `Resources` folders. The asset is already part of the application when a script asks for it.

Two representations are worth knowing as a script author:

- **Value types keep C#'s copy semantics.** `Vector2`, `Vector3`, `Quaternion`, `Color`, `Bounds` and your own structs are copied on assignment and when passed, exactly as C# specifies. Arithmetic on them writes into storage the caller owns instead of allocating an object for each result, so vector math in `Update` doesn't produce garbage.
- **A rectangular array is one flat array.** `int[,]` and arrays of higher rank are stored as a single array with every index checked against its own dimension. A tile grid costs one allocation and each access is one multiply and one add.

The `codenameone-unity-compat` dependency is added to the `common` module by the project's `unity-compat` profile, which activates when `src/main/unity` exists.

116.6. Gradle projects

A Gradle project builds a Unity project the same way. The plugin sees `src/main/unity`, adds the `codenameone-unity-compat` runtime to the application and runs a `compileUnity` task before the Java sources compile, so there is no dependency to declare and no task to call. A Maven project that has a Unity project keeps it when you convert it with `cn1:convert-to-gradle`.

The import is a Maven goal. In a project that was created for Gradle, copy `Assets` and `ProjectSettings` into `src/main/unity` by hand. Then either delete the main class the project came with, and the build generates one that starts the game, or change it as The entry point describes.

Name the .NET SDK with `-Pcn1.unity.dotnet` when it isn't on the `PATH`:

```
./gradlew run
./gradlew buildIos -Pcn1.unity.dotnet=/opt/dotnet/dotnet
```

Gradle skips `compileUnity` as up to date while the Unity project is unchanged. To leave the Unity project out of one build, exclude the task with `-x compileUnity`; the classes an earlier build produced stay in place. The work files and the logs of the C# compiler, the translator and the scene compiler are in `build/cn1-unity/state/unity`.

116.7. What a project can use

This is the surface the five games in the next sections were built on. It covers what a 2D game with sprites, tile maps, physics, animation and a canvas interface is made of.

116.7.1. C# and the base library

- The language as Unity projects use it: classes, structs, interfaces, enums, generics, delegates and events, lambdas and closures, iterators, `foreach`, `ref` and `out` parameters, `switch` on strings and switch expressions, tuples, string interpolation, exceptions, properties, indexers and operator overloading.
- Strings: concatenation, `Format` with plain `{0}` items, `Join`, `Split` on characters or on strings with or without `StringSplitOptions`, `Substring`, `IndexOf`, `Contains`, `StartsWith`, `EndsWith`, `Replace`, `Trim`, and the invariant case conversions.
- Numbers: `int.Parse`, `int.TryParse`, `System.Math` and `Mathf`.
- `List<T>` and `Dictionary<K,V>`. A dictionary enumerates in insertion order and has `TryGetValue`, `ContainsKey`, `Remove`, `Keys`, `Values` and `foreach` over its pairs.
- Arrays, including rectangular arrays of any rank with `GetLength`.
- The `Action` and `Func` delegates and these LINQ operators: `Where`, `Select`, `Any`, `All`, `Count`, `Contains`, `First`, `FirstOrDefault`, `Last`, `LastOrDefault`, `ElementAt`, `Take`, `Skip`, `Distinct`, `Concat`, `Reverse`, `ToList` and `ToArray`.

The script below uses several of these together: a level read from a text asset in a `Resources` folder into a two-dimensional array, with the tiles it creates tracked in a dictionary. It builds as written.

```
using System;
using System.Collections.Generic;
using UnityEngine;

public class Board : MonoBehaviour
{
    public GameObject tilePrefab;

    private int[,] cells;
    private readonly Dictionary<GameObject, Vector2> tiles = new Dictionary<GameObject, Vector2>();

    void Start()
    {
        TextAsset level = Resources.Load<TextAsset>("level1");
```

```
        string[] rows = level.text.Split(new[] { '\n' }, StringSplitOptions.RemoveEmptyEntries);
        cells = new int[rows.Length, rows[0].Split(',').Length];
        for (int r = 0; r < cells.GetLength(0); r++)
        {
            string[] columns = rows[r].Split(',');
            for (int c = 0; c < cells.GetLength(1); c++)
            {
                int.TryParse(columns[c], out cells[r, c]);
                if (cells[r, c] != 0)
                {
                    GameObject tile = Instantiate(tilePrefab, new Vector3(c, -r, 0), Quaternion.identity);
                    tiles[tile] = new Vector2(c, r);
                }
            }
        }
        PlayerPrefs.SetInt("lastLevel", 1);
    }
}
```

116.7.2. Scripts and objects

- `MonoBehaviour` with these messages: `Awake`, `OnEnable`, `Start`, `FixedUpdate`, `Update`, `LateUpdate`, `OnDisable`, `OnDestroy`, and the 2D collision and trigger messages (`OnCollisionEnter2D`, `OnCollisionStay2D`, `OnCollisionExit2D` and the three `OnTrigger` equivalents).
- `OnMouseDown` and `OnMouseUp` on an object with a 2D collider, with the pointer placed in the world by the main camera. `OnApplicationPause(bool)` and `OnApplicationFocus(bool)` when the game is paused and resumed.
- Coroutines with `yield return null`, `WaitForSeconds`, `WaitForEndOfFrame` and `WaitForFixedUpdate`, a `Start` written as a coroutine, `StopCoroutine` and `StopAllCoroutines`.
- `Invoke`, `InvokeRepeating`, `CancelInvoke` and `IsInvoking`.
- `GameObject` and `Transform` hierarchies, `Instantiate` with or without a position, a rotation and a parent, `Destroy` with an optional delay, `SetActive`, tags and layers, `Find`, `FindWithTag`, `FindGameObjectsWithTag`, `FindObjectOfType`, `AddComponent`, and `GetComponent` with its `InChildren` and `InParent` forms.
- Serialized fields of scripts, as the Inspector stored them: numbers, strings, enums, vectors, colors, arrays and lists, structs, and references to objects, components, prefabs, sprites, audio clips and text assets.
- Prefabs, prefab instances placed in a scene with their property overrides, and nested prefabs.
- `SceneManager.LoadScene` by name or by build index, `Time` with `timeScale` and `timeSinceLevelLoad`, `Random`, `Screen.width` and `Screen.height`, `Debug.Log` and its warning and error forms, and `UnityEngine.Assertions.Assert`.
- `Application.platform` and `Application.isMobilePlatform`, answered from the device the game runs on: `IPhonePlayer` on iOS, `Android` on Android, `WebGLPlayer` in a browser, and the desktop's own player on macOS, Windows and Linux. The simulator reports the desktop it runs on.

116.7.3. Rendering

- `SpriteRenderer` with sorting layers and orders, flipping and tinting.

- Sprites imported as single images, sprite sheets sliced in the Sprite Editor, pivots and pixels per unit. A polygon sprite is cut to its outline when the project is built and drawn as that image.
- An orthographic `Camera` with its background color and the conversions between screen, viewport and world points.

116.7.4. Animation

- `Animator` with the controllers and clips of the project. The build compiles each `.controller` and `.anim` file into code, so nothing is parsed on the device.
- State machines with float, integer, bool and trigger parameters, transitions with conditions and exit time, and transitions from Any State.
- Curves that animate a sprite renderer's sprite, color and enabled flag, a transform's position, scale and rotation about z, and whether a GameObject is active.
- Animation events, which call the method they name on the scripts of the animated object.
- From a script: `Play`, `CrossFade`, `SetFloat`, `SetInteger`, `SetBool`, `SetTrigger`, `ResetTrigger` and their getters, `speed`, `GetCurrentAnimatorStateInfo`, `IsInTransition`, `StringToHash`, and assigning `runtimeAnimatorController` to swap the controller.

116.7.5. Tile maps

- `Grid`, `Tilemap` and `TilemapRenderer`, with the cells the Tile Palette painted.
- `TilemapCollider2D`, alone or merged into outlines by a `CompositeCollider2D`.
- From a script: `GetTile`, `SetTile`, `HasTile`, `GetSprite`, `ClearAllTiles`, `WorldToCell`, `CellToWorld` and `GetCellCenterWorld`.

116.7.6. Particles

- `ParticleSystem`, simulated on the CPU from a seeded sequence, so an effect plays the same way on every target.
- The main module, emission by rate and in bursts, the emitter shape, and the velocity, color, size and rotation over lifetime modules, as the scene stores them.
- From a script: `Play`, `Stop`, `Pause`, `Clear` and `Emit`, the playing state and `particleCount`, and the `main`, `emission` and `velocityOverLifetime` modules.

116.7.7. Physics

- `Rigidbody2D`: dynamic, kinematic and static bodies, velocity, forces and torques, `MovePosition` and `MoveRotation`, mass, drag, gravity scale, `constraints` and `collisionDetectionMode`.
- Box, circle, polygon, capsule and edge colliders, tile map and composite colliders, triggers, and `Collision2D` with its contacts.
- `PlatformEffector2D` for one-way platforms.
- Physics materials (friction and bounciness), the project's gravity and the layer collision matrix, with `Physics2D.IgnoreLayerCollision` to change it from a script.

- Casts: `Physics2D.Raycast`, `Linecast`, `CircleCast`, `BoxCast` and `CapsuleCast`. Each has the form that returns the nearest hit, the `All` form, the `NonAlloc` form and the form that takes a `ContactFilter2D` with an array or a list for the results.
- Overlap tests: `OverlapPoint`, `OverlapCircle`, `OverlapBox`, `OverlapArea` and `OverlapCapsule`, in the same four forms.
- `RaycastHit2D`, `ContactFilter2D` and `LayerMask`, including a `LayerMask` field set in the Inspector, with `Physics2D.queriesHitTriggers`, `queriesStartInColliders` and `SyncTransforms`.
- On a collider or a body: `OverlapPoint`, `IsTouching`, `IsTouchingLayers` and `Cast`, and `Collider2D.bounds`.

A cast isn't stepped along its path. The runtime solves each one in closed form, so the distance, the normal and the point it reports are exact to the rounding of the arithmetic, and a fast or thin shape can't slip past a collider. A query sees bodies where the last physics step put them; call `Physics2D.SyncTransforms` after a script moves a transform and before it asks.

116.7.8. Input

- `GetKey`, `GetKeyDown` and `GetKeyUp` by `KeyCode` or by name, `anyKey` and `anyKeyDown`.
- The axes and buttons the project's input settings define on keys, through `GetAxis`, `GetAxisRaw` and `GetButton`.
- The mouse: `GetMouseButton`, `GetMouseButtonDown`, `GetMouseButtonUp` and `mousePosition`, and the `Mouse X` and `Mouse Y` axes for its movement.
- Touch: `touchCount`, `touches` and `GetTouch`, with a `Touch` that carries its `fingerId`, `position`, `deltaPosition`, `tapCount` and a `phase` of `Began`, `Moved`, `Stationary` or `Ended`. `multiTouchEnabled` and `simulateMouseWithTouches` work as documented.

116.7.9. User interface, audio and data

- A `Canvas` in Screen Space, overlay or camera, with a `CanvasScaler` and `RectTransform` anchoring.
- `Text` with size, style, alignment, wrapping and best fit.
- TextMesh Pro text, as `TMP_Text`, `TextMeshPro` and `TextMeshProUGUI`: `text`, `SetText`, size, style, alignment, wrapping and auto sizing, drawn in the platform's font.
- `Image`, simple or filled horizontally or vertically (`fillAmount` drives a health bar).
- `Button` with its color tint states, the `onClick` calls set up in the Inspector, and `onClick.AddListener` from a script.
- `AudioSource` and `AudioClip`, played through Codename One's media API: `Play`, `PlayOneShot`, `Stop`, `Pause`, `loop`, `volume` and `PlayClipAtPoint`.
- `PlayerPrefs` for integers, floats and strings, saved on the device.
- `Resources.Load` for text assets, images imported as one sprite, audio clips and prefabs, and `TextAsset` with `text` and `bytes`.

116.7.10. Follow cameras

- Cinemachine's `CinemachineBrain` and `CinemachineVirtualCamera` with a `CinemachineFramingTransposer` or a `CinemachineTransposer` body: a camera that follows its target with the offset, damping, dead zone and soft zone the scene sets.
- Several virtual cameras by priority, with a cut from one to the next, and `Follow` assigned from a script.

116.8. The same game on every target

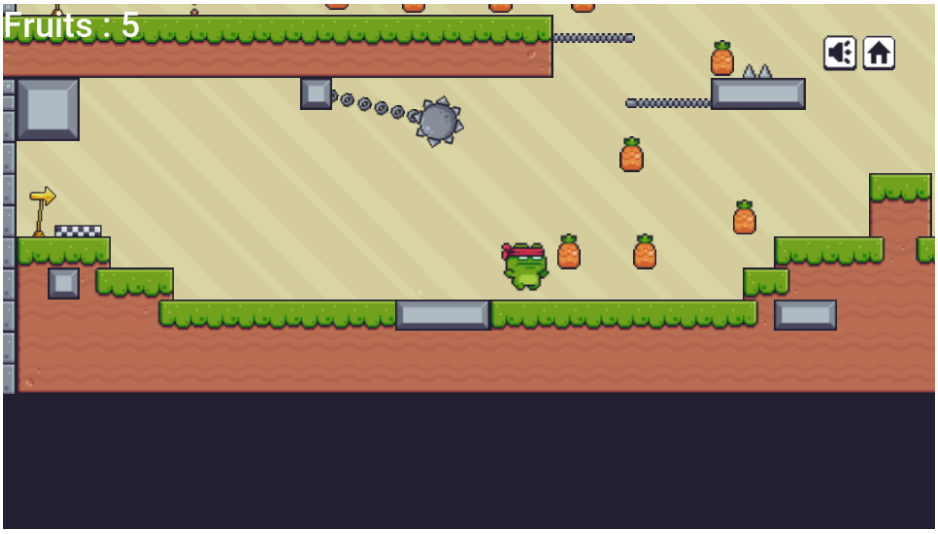
Arithmetic on `float` gives the same result on every target, and `UnityEngine.Random` produces the same sequence from the same seed. A game that's given a fixed seed and the same input plays the same way in the simulator, in a native build and in the browser.

That takes work in two places, because the targets don't agree by default. The C compiler that builds the iOS and desktop binaries may fuse a multiplication and an addition into one instruction that rounds once instead of twice, so the native builds turn that contraction off. A JavaScript number is a double, so on the JavaScript port every `float` result is rounded back to single precision before it's used.

The evidence is a trace comparison. Each game in the next section was run from a fixed seed with scripted input on three targets: a JVM, the C code ParparVM generates, and the JavaScript port under Node.js. Each run wrote a trace of the game's log lines, its object counts and its draw list, with positions in hundredths of a pixel and rotations in hundredths of a degree. The three traces of each game are byte for byte the same: 3,503 lines for Fruitopia, 220 for Asteroids, 852 for Pong, 244 for Snake and 445 for Sokoban. Fruitopia's run goes through its menu and its lobby, plays a level to the flag and returns to the lobby, 1,400 frames of animation, particles, tile map collisions and a follow camera. Asteroids moves more than 1,100 objects every frame, so one differently rounded multiply shows up in its trace within a few hundred frames.

`Random` is seeded from the clock unless you set a seed. To make a run repeatable, set the `unity.seed` display property before the game starts, for example `Display.getInstance().setProperty("unity.seed", "7")` at the top of the main class's `init` method.

116.9. Games that run



Five open source Unity games build and run with no change to their scripts, scenes or assets. Each is a repository its author published under the MIT license. They aren't part of Codename One; clone one and import it to try it.

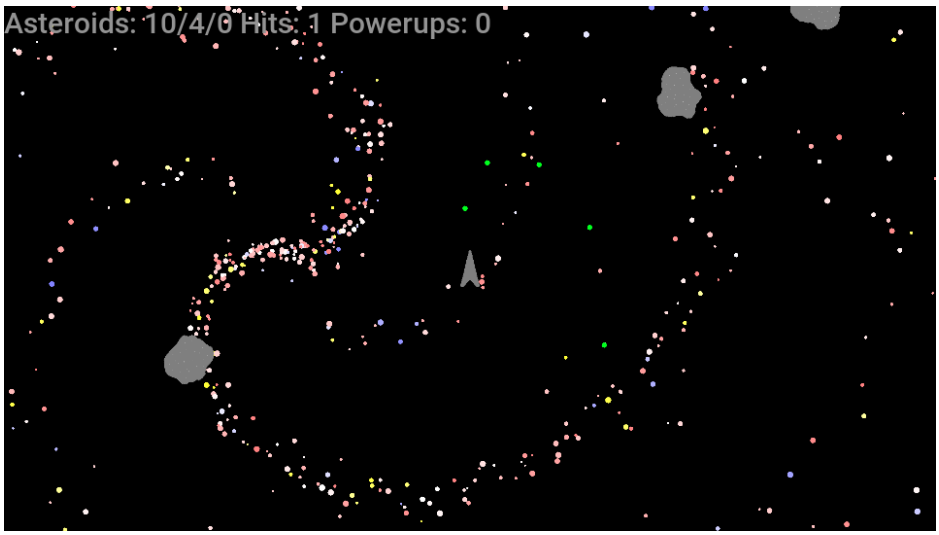
Every image in this section is a frame the Codename One runtime drew from the game's own scenes and sprites, at 960 by 540 pixels.

116.9.1. Fruitopia

`thisshrek/Fruitopia` [https://github.com/thisshrek/Fruitopia], MIT license, copyright 2024 Mohamed Kharrat. Twelve scripts, 733 lines. Its art is the Pixel Adventure set by Pixel Frog, released under CC0 and credited in the game's README.

A pixel-art platformer with a menu, a lobby and levels to run through: collect the fruit, avoid the traps, reach the flag. It's the widest test of the five. Its levels are tile maps with composite colliders and one-way platforms. Its hero, fruit, traps and menus are driven by 65 `Animator` components that play 40 clips. The dust behind the hero is a particle system, the labels are TextMesh Pro text, and a Cinemachine virtual camera follows the hero. The hero moves through `Rigidbody2D` and finds the ground with `Physics2D.OverlapBox`.

The text in these frames is in the platform's font rather than the game's font asset, which is how the runtime draws TextMesh Pro text.



The build reports six warnings for this project, and each names something the project itself is missing or does that Unity also drops. Two levels place a prefab whose file isn't in the repository, one object carries a script that isn't under `Assets`, and three objects carry a static class as a component. The menu, the lobby and the first level play from start to finish.

116.9.2. Asteroids

`sdxsharp/unity-asteroids` [https://github.com/sdxsharp/unity-asteroids], MIT license, copyright 2022 `sdxsharp`. Five scripts, 546 lines, saved by Unity 2021.3.

An arcade shooter that keeps between 1,157 and 1,180 objects alive, most of them the stars of its background. It exercises rigid bodies driven by velocity, polygon and circle colliders, collision

messages, prefabs instantiated and destroyed as the game runs, seeded `Random`, the input axes and a canvas with a score line.

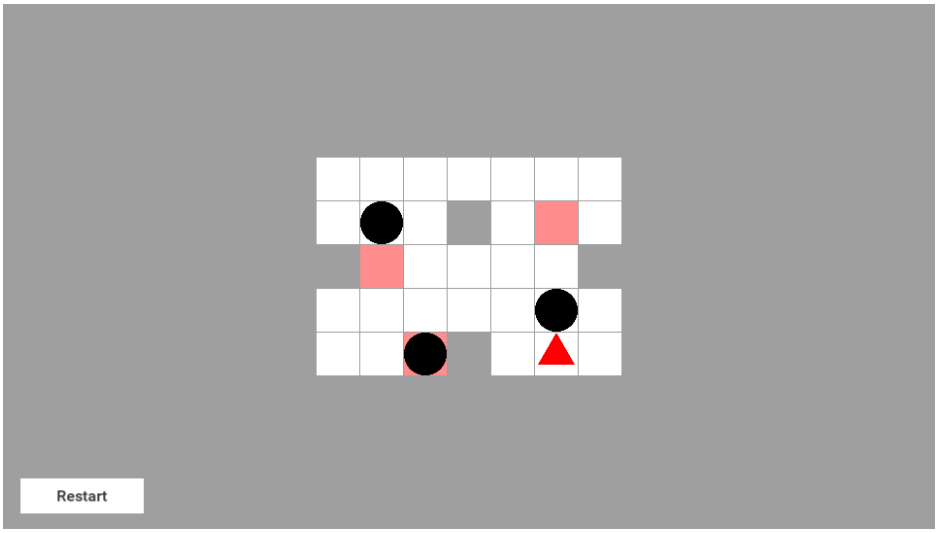
116.9.3. Pong

MalachiMackie/Unity-Pong [https://github.com/MalachiMackie/Unity-Pong], MIT license, copyright 2021 Malachi Mackie. Seven scripts, 557 lines, saved by Unity 2021.1.

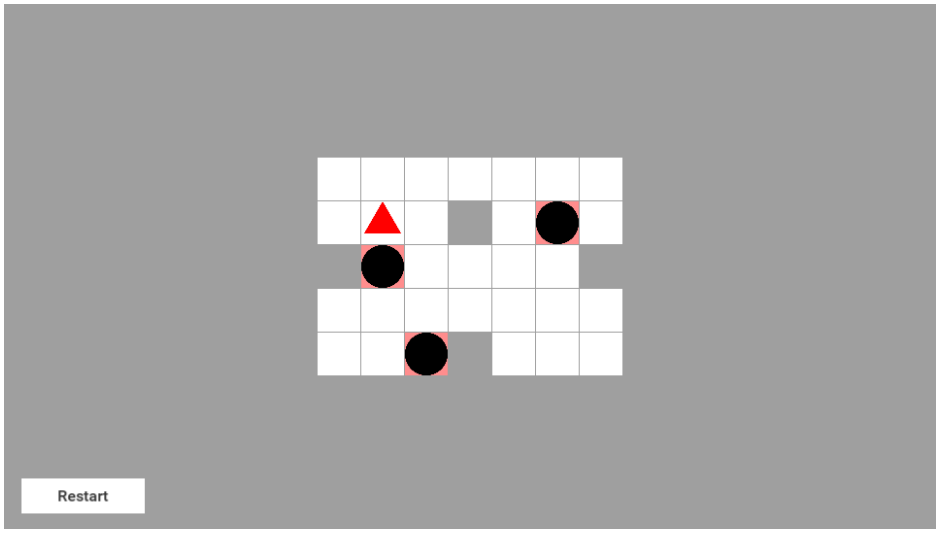
A two-player ball game. It uses prefab instances with property overrides, physics materials for the bounce, audio clips, C# events and delegates with tuple payloads, LINQ and switch expressions.

116.9.4. Snake

Wesley-Oliveira/Classic-Snake-Game-Unity-2D [https://github.com/Wesley-Oliveira/Classic-Snake-Game-Unity-2D], MIT license, copyright 2020 Wesley Oliveira. Two scripts, 184 lines, saved by Unity 2019.3.



A grid game with a menu. Its menu is canvas buttons whose `onClick` calls were set up in the Inspector, its record is kept in `PlayerPrefs`, and the snake moves on a coroutine that respects `Time.timeScale`.



116.9.5. Sokoban

`juwalbose/UnityTileBasedSokoban` [https://github.com/juwalbose/UnityTileBasedSokoban], MIT license, copyright 2017 Juwal Bose. One script, 264 lines, saved by Unity 2017.1.

A tile puzzle. The level is a text file loaded with `Resources.Load`, split and parsed into an `int[,]` grid, with the tile objects tracked in a `Dictionary<GameObject, Vector2>`. The script creates every tile as a `GameObject` with a `SpriteRenderer` it adds itself. The hero and the balls are polygon sprites, and the Restart button reloads the scene through a persistent call to `SceneManager.LoadScene`.

116.10. Measurements

The table covers the four smaller games above; Fruitopia follows it. The numbers measure the game and the compatibility runtime alone, in a harness that runs the game without a display: the same scripted run that produced the traces, three runs each, median reported. A shipped application adds the Codename One port for its platform on top.

Game	Objects alive	Native executable	JavaScript, gzip	Peak memory, native
Asteroids	1,157 to 1,180	1.33 MB	246 KB	15.7 MB
Pong	13	1.36 MB	244 KB	6.2 MB
Snake	26 to 31	1.33 MB	243 KB	5.1 MB
Sokoban	40	1.30 MB	241 KB	4.8 MB

- **Native executable** is the stripped macOS binary of the game, the runtime and the Java class library, translated to C by ParparVM and linked with link-time optimization.
- **JavaScript, gzip** is the script the JavaScript port loads for the same code, compressed with `gzip -9`.
- **Peak memory** is the most physical memory that native executable held over an 1,800-frame run, as `/usr/bin/time -l` reports it.

The translated code is small next to the runtime it runs on. Sokoban’s classes and the whole compatibility runtime pack into a 268 KB jar, of which the runtime is 252 KB. The games were measured against successive builds of the runtime, so a difference of 2% or 3% between rows isn’t significant.

Fruitopia is the largest of the five. These figures are from its scripted 1,400-frame run in the same harness. Between 59 and 80 objects are alive and each frame issues 350 to 500 draw commands.

- The compatibility runtime it ships with is 382 KB. The rest of its jar is the game’s own audio.
- The native executable, linked with link-time optimization and stripped, is 2.67 MB.
- The JavaScript for the same code is 387 KB after `gzip -9`.

- Peak memory over the run was about 10 MB for the native executable, about 99 MB on a JVM and about 176 MB under Node.js.
- On the JVM the simulation allocated under 2 KB per frame over the whole run, three scene loads included.

On speed: Asteroids, the heaviest of the four in the table, spent under half a millisecond of CPU per frame in the native build, simulation and draw list together, on a development machine that was busy with other builds. The other three were below what the timer resolves. Treat that as an order of magnitude and measure your own game on the device you ship for.

116.11. Scope and porting notes

The compatibility layer targets 2D games built from sprites, tile maps, 2D physics, animation controllers, particles, a canvas interface and scripts. This section lists what's outside that surface today, what the build does when it meets each item, and what to do about it.

116.11.1. How the build tells you

A port doesn't fail at run time for a reason the build could have named. There are four places it speaks up:

- A `UnityEngine` member the runtime doesn't have is a C# compiler error with the file and the line.
- A .NET base library member the runtime doesn't have stops the build at the translation step, with every such member listed at once and, under each, the script file, the line and the method that uses it.
- A component a scene has and the runtime doesn't is a warning that names the scene, the GameObject and the component. The component is left out and the rest of the scene still builds.
- A script method Unity would call by name and the runtime doesn't is a warning with the class, the method, the file and the line.

116.11.2. Rendering notes

- **3D.** Meshes, lights, 3D physics, shaders and materials other than the default sprite material are outside the scope. Their components are left out with a warning. A perspective camera is made orthographic, and a rotation about the x-axis or the y-axis is dropped, each with a warning.
- **Animation controllers.** The first layer of a controller is played, and the build warns when a controller has more. A state that plays a blend tree shows nothing, and a transition into a sub-state machine is left out, each with a warning. Give such a state a plain clip, or drive the blend from a script with `Play` and `CrossFade`. An override controller plays nothing, with a warning; assign `runtimeAnimatorController` from a script instead.
- **Animated properties.** A clip animates a sprite renderer's sprite, color and enabled flag, a transform's position, scale and rotation about z, and a GameObject's active flag. A curve on another property is left out with a warning that names it; set that property from an animation event or from `Update`.
- **Timelines** aren't run. Sequence the same steps in a coroutine.

- **Particle modules.** The main, emission, shape, and velocity, color, size and rotation over lifetime modules are simulated. Another module that's switched on, such as Noise, Collision, Trails, Sub Emitters or Texture Sheet Animation, does nothing, and the build warns for each. A system that emits from a mesh, a donut or a sprite emits from its own position, one that stretches its particles or draws meshes draws plain sprites facing the camera, and a system with `Prewarm` on starts empty. Of the modules a script can reach, `main`, `emission` and `velocityOverLifetime` are in the API.
- **Scripted tiles.** A rule tile or an animated tile isn't run. The cells a scene was painted with show the sprites the editor chose for them, and a cell a script sets with such a tile shows its default sprite, with a note. Use plain tiles for cells a script changes.
- **Line and trail renderers, sprite masks.** The components are left out with a warning. An effect made of short-lived sprite objects that a script instantiates and destroys carries over as it is.
- **Sliced and tiled sprites.** A nine-sliced or tiled `SpriteRenderer` or `Image` draws its sprite stretched, with a warning. A radial fill draws whole.
- **Built-in and package sprites.** The sprites that belong to the Unity editor or to a Unity package aren't in the project, so the build draws a plain rectangle or a white disc in their place and says so. Add your own sprite to the project to control the look.

116.11.3. Physics notes

- **Queries.** The casts and overlap tests are listed under What a project can use. `Physics2D.Distance`, `Collider2D.Raycast` and `Physics2D.GetRayIntersection` aren't in the API, so a script that calls one is a compile error. `Physics2D.Raycast` with a layer mask or a `ContactFilter2D` answers what `Collider2D.Raycast` is usually asked, and `OverlapPoint` at the pointer's world position does the job of `GetRayIntersection` in a 2D scene.
- **Edge radius.** An `EdgeCollider2D` with an edge radius collides as a thin line, with a warning. Use a capsule or a box collider where the thickness matters.
- **Continuous collision detection.** A body set to Continuous is swept so that it can't pass through a thin collider. The physics engine decides this for the whole world: one Continuous body makes it sweep the others too.
- **Joints and other effectors.** Joints are left out with a warning. `PlatformEffector2D` is the effector that's supported; a collider used by another effector collides as itself, with a warning. Apply the force of an area or point effector from `OnTriggerStay2D`.
- **Automatic mass.** A body set to **Use Auto Mass** uses the mass the file records, with a warning.

116.11.4. Script notes

- **Messages.** The runtime calls the messages listed under What a project can use. A method named for another Unity message, such as `OnBecameInvisible`, `OnMouseDrag` or `OnGUI`, compiles and is never called. The build warns for each one, with the class, the method, the file and the line, so the list is in the build output. A drag can be read in `Update` from `Input.GetMouseButton` and `Camera.ScreenToWorldPoint`.
- **Coroutine waits.** `WaitUntil`, `WaitWhile` and `WaitForSecondsRealtime` aren't in the API. A `while` loop around `yield return null` does the same job.

- **Scenes.** One scene is loaded at a time. `DontDestroyOnLoad` keeps a root object across a load, with everything below it and its running coroutines and pending `Invoke` calls. Called for a child object it logs a message and keeps nothing, as in Unity.
- **The base library.** The runtime implements the part of .NET listed above, not the whole library. `List<T>.Sort`, `StringBuilder`, format strings such as `ToString("F2")`, `float.Parse`, `HashSet<T>`, `Queue<T>`, `Stack<T>`, `DateTime` and `System.Random` are the ones a port meets first. The translation step lists each use; the usual replacement is a few lines in the script, such as a hand-written insertion sort or `UnityEngine.Random`.
- **Static fields of generic types.** Each constructed type has its own, as in .NET: `Singleton<GameManager>.Instance` and `Singleton<AudioManager>.Instance` are two fields, and a static constructor runs once for each. Three shapes can't be translated, and the build stops with the type, the method and the line: an instance method of a generic struct that reads its static fields, a virtual or interface generic method that reaches them through its own type argument, such as `Slot<T>.Value` inside `virtual T Read<T>()`, and a type that names itself with an ever-larger argument, such as `Chain<T>` calling `Chain<List<T>>`. Make the struct a class, make the method non-virtual, or keep that state in a non-generic class.
- **Reflection, `System.IO`, threads, `async` and `await`, networking and `unsafe` code.** None of these are translated. Keep saved data in `PlayerPrefs`, load bundled data with `Resources.Load`, and run timed work in coroutines. Networking belongs on the Java side of the application.
- **Compiled plugins.** Only C# source is translated. The import lists every `.dll` and native library under `Assets` as not built. Use the source of the library where its license allows.
- **Packages from the Package Manager.** The build compiles what's under `Assets`. Copy the source of a package the scripts need into `Assets`.
- **Serialized fields.** A field whose type is a serializable class of your own keeps the value its constructor gave it, and the build warns with the field's name. Make the type a struct, which is read, or assign the value in `Awake`.
- **Editor scripts and custom inspectors.** Scripts in an `Editor` directory are left out, the way Unity leaves them out of a player build.

116.11.5. Input notes

- **The Input System package.** The runtime implements the `UnityEngine.Input` class. A script written against the newer Input System package doesn't compile; read the same keys, axes and touches through `Input`.
- **Touch phases.** A touch goes through `Began`, `Moved`, `Stationary` and `Ended`. `Canceled` is never reported, so move the cleanup a script keeps there into `Ended`.
- **Joystick axes and the scroll wheel.** An axis the input settings bind to a joystick reads as zero, with a note, and so does `Mouse ScrollWheel`. The keys bound to the same axis work.
- **Space and Return.** The desktop port reports the space bar and the Enter key as one fire button, so on the desktop both `KeyCode.Space` and `KeyCode.Return` read as pressed when either is. A game that gives the two keys different meanings on the same screen sees both.

116.11.6. User interface notes

- **Controls.** `Canvas`, `CanvasScaler`, `Text`, `Image`, `Button`, `GraphicRaycaster` and `EventSystem` are supported. Another control of Unity's interface package — a slider, a toggle, an input field, a scroll view or a layout group — is left out with a warning that names the scene, the GameObject and the Unity type, and the build continues. A script field that pointed at the control is `null`, so guard the script's use of it. Replace the control with buttons and images, or show that screen with Codename One components around the game, where every Codename One control is available.
- **World Space canvases** aren't drawn, with a warning.
- **Fonts.** Text is drawn in the platform's font at the size, style and alignment the scene sets. A font asset the project names isn't used, which the build notes for each text.
- **TextMesh Pro.** TextMesh Pro text is drawn the same way: the platform's font at the size asked for, without the font asset, its material, an outline or rich text tags, with a note for the scene. Tags in a string are therefore drawn as written; keep them out of text shown here.
- **Button transitions.** Color tint is supported and changes at once rather than fading. A sprite swap or animation transition leaves the button looking the same in every state; it still works.
- **Keyboard navigation between controls** isn't implemented. Controls respond to the pointer.

116.11.7. Camera notes

- **Cinemachine.** A virtual camera follows its target through a framing transposer or a transposer, and the brain cuts between virtual cameras. Blends, aim behaviors, noise and extensions such as a confiner aren't implemented, which the build notes once for a scene. A look-ahead time on a framing transposer is ignored, with a note. To keep the camera inside a level, clamp its position in `LateUpdate`.

116.11.8. Audio and asset notes

- **Formats.** Clips are played by each platform's own media player, so try the game's sound files on every target you build for.
- **Pitch and looping.** A clip plays at its recorded speed whatever `AudioSource.pitch` says, and a looped clip restarts when it ends, which can leave a short gap.
- **`Resources`.** `Resources.Load` finds text assets, single-sprite images, audio clips and prefabs. `LoadAll` isn't in the API. An image sliced into several sprites isn't found by `Resources.Load`, with a note; refer to its sprites from a serialized field instead.
- **Asset bundles and the `Addressables` package** aren't supported. Refer to assets from a scene, a prefab or a `Resources` folder.
- **`Texture2D`** and run-time texture generation aren't in the API.
- **File names.** Images and sounds become application resources, which have no folders. Two images with the same file name in different folders both ship, each under a name of its own, and every sprite shows its own image. Two audio clips with the same file name still collide, and the build warns about each pair. Rename one.
- **Scripts that can't be components.** A scene that attaches a static class, an abstract class or a

class that isn't a `MonoBehaviour` as a component gets a warning, and the component is left out, as Unity leaves it out.

116.12. Troubleshooting

The build can't find the .NET SDK. The message names the three places it looked:

```
src/main/unity holds a Unity project, and compiling its C# scripts needs the .NET SDK, which was not found.
```

Install the SDK and put `dotnet` on the `PATH`, or pass `-Dcn1.unity.dotnet=/path/to/dotnet`. A .NET runtime without the SDK isn't enough, and the build says so when `dotnet --version` reports no SDK. An SDK older than version 6 is reported as too old.

The C# scripts don't compile. A script uses a `UnityEngine` type or member outside the runtime's API. The build prints the C# compiler's errors, each with its file, line and column:

```
The C# scripts in src/main/unity/Assets did not compile:
/work/mygame/common/src/main/unity/Assets/Scripts/Player.cs(14,38): error CS0117: 'Physics2D' does not contain a
definition for 'Distance'
```

The complete compiler output is in `dotnet.log`. Change the script, or check Scope and porting notes for the replacement.

The translation step fails. The scripts compiled, and they use a part of the .NET base library the runtime doesn't have. The translator lists every missing member, and under it each place that uses it:

```
The C# scripts in src/main/unity could not be translated:
error: the runtime library lacks 2 members the code uses:
  class  com/codename1/unitycompat/system/text/StringBuilder
      used by HighScores.cs:17, in HighScores::Print() : string
  method com/codename1/unitycompat/system/collections/generic/List_1.Sort()V
      used by HighScores.cs:12, in HighScores::Start() : void
```

The class after `unitycompat/system/` is the .NET class, and each `used by` line is the script file, the line and the method to change.

A control or a package component is left out. A scene or prefab has a component whose script isn't under `Assets`: an interface control outside the supported set, or a component of a Package Manager package. The build goes on and warns, once for the component and once for each script field that referred to it:

```
First.unity: GameObject 'Gauge' (component file ID 202) has a UnityEngine.UI.Slider component (script GUID
67db9e8f0e2ae9c40bc1e2b64352a6b4), and the compatibility runtime has no UnityEngine.UI.Slider; the component was left
out, and whatever refers to it is left null
First.unity: field gauge of the Keeper script on GameObject 'Keeper' (component file ID 102) refers to a
UnityEngine.UI.Slider component (script GUID 67db9e8f0e2ae9c40bc1e2b64352a6b4) of GameObject 'Gauge' (component file ID
```

```
202), which was left out; it was left null
```

Replace the control, or make the script check the field for `null`. For a package whose source you have, copying its scripts into `Assets` compiles them with the project. A scene the build settings list that isn't in the project is left out with a warning too.

A script method is never called. Unity calls some methods by name, and the runtime sends the ones listed under What a project can use. The build warns about any other:

```
Keeper.OnBecameInvisible (Keeper.cs:98): Unity calls this method by its name and the compatibility runtime does not send
the OnBecameInvisible message; the method is never called
```

A component is missing in the running game. Read the warnings of the last build that compiled the Unity project; a build that found the project unchanged doesn't repeat them. `translate.log` and `scene-compiler.log` in `common/target/unity` keep them, each prefixed `warning:` or `note:`.

The game looks or behaves differently. Check, in this order: the warnings in those two logs; the notes there about substituted sprites and fonts; and whether a script relies on something listed under Scope and porting notes. `Debug.Log` output appears in the simulator's console.

The main class wasn't updated by a second import. The import leaves a main class you changed after the first import untouched, and says so. Delete the class and import again to regenerate it.

116.13. Independent implementation

The runtime is an independent implementation of the parts of the Unity scripting API this chapter lists, written from Unity's public documentation and from the observable behavior of projects. It contains no Unity code and no Unity assemblies, and the build doesn't read or need a Unity installation. The same holds for the two packages the runtime answers for. Its TextMesh Pro and Cinemachine classes are Codename One's own implementations of the parts of those documented APIs this chapter lists, and contain no code from either package. Codename One isn't affiliated with or endorsed by Unity Technologies. Unity is a trademark of Unity Technologies.

Your scripts and assets stay under the terms you hold them under. Assets from the Unity Asset Store and other third parties have their own license terms. Check that those terms allow use outside the Unity engine before you ship a port that includes them.

Chapter 117. Writing applications and backends in Python

Python source builds as a Codename One application. The build translates each module to Java, compiles it with the rest of the project, and from there it goes wherever Java goes: iOS, Android, the JavaScript port, the desktop ports, the simulator, and native server binaries built on the Codename One backend.

No Python interpreter ships with the application. Each module becomes a Java class, each function a method, and a small runtime supplies Python's object model, its built-in types and the standard library modules applications use. Annotated code is compiled to unboxed Java arithmetic, so a typed numeric loop runs at the speed of the equivalent Java.

Two things follow from compiling ahead of time rather than interpreting:

- The program is known in full at build time. A module imported by a name computed while the program runs, `exec`, `eval` and `compile` of a string, and frame introspection are build errors that name the file and the line. None of them reaches a device as a hidden failure.
- Packages with C extensions are supported. The package's Python is translated like your own code, and each compiled module is replaced by a Java class with the same functions; see C extensions. The most used ones — `numpy`, `pydantic`'s core, `yaml`'s scanner — are already provided, as Codename One implementations of the same public API.

117.1. Adding Python to a project

Put the sources in `common/src/main/python`, or import an existing Python project into a Codename One application:

```
mvn cn1:import-python-project -Dsource=/path/to/my-python-app
```

The import copies the `.py` files, adds the Python runtime dependency and the `transpile-python` goal to the common module, records the entry module and makes the application's main class run it. Then build and run the project as usual; the translation runs in `generate-sources`. Gradle projects get the same step as the `transpilePython` task.

The goal reads these properties:

Property	Meaning
`cn1.python.sourceDir`	The Python sources, `src/main/python` by default.
`cn1.python.mainModule`	The module run as `__main__` when the application starts.
`cn1.python.outputDir`	Where the generated Java goes.
`cn1.python.skip`	`true` skips the step.

117.2. Debugging

The translated classes carry the Python source's file and line numbers in place of the generated Java's. A stack trace names the Python file and line:

```
com.codename1.python.runtime.PyException: ValueError: bad 6
    at com.codename1.generated.python.py_app$2eutil.M_L1_Thing_boom(util.py:7)
    at com.codename1.generated.python.py_main.lambda$exec$1(main.py:6)
    at com.codename1.generated.python.py_main.exec(main.py:10)
```

The same lines reach a Java debugger attached to the simulator or to a server binary run on the JVM. Each class also carries a JSR-45 source map whose default stratum, `Python`, gives the file's path within the source directory, for example `app/util.py`. Breakpoints are set by Python line number, and a debugger that resolves sources through the source map opens the `.py` file. With `jdb`:

```
jdb -sourcepath common/src/main/python -classpath ... MyAppStub
stop at com.codename1.generated.python.py_app$2eutil:6
```

The mapping is applied to the compiled classes by the build's `remap-compat` step (`cn1RemapCompat` in Gradle), so the generated Java in `target/generated-sources/python` still shows the Python line that each statement came from, as a `/* line N */` comment above it.

117.3. Calling Codename One and Java from Python

Any class on the project's class path is importable under the `java.` prefix:

```
from java.com.codename1.ui import Form, Button, Label, TextField, Dialog
from java.com.codename1.ui.layouts import BoxLayout

def main():
    form = Form("Hello Python", BoxLayout.y())
    name = TextField("", "Your name")
    out = Label("Hello, world!")

    def on_greet(event):
        out.setText(f"Hello, {name.getText().strip()}!")
        form.revalidate()

    button = Button("Greet")
    button.addActionListener(on_greet)
    form.add(name).add(button).add(out)
    form.show()

main()
```

A Python function or lambda passed where Java expects a listener or another single-method interface becomes an implementation of that interface. Overloads are chosen at build time when the argument types are known, and otherwise by the runtime from the values passed.

Values cross the boundary as follows:

Python	Java
`int`	`long`, or `BigInteger` past 64 bits
`float`	`double`
`bool`	`boolean`
`str`	`String`
`bytes`	`byte[]`
`None`	`null`
`list`, `dict`	`java.util.List`, `java.util.Map`

Java collections behave as their Python counterparts in Python code: `len`, indexing, `in` and iteration work on an `ArrayList` or a `HashMap`, and a Java exception arrives as a Python exception whose message names the Java type.

To call into Python from Java, import the module through the runtime and call its attributes. The build generates `com.codename1.generated.python.PythonModules`, which registers every translated module. When Python is the application's entry point, its main class calls `PythonModules.registerAll()` at startup; a Java application that uses Python as a library calls it once before importing anything:

```
PyModule pricing = Py.importModule("pricing");
Object total = Py.call(Py.getattr(pricing, "total"), cart);
```

117.4. Building the user interface in Python

The user interface is Codename One's, called from Python, so everything in the rest of this guide applies: layouts, themes and CSS, the component inspector, and the same look on every platform. The examples below are complete applications. Each is a `main.py` you can put in `common/src/main/python`.

117.4.1. A list loaded from the network

The first example fetches JSON with `requests` on a worker thread, shows a progress indicator while it waits and fills a list when the response arrives. Pull the list down, or tap the toolbar button, to load it again.

```
import threading

import requests

from java.com.codename1.components import InfiniteProgress, MultiButton
```

```
from java.com.codename1.ui import Display, FontImage, Form
from java.com.codename1.ui.layouts import BoxLayout

API = "https://api.github.com/repos/codenameone/CodenameOne/releases"

def fetch_releases():
    response = requests.get(API, params={"per_page": 20}, timeout=15)
    response.raise_for_status()
    return [(r["name"] or r["tag_name"], r["published_at"][:10]) for r in response.json()]

def show_releases(form, releases):
    form.removeAll()
    for name, date in releases:
        row = MultiButton(name)
        row.setTextLine2(date)
        row.addActionListener(lambda e, n=name: Display.getInstance().execute(
            "https://github.com/codenameone/CodenameOne/releases/tag/" + n))
        form.add(row)
    form.revalidate()

def load(form):
    progress = InfiniteProgress().showInfiniteBlocking()

    def work():
        try:
            releases = fetch_releases()
        except requests.RequestException as e:
            releases = [("Couldn't load releases", str(e))]
        # Components belong to the EDT: hand the result back to it.
        Display.getInstance().callSerially(lambda: (progress.dispose(), show_releases(form, releases)))

    threading.Thread(target=work, daemon=True).start()

def main():
    form = Form("Releases", BoxLayout.y())
    form.getToolbar().addMaterialCommandToRightBar("", FontImage.MATERIAL_REFRESH, lambda e: load(form))
    form.getContentPane().addPullToRefresh(lambda: load(form))
    form.show()
    load(form)

main()
```

Three conventions carry over from Codename One's Java API:

- Network calls run off the event dispatch thread. A Python thread is fine for that, and `callSerially` hands the result back to the thread that owns the components.
- A component added to a form that's already showing appears after `revalidate()`.
- A Python function goes wherever an `ActionListener` or a `Runnable` is expected. A default argument, as in `lambda e, n=name: …`, captures the loop's value for each row, as it would in any Python callback.

117.4.2. A model, two forms and storage

The second example keeps notes in SQLite through the standard `sqlite3` module, models them as a dataclass and moves between a list and an editor form. The editor saves when the user goes back, and asks before deleting.

```
import sqlite3
from dataclasses import dataclass
from datetime import date

from java.com.codename1.components import MultiButton
from java.com.codename1.ui import Button, Dialog, FontImage, Form, TextArea, TextField
from java.com.codename1.ui.layouts import BorderLayout, BoxLayout

@dataclass
class Note:
    id: int | None
    title: str
    body: str
    day: str

class Notes:
    def __init__(self, path: str = "notes.db"):
        self.db = sqlite3.connect(path)
        self.db.execute("CREATE TABLE IF NOT EXISTS note"
                        " (id INTEGER PRIMARY KEY, title TEXT, body TEXT, day TEXT)")

    def all(self) -> list[Note]:
        rows = self.db.execute("SELECT id, title, body, day FROM note ORDER BY id DESC")
        return [Note(*row) for row in rows]

    def save(self, note: Note) -> None:
        with self.db:
            if note.id is None:
                self.db.execute("INSERT INTO note (title, body, day) VALUES (?, ?, ?)",
                                (note.title, note.body, note.day))
            else:
                self.db.execute("UPDATE note SET title = ?, body = ? WHERE id = ?",
                                (note.title, note.body, note.id))

    def delete(self, note: Note) -> None:
        with self.db:
            self.db.execute("DELETE FROM note WHERE id = ?", (note.id,))

class NotesApp:
    def __init__(self):
        self.store = Notes()
        self.home = Form("Notes", BoxLayout.y())
        self.home.getToolbar().addMaterialCommandToRightBar("", FontImage.MATERIAL_ADD,
                                                            lambda e: self.edit(Note(None, "", "", str(date.today()))))
        self.refresh()

    def refresh(self):
        self.home.removeAll()
        for note in self.store.all():
            row = MultiButton(note.title or "Untitled")
            row.setTextLine2(note.day)
            row.addActionListener(lambda e, n=note: self.edit(n))
            self.home.add(row)
        self.home.revalidate()
```

```
    def edit(self, note: Note):
        form = Form("Edit", BorderLayout())
        title = TextField(note.title, "Title")
        body = TextArea(note.body, 8, 40)
        form.add(BorderLayout.NORTH, title).add(BorderLayout.CENTER, body)

        def back(e):
            note.title, note.body = title.getText(), body.getText()
            self.store.save(note)
            self.refresh()
            self.home.showBack()

        form.getToolbar().setBackCommand("", back)
        if note.id is not None:
            def delete(e):
                if Dialog.show("Delete", f"Delete '{note.title}'?", "Delete", "Cancel"):
                    self.store.delete(note)
                    self.refresh()
                    self.home.showBack()
            delete_button = Button("Delete")
            delete_button.addActionListener(delete)
            form.add(BorderLayout.SOUTH, delete_button)
        form.show()

    def start(self):
        self.home.show()

NotesApp().start()
```

The structure is the one a Python developer would write for any user interface toolkit: a storage class with no user interface code, and a class that owns the forms and turns model objects into components. `show()` moves forward to a form, `showBack()` returns with the reverse transition, and the toolbar's back command is also what Android's back button runs.

117.5. Libraries

The standard library modules applications use most are included: `json`, `re`, `datetime`, `decimal`, `fractions`, `collections`, `itertools`, `functools`, `dataclasses`, `enum`, `typing`, `inspect`, `asyncio`, `logging`, `pathlib`, `os.path`, `csv`, `struct`, `hashlib`, `base64`, `uuid`, `random`, `statistics`, `heapq`, `bisect`, `textwrap`, `string`, `argparse`, `tomllib`, `sqlite3`, `threading`, `queue`, `concurrent.futures`, `pickle`, `shelve`, `urllib.request`, `http.client`, `email.message`, `zlib`, `gzip`, `zipfile`, `zoneinfo`, `unittest` (with `unittest.mock`) and others. A small `pytest` is included as well: `raises`, `approx`, marks, fixtures and parametrized tests.

These third party packages are provided, each tested against the output of the real package:

Package	Notes
`requests`, `httpx`	Over Codename One's network stack.
`pydantic`	Models, fields, validators, `TypeAdapter`, JSON round trips.
`attrs`, `python-dateutil`, `PyYAML`	

Package	Notes
numpy	ndarray of float64, int64 and bool with broadcasting, views, fancy indexing, ufuncs, reductions, sorting and numpy.linalg. The kernels are Java loops over primitive arrays. numpy.random draws from Python's generator, so its streams differ from NumPy's.
pandas	Series and DataFrame over the numpy subset: index alignment, selection with loc, iloc and masks, missing values, statistics and describe, groupby on one key, merge, concat, and CSV and JSON reading and writing. Printing matches pandas, including how long and wide frames are shortened. Date indexes, MultiIndex, pivot tables, categoricals and rolling windows aren't supported.
Pillow	PIL.Image in the RGB, RGBA, L, LA, P and 1 modes: conversion, cropping, rotation, pasting, channels and point operations, computed as Pillow computes them. ImageDraw draws points, lines, rectangles, ellipses, polygons and text. On a server, decoding and encoding PNG and JPEG, resizing and text use the backend's com.codename1.backend.image package and give Pillow's exact pixels: every resizing filter, LANCZOS and BICUBIC included, matches Pillow, ImageFont.truetype loads TrueType fonts and ImageFont.load_default() returns the scalable Aileron font. Text follows Pillow's basic layout without hinting, so at small sizes a glyph can sit a pixel away from where Pillow puts it. On a device, decoding, encoding, resizing and text go through Codename One's image support (Image, ImageIO, Graphics and the native font), which also reads GIF, BMP and WebP. ImageFont.truetype loads the font through Font.createTrueTypeFontFromData where the platform supports it and falls back to the native font elsewhere, and ImageFont.load_default() is the native font. Those results are drawn by the platform, so they look right but aren't Pillow's exact pixels.
flask, fastapi, uvicorn	See Python backends.

117.5.1. Packages from PyPI

cn1:import-python-project installs the project's requirements, read from pyproject.toml and requirements.txt, from PyPI. Each requirement and everything it depends on is resolved to the newest release its version specifiers accept, its download is checked against the SHA-256 PyPI publishes, and its Python sources go into common/src/main/python-packages. The build translates that directory together with src/main/python. Requirements on packages the runtime already provides, such as requests or numpy, aren't downloaded.

The versions chosen are recorded in python-packages/python.lock. Importing again installs the same versions, so a dependency changes only when you delete its line from the lock, or the file itself, and import again.

Property	Meaning
`cn1.python.offline`	`true` lists the requirements without downloading them.
`cn1.python.index`	Another index that serves PyPI's JSON API, such as a company mirror.

You can also copy a package's sources into the source directory by hand; they translate like the application's own modules.

117.5.2. C extensions

A package with a C extension is supported. Its compiled modules are what CPython loads from C; everything around them is ordinary Python. The build translates that Python as usual, and each compiled module is replaced by a Java class that registers the same functions. Most C extensions are small accelerators or thin wrappers over a system facility, so the Java is usually short, and often a call into a Codename One API that already does the job.

The import finds the compiled modules (`.so` and `.pyd` files in a wheel, `.pyx` sources in a source distribution) and the names the package's Python uses from each one. For every module it generates a class in `common/src/main/java/com/codename1/python/ext` with a stub per function, and lists it in `python-packages/cn1-native-modules.properties`:

```
public final class MarkupsafeSpeedups {
    public static void install() {
        new NativeModule("markupsafe._speedups")
                .function("escape", args -> {
                    throw NativeModule.notImplemented("markupsafe._speedups.escape");
                })
                .install();
    }
}
```

Replace each stub's body with Java. The functions receive plain Java values (a `Number` for an `int` or a `float`, `String`, `byte[]`, `java.util.List` for a list or tuple, `java.util.Map` for a dict, `null` for `None`) and return the same kinds; an `Object[]` comes back to Python as a tuple. Raise a Python exception with `Py.error(Py.TYPE_ERROR, "…")` and its siblings, and use `NativeModule.raw` for a function that needs the Python objects themselves. Until a stub is filled in, calling it raises a `NotImplementedError` that names it. The import never overwrites a class that already exists, so importing again keeps your code.

Many packages ship a C accelerator together with a pure Python version of the same code, and import the compiled module inside `try: … except ImportError:`. When every import of a compiled module is guarded that way, the import reports it as optional and generates nothing: the pure Python version runs instead.

117.5.3. Threads

`threading`, `queue` and `concurrent.futures` run on Java threads. As in CPython, one global interpreter lock serializes Python code: it's released while a thread sleeps, waits on a lock, a queue or a future,

or waits for a network response, so threads help with blocking work and not with computation. `ProcessPoolExecutor` is accepted and runs its tasks on threads.

Codename One's user interface belongs to its event dispatch thread. Python code started by the application runs on that thread, so update components from a worker thread with `Display.getInstance().callSerially`, as Java code does.

117.5.4. `sqlite3`

`sqlite3` runs on the platform's own SQLite through Codename One's `Database`. On iOS, Android and the simulator a value comes back in the storage class SQLite recorded for it. The Linux, Windows and JavaScript ports don't report storage classes, so a value comes back as an `int` or a `float` when its text is a number, and as a `str` otherwise.

117.6. Python backends

A Flask or FastAPI application builds into a single native server executable. The application starts the server the way it always does:

```
from flask import Flask, jsonify

app = Flask(__name__)

@app.get("/fib/<int:n>")
def fib(n):
    a, b = 0, 1
    for _ in range(n):
        a, b = b, a + b
    return jsonify({"n": n, "fib": str(a)})

if __name__ == "__main__":
    app.run(host="0.0.0.0", port=8080)
```

`app.run()` and `uvicorn.run(app)` are lowered onto the Codename One backend's HTTP server, so the same file still runs under CPython for development:

```
scripts/python-backend/build.sh scripts/python-backend/samples/flask-todo ./todo-server
./todo-server
```

Routing, converters, JSON bodies, `abort`, error handlers and the default error pages of Flask, and FastAPI's path, query, body and header parameters, dependencies, `response_model` and OpenAPI generation are supported, and Flask sessions, `flash`, Jinja templates (`extends`, `block`, `include`, macros, `call`, `import`, `filter` blocks, loops, conditions and the common filters, with autoescaping), multipart file uploads and streamed responses work as well. A streamed response is sent chunk by chunk as its generator yields. Session cookies use Flask's own `itsdangerous` format, so a server built here and

one running under CPython read each other's sessions when they share a secret key.

FastAPI middleware works as in Starlette: `@app.middleware("http")`, `BaseHTTPMiddleware` subclasses, `CORSMiddleware`, `GZipMiddleware` and `TrustedHostMiddleware`. WebSocket endpoints are supported, including `TestClient.websocket_connect`. A WebSocket endpoint runs on a real asyncio event loop, so it can await `asyncio.sleep`, tasks and queues while its socket is open, and pure ASGI middleware sees WebSocket connections as it does in Starlette. Denying a connection answers with the status the endpoint or middleware chose, such as 403.

117.6.1. SQLAlchemy

SQLAlchemy's Core and ORM run over the platform's SQLite, and on a backend over the PostgreSQL, MySQL and MariaDB drivers the Codename One backend ships. The engine URL picks the database, as it does under CPython:

```
import os
from sqlalchemy import ForeignKey, String, create_engine, select
from sqlalchemy.orm import (DeclarativeBase, Mapped, Session, mapped_column,
                            relationship, selectinload)

class Base(DeclarativeBase):
    pass

class Author(Base):
    __tablename__ = "authors"
    id: Mapped[int] = mapped_column(primary_key=True)
    name: Mapped[str] = mapped_column(String(80))
    books: Mapped[list["Book"]] = relationship(
        back_populates="author", cascade="all, delete-orphan")

class Book(Base):
    __tablename__ = "books"
    id: Mapped[int] = mapped_column(primary_key=True)
    title: Mapped[str] = mapped_column(String(200))
    author_id: Mapped[int] = mapped_column(ForeignKey("authors.id"))
    author: Mapped[Author] = relationship(back_populates="books")

engine = create_engine(os.environ.get("DATABASE_URL", "sqlite:///library.db"))
Base.metadata.create_all(engine)

with Session(engine) as session:
    session.add(Author(name="Ursula", books=[Book(title="The Dispossessed")]))
    session.commit()
    query = select(Author).options(selectinload(Author.books)).order_by(Author.id)
    for author in session.scalars(query):
```

```
        print(author.name, [b.title for b in author.books])
```

Declarative models with `Mapped` annotations, relationships in both directions (including many-to-many and cascades), `selectinload` and `joinedload`, joins, aliases, subqueries, common table expressions, unions, single and joined table inheritance and `text()` queries are supported. `Numeric` columns come back as `decimal.Decimal` and `DateTime` and `Date` columns as `datetime` values on every database. A `text()` query has no column types, so on a server database its numbers and dates come back as the text the server sent. SQLAlchemy's own drivers, such as `psycopg`, aren't used: the URL `postgresql+psycopg://` selects the backend's driver.

117.6.2. Stack size

Every request runs on a virtual thread with 1MB of C stack, because transpiled Python frames are large and `re` recurses. A handler that recurses deeper than that raises it with a build hint in `codenameone_settings.properties`, in bytes or with a `KB` or `MB` suffix:

```
codename1.arg.python.virtualThreadStack=2MB
```

`CN1_HTTP_VT_STACK` can still raise it when the server starts, and the larger of the two applies.

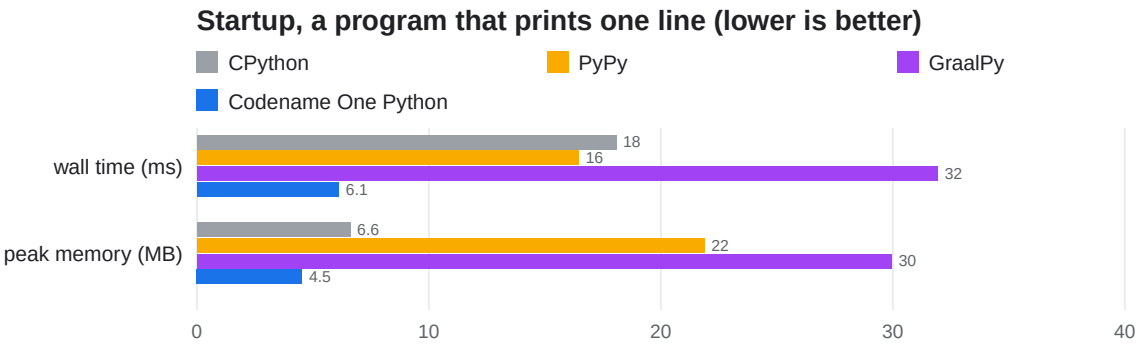
117.7. Compared with CPython, PyPy and GraalPy

The same programs, run on one Apple Silicon Mac with `scripts/python-compare/compare.py` and `scripts/python-compare/common_compare.py`. Codename One rows are native executables. The interpreters are CPython 3.14, PyPy 3.11 (7.3.20) and GraalPy 3.13 (Community edition 25.4, on its own JVM). Every program runs in a process of its own. Memory is the process's physical footprint, the figure the operating system meters a process by and the one a memory limit is measured in, read the same way for every runtime.

117.7.1. One binary, two trade-offs

Every Codename One figure below appears twice, from the same executable.

Codename One is the program on a machine with memory to spare. Its collector adapts to the load. While collecting costs the program little CPU it keeps the heap close to what the program uses. When the program is busy enough that more frequent collections would cost it throughput, it lets the heap grow instead: idle memory on the machine earns nothing, and the speed it buys is real. That's a choice the runtime makes because the memory is there, not a size it needs.

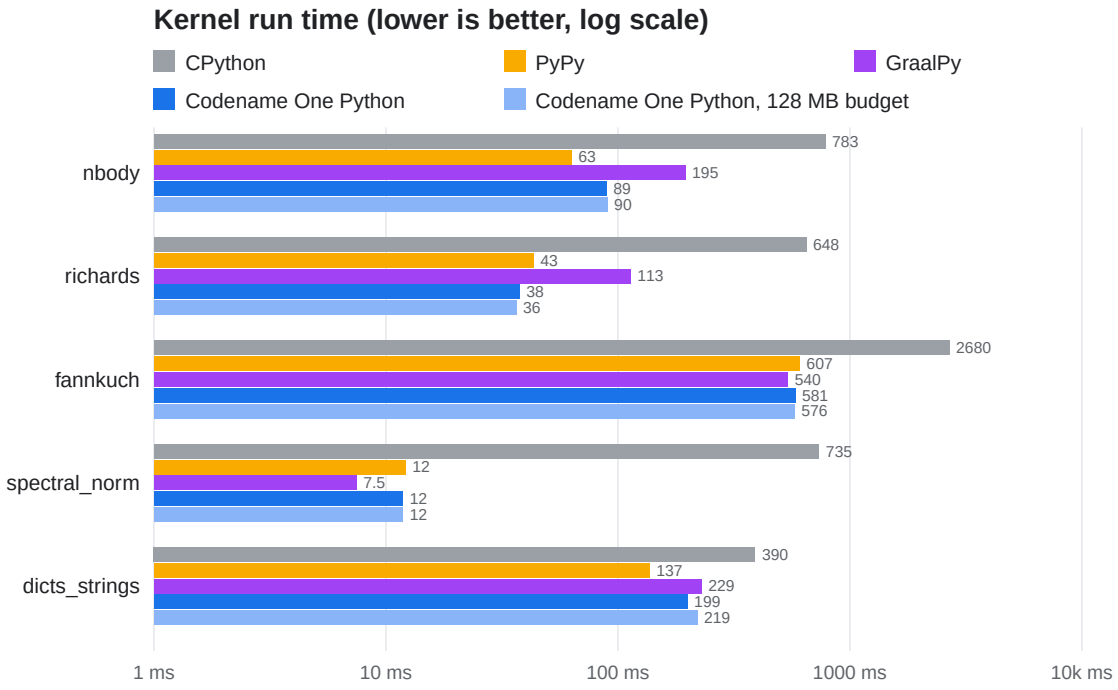


Codename One, 128 MB budget is the same executable given a memory limit, the way a container, a small cloud instance or a phone would give it one. With a budget, the collector stops spending memory for speed: it keeps the heap tight, and paces allocation so the process stays inside the limit. The budget is a hard cap, not a target: when the limit is near, a thread that needs memory waits for the collector rather than going over. The trade flips, and the program gives back some speed to use less memory.

Collecting garbage has a cost, and at high throughput it shows: under a budget, more of the CPU

goes to the collector instead of the program. The server figures below make that visible.

117.7.2. Startup

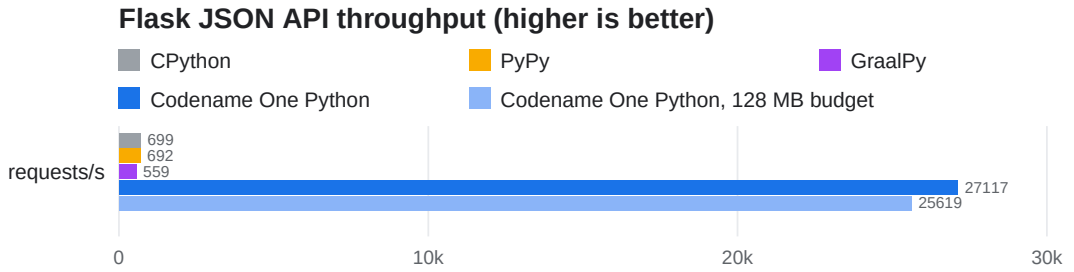


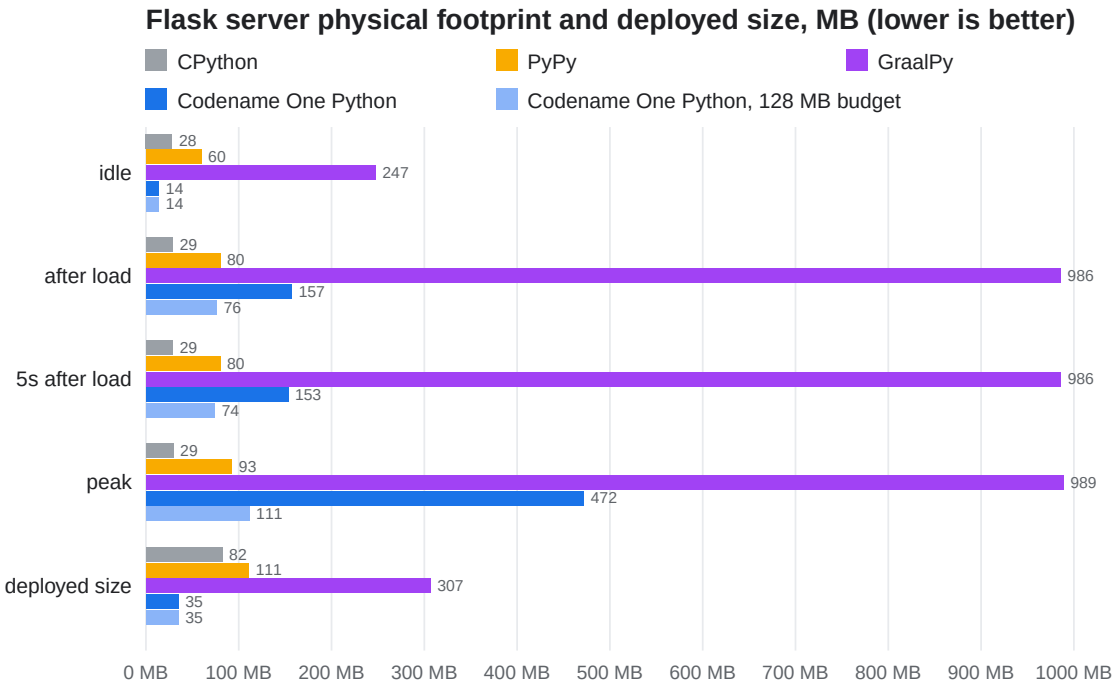
A program that prints one line, best of ten runs:

	Wall time (ms)	Peak footprint (MB)
CPython 3.14	18.1	6.6
PyPy 3.11	16.5	21.9
GraalPy 3.13	31.9	30.0
Codename One	6.1	4.5

117.7.3. Python kernels

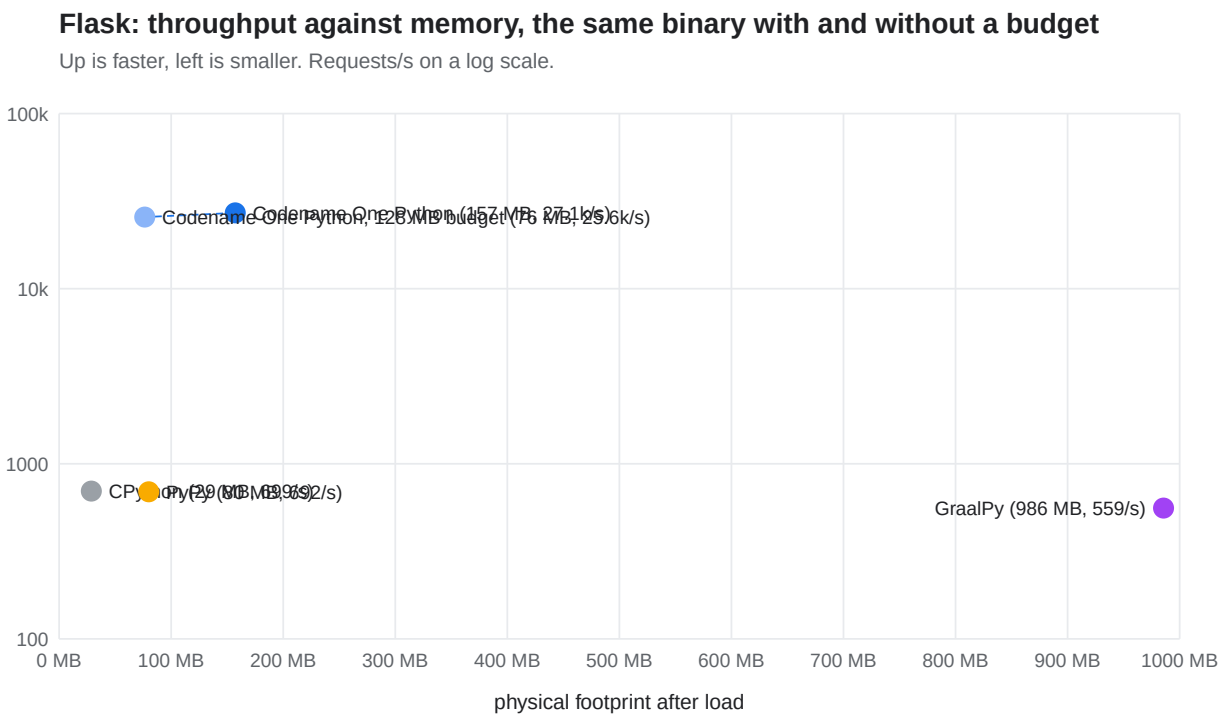
Classic benchmark programs written for Python (`scripts/python-bench/kernels`), fastest round in milliseconds, then peak footprint in MB:





Kernel	CPython 3.14		PyPy 3.11		GraalPy 3.13		Codename One		Codename One, 128 MB budget	
nbody	783	7.1	63	22.7	195	126	89	5.1	90	5.1
richards	648	7.6	43	24.5	113	157	38	5.3	36	5.4
fannkuch	2680	6.9	607	23.2	540	138	581	5.1	576	5.1
spectral_norm	735	6.9	12	22.5	7.5	146	12	5.1	12	5.1
dicts_strings	390	53.5	137	90.1	229	294	199	122	219	88

The numeric kernels allocate almost nothing, so the budget changes nothing there. `dicts_strings` builds large dictionaries and strings, and shows the trade in miniature: under the budget it gives up about a tenth of its speed for more than a quarter less memory.



117.7.4. A Flask server

The Flask sample above, under thirty seconds of `ab -c 8` after a warm-up. Every server gets the same length of load rather than the same number of requests, so a fast server isn't measured before its collector has settled. Footprint is read when the load ends, again five seconds later, and at its peak. Each server runs the way `app.run()` starts it: Werkzeug's threaded server under CPython, PyPy and GraalPy, and the native backend server under Codename One, which lowers the same call onto it.

	First response (ms)	Requests per second	p99 (ms)	Idle (MB)	After load (MB)	5 s later (MB)	Peak (MB)
CPython 3.14	115	699	12	28.1	28.8	28.8	29.4
PyPy 3.11	305	692	15	59.7	80.0	80.0	92.6
GraalPy 3.13	906	559	38	247.4	985.6	985.8	988.6
Codename One	66	27,117	2	14.0	157.2	153.2	471.9
Codename One, 128 MB budget	27	25,619	2	13.9	76.4	74.2	111.4

Why these numbers are suspicious

Read that table with suspicion. Codename One serves 37 times as many requests as CPython, and the gap doesn't fit anything else on this page. On the kernels above, Codename One runs about as fast as PyPy, and PyPy is many times faster than CPython. Yet here PyPy serves 692 requests a second and CPython 699: the interpreter that runs Python several times faster gains nothing. When a faster engine doesn't move the result, the engine isn't what's being measured.

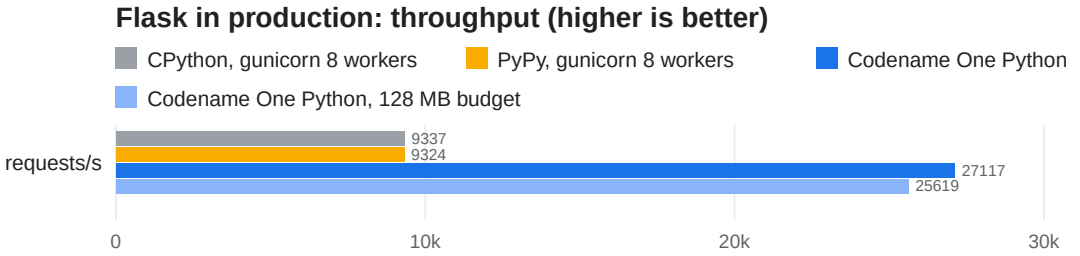
How the cause was found

Three measurements found what was being measured instead.

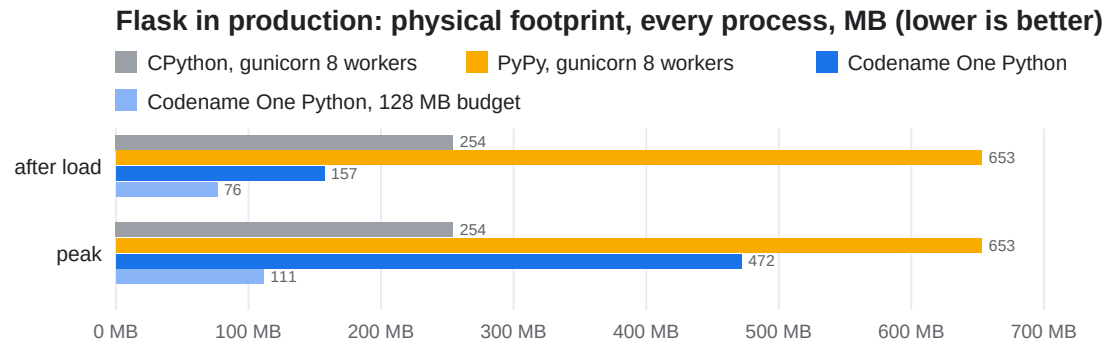
First, Flask alone, with no server. `scripts/python-compare/flask_cost.py` sends the same request through Flask's test client, which calls the application directly without a socket, so it times only the routing, the view and the JSON response. On one core CPython handles about 14,000 of these requests a second, PyPy about 28,500 and GraalPy about 5,800. Flask is fast enough on every interpreter: under `app.run()`, 95% of each request's time went somewhere else.

Second, concurrency. With one connection at a time Werkzeug's server answered 86 requests a second, with 8 connections 686, and with 32 connections 2,707. Throughput rose in step with the number of connections while the server used about a tenth of one core. A server bound by computation stops scaling once its core is busy; this one was mostly waiting.

Third, one request timed by hand: send it, then note when the first byte of the response arrives and when the server closes the connection. The response arrived after 0.4 ms. The server closed the connection about 12 ms after that.



The 12 ms is in `werkzeug/serving.py`. After every response the development server drains whatever the client might still be sending, so that a client whose upload was too large sees the error page rather than a reset connection. It keeps reading until a `select` with a 10 ms timeout finds nothing more, so every connection stays open for at least 10 ms after its response. `ab` speaks HTTP/1.0 and



counts a request as done when the server closes the connection. Eight connections that each take about 12 ms come to about 670 requests a second, whichever interpreter runs the Python. That's the number CPython and PyPy both reached.

The Werkzeug documentation is clear that its server is for development, so none of this is a defect. It means the table above compares Codename One's production server with Python's development server.

A fair comparison

In production a Flask application runs behind a WSGI server such as gunicorn, with several worker processes: each worker is a whole interpreter, and they handle connections in parallel. The rows below serve the same application with `gunicorn -w 8`, under the same load. Their footprint is the master process and all eight workers added together, because that's what the machine pays for. GraalPy is missing: gunicorn imports the `grp` module, which GraalPy doesn't provide.

	Requests per second	p99 (ms)	After load (MB)	Peak (MB)
CPython 3.14, gunicorn 8 workers	9,337	1	254.2	254.2
PyPy 3.11, gunicorn 8 workers	9,324	2	653.2	653.2
Codename One	27,117	2	157.2	471.9
Codename One, 128 MB budget	25,619	2	76.4	111.4

Behind gunicorn, CPython serves 13 times as many requests as it did under `app.run()`. Codename One under its budget still serves 2.7 times as many, in 30% of CPython's memory and 12% of PyPy's. That's the gap to plan around: about three times the throughput, not 37 times, and a fraction of the memory.

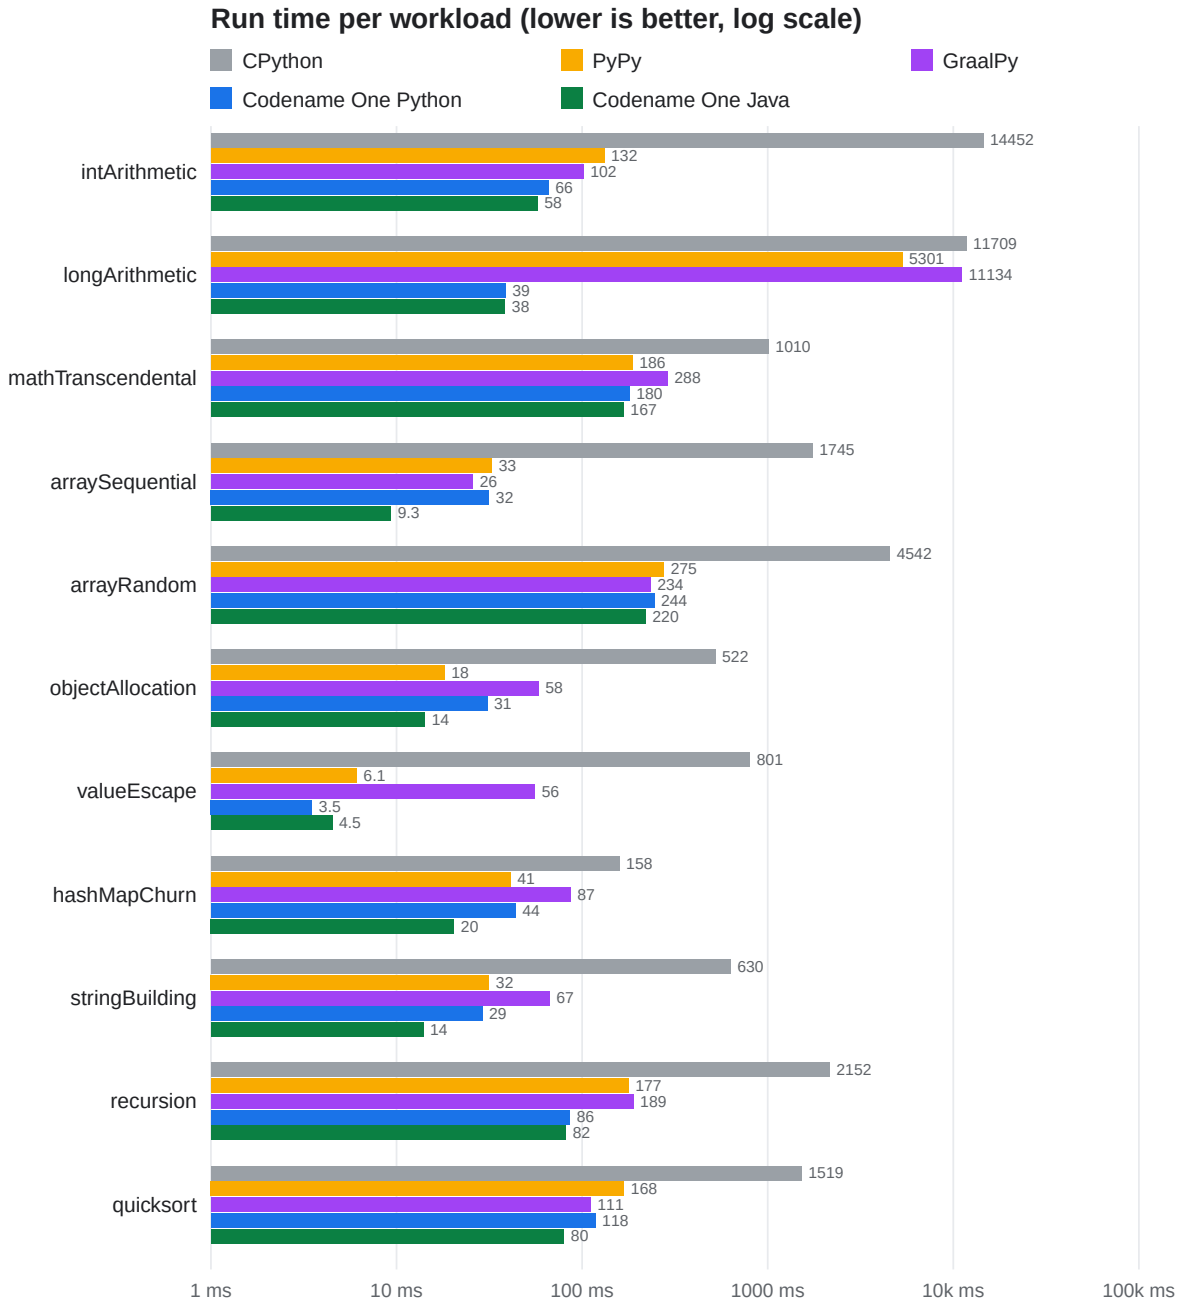
What the fair comparison means

The difference comes from how each server is built, more than from how fast each runs Python:

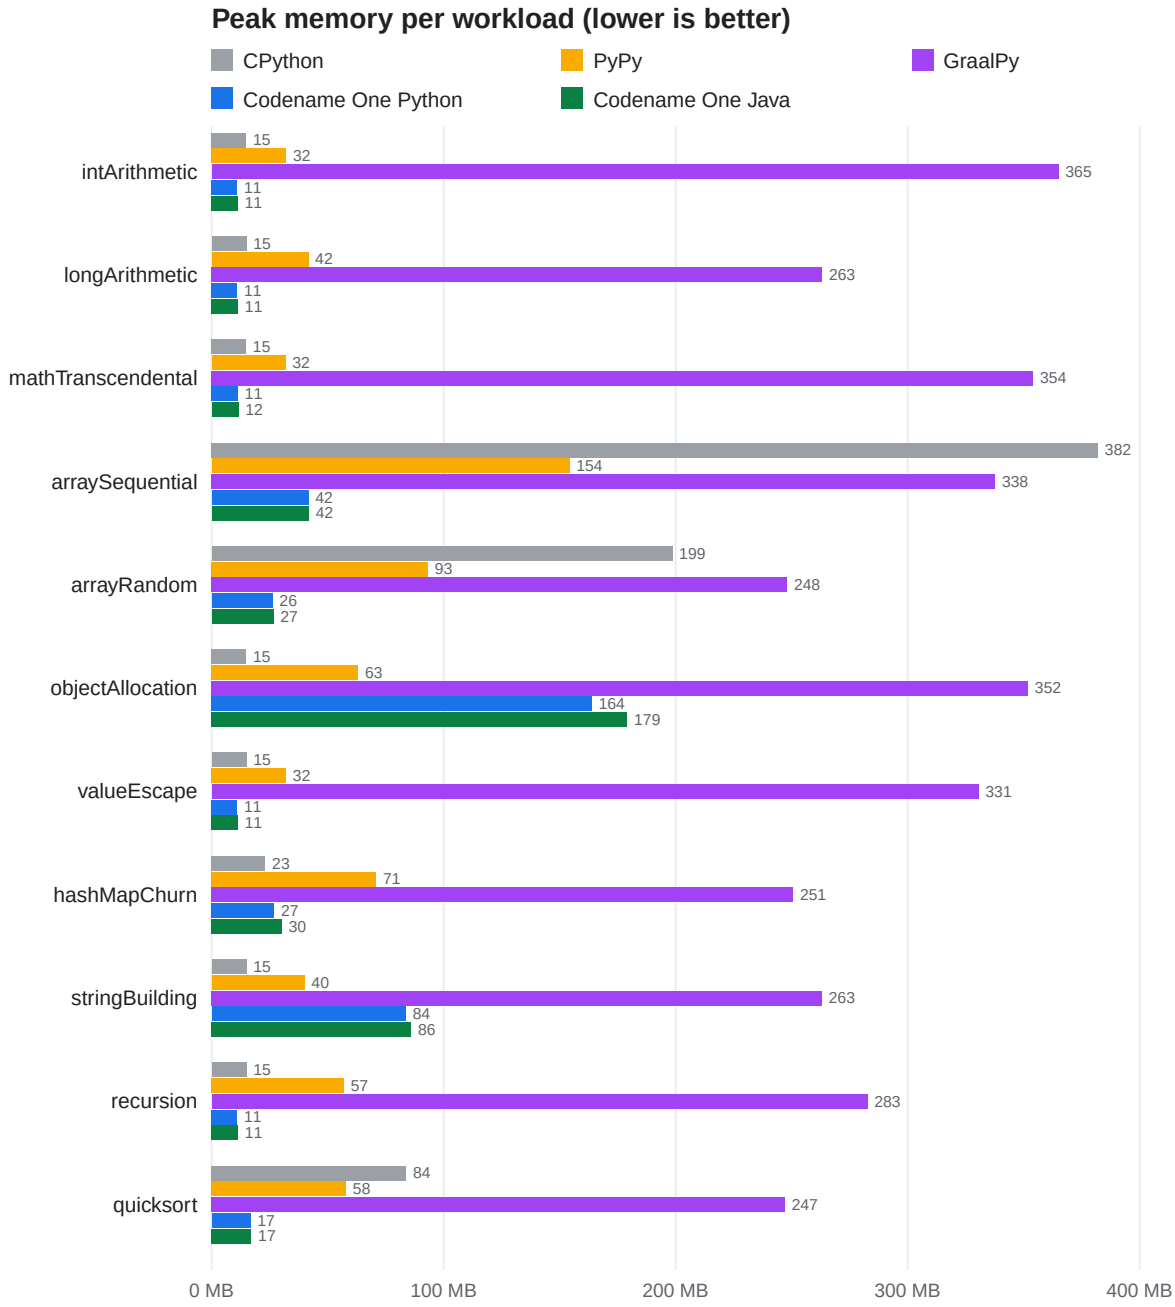
- **One process instead of eight.** Gunicorn gets its parallelism by running a whole interpreter per worker, and each one costs 30 MB under CPython and more than 70 MB under PyPy. Codename One serves every connection from one process.
- **The server is native code.** Codename One accepts connections, parses requests and writes responses in compiled code, outside the global interpreter lock, on several threads at once. Only the view itself runs as Python, one thread at a time, as under CPython.
- **Python runs compiled.** The view and Flask's routing run as compiled code, at PyPy's speed or close to it, from the first request, with no JIT to warm up.

PyPy and CPython reach the same throughput behind gunicorn too, although PyPy runs Flask's own code about twice as fast, so with eight workers the Python code isn't the limit for either of them. What PyPy does change is memory: its eight workers, each with its own JIT, use two and a half times CPython's.

	Deployed size (MB)
CPython 3.14	82.2
PyPy 3.11	110.5
GraalPy 3.13	305.8
Codename One	35.0



The deployed size is the interpreter's installation plus Flask and its dependencies (and gunicorn, under 1 MB), against the one executable.



Where an application needs CPython instead: code that builds source text and runs it with `exec`, and packages whose C code is the bulk of the package rather than an accelerator under its Python, such as `scipy` or `torch`. Replacing those means writing a numerical library in Java, not a few functions.

117.8. Python against Java on Codename One

The workloads below are the ones every Codename One port is measured with, `com.bench.CommonWorkloads`, ported line by line to Python in `scripts/python-bench/common`. Each one returns a checksum, and every runtime has to return the checksum Java returns, so all five columns compute the same thing. The Python port reproduces Java's 32 and 64-bit wrap-around with masks, since a Python `int` never overflows.

The **Codename One Java** column is the Java original compiled by Codename One into the same executable. It's the floor: the speed and memory Codename One reaches for this work when written in Java, and the target for the same program written in Python.

What the numbers say:

- **Python reaches Java's memory.** On every workload the compiled Python uses about the memory the Java program uses, and sometimes less: integers, floats and integer lists are held unboxed, a list of integers that fit 32 bits takes four bytes an item as a Java `int[]` does, and objects that don't escape a function are never allocated.
- **And mostly its speed.** Six of the eleven run within 15% of Java, among them the arithmetic, recursion and the transcendental math; the rest take 1.5 to 3.4 times as long. What remains is the cost of a Python `int` being unbounded: where the compiler can't prove a value stays within 64 bits, the generated code carries the check and a slow path Java doesn't need.
- **Against the interpreters.** Codename One Python is the fastest of the four Python runtimes on six workloads and within 10% of the fastest JIT on three more, without a warm-up; GraalPy is faster at sequential array access and PyPy at allocating objects. It uses a third of PyPy's memory and a twentieth of GraalPy's on most of them. `longArithmetic` multiplies 64-bit values whose product needs 128 bits and masks it back: the interpreters compute it with arbitrary precision integers, and the compiler recognizes the wrap-around and computes it in a Java `long`.

117.8.1. Tuning a hot spot in Java

A profile usually shows a handful of functions that dominate the run time. Any of them can be rewritten as a Java method in the same project and called from Python like any other Java class. The rest of the program stays Python.

The integer kernel in Python:

```
M32 = 0xFFFFFFFF

def i32(v: int) -> int:
    return ((v + 0x80000000) & M32) - 0x80000000

def int_arithmetic() -> int:
    a: int = 0x12345678
    b: int = i32(0x9E3779B9)
    checksum: int = 0
    for _ in range(40000000):
        a = i32((a * 1103515245 + 12345) ^ ((b & M32) >> 3))
        b = i32((b + a) * 5 - (a << 7))
        checksum += (a ^ b) & 0xFFFF
    return checksum + a + b
```

The same function in Java, under `common/src/main/java`:

```
package com.codenameone.developerguide.python;

public final class CommonWorkloads {
    public static long intArithmetic() {
        int a = 0x12345678;
        int b = 0x9E3779B9;
        long checksum = 0;
        for (int i = 0; i < 40000000; i++) {
            a = (a * 1103515245 + 12345) ^ (b >>> 3);
            b = (b + a) * 5 - (a << 7);
            checksum += (a ^ b) & 0xFFFF;
        }
        return checksum + a + b;
    }
}
```

And the Python that calls it:

```
from java.com.codenameone.developerguide.python import CommonWorkloads

checksum = CommonWorkloads.intArithmetic()
```

The Java `int` wraps by itself, so the masks disappear and the loop compiles to a few machine instructions. In the run above that took the workload from 1.75 seconds to 65 milliseconds, faster than PyPy and GraalPy, in 11 MB.

Guidelines for choosing what to move:

- Measure first. Only a loop that dominates a profile is worth a second language.
- Move whole loops, not single operations. Every call across the boundary converts its arguments, so a Java method called once per element gains little; one called once per batch gains the most.
- Pass primitive values and Java arrays where possible. A Python `list` passed to Java arrives as a `java.util.List` of boxed values.
- Annotate the Python that stays. Codename One compiles functions whose parameters and locals have known types (`int`, `float`, `bool`, `str`, lists of them and classes with `slots`) to typed Java code. The rest takes the generic path, which is the one that CPython-like timings come from.

Chapter 118. Running Swing and JavaFX applications

An existing desktop application written with Swing and AWT, with the SwingX component set, or with JavaFX can build and run as a Codename One application without changes to its Java code. The desktop sources go into a Codename One project, the build maps them onto Codename One's implementation of the `java.awt`, `javax.swing`, `org.jdesktop.swingx` and `javafx.*` APIs, and the result runs on every Codename One target: iOS, Android, the web, the native desktop ports and the simulator.

No desktop Java runtime is involved. Buttons, text fields, check boxes, sliders and tabs are Codename One components that take the platform's theme, layout managers and layout panes run the rules they run on the desktop, and code that paints with `Graphics2D` or a JavaFX `Canvas` draws through Codename One's graphics.

118.1. Motivation

A Swing or JavaFX application that already works has three reasons to move.

It reaches every platform from one code base. The same sources build for iPhone and iPad, Android phones and tablets, the browser, and native Linux, macOS and Windows. Nothing is rewritten per platform, and the desktop version keeps its windows, menus, and keyboard.

It ships as one native program. A native desktop build is a single executable with no Java runtime to bundle, install, or update. It starts faster, holds less memory and downloads smaller than the same application with a trimmed Java runtime beside it. Section 118.14.1, "Size, memory and start-up" measures all three for eight applications, built both ways.

It gets the APIs desktop Java never had. The desktop sources compile next to the Codename One API and can call it directly, as Section 118.11, "Calling Codename One from desktop code" shows. That fixes several of the oldest pain points of Swing and JavaFX development:

What a desktop developer reaches for	What Codename One has
A camera, a microphone, the photo library	`Capture` takes photos, video and audio with the device's camera and microphone. See Section 88.7, "Capture - photos, video, audio".
An embedded browser without a heavyweight engine to ship	`BrowserComponent` is the platform's own web view, with a two-way bridge to JavaScript. See Section 8.28, "BrowserComponent & WebBrowser".
A local database	SQLite on every platform through `Database`, and an annotation-driven ORM over it. See Section 26.4, "SQL" and Annotation ORM Section.
JSON without a reflection library	`@Mapped` classes and `Mappers` convert objects to JSON and XML with code generated at build time. See Annotation Mapping Section.

What a desktop developer reaches for	What Codename One has
REST clients and OpenAPI	`Rest` for ad hoc calls, typed `@RestClient` interfaces, and `cn1:generate-openapi` to generate a client from an OpenAPI (Swagger) specification. See Section 26.7, “Rest API” and Section B.12, “Generate OpenAPI client (`generate-openapi`)”.
A server in the same language	A Java backend that shares its contract and data classes with the app. See Chapter 35, *Server-side backend* and Chapter 36, *Backend controllers, contracts and WebSockets*.
Styling without look-and-feel code	CSS compiled into a theme at build time, and applied live in the simulator as you save. See Section 118.7, “Styling and theming” and Chapter 16, *CSS*.
AI agents that can work with the app	Over the Model Context Protocol (MCP), an agent reads and drives a development build’s user interface, and a backend publishes tools for agents in production. See Chapter 90, *MCP Headless API* and Chapter 47, *Backend MCP and the agent loop*.

Push notifications, biometrics, maps, in-app purchase and the rest of the guide are available in the same way.

The layer implements the parts of each toolkit applications use, and the build tells you, file by file and line by line, about anything an application uses that it doesn’t implement (Section 118.5, “Unsupported API is a build error”). New code can use either API: the two live in one project.

118.2. Quick start

Create a Codename One application project (for example from the initializr [https://start.codenameone.com]), then import the desktop project into it:

```
mvn cn1:import-desktop-project -Dcn1.desktop.import=/path/to/MyDesktopApp
```

The goal accepts a Maven or a Gradle project. It copies the project’s `src/main/java`, `src/main/kotlin` and `src/main/resources` into `common/src/main/desktop`, generates the Codename One main class that starts the application (Section 118.3, “The entry point”), and lists what becomes of each of the project’s dependencies.

Two more parameters settle the cases the goal can’t decide for itself:

```
mvn cn1:import-desktop-project -Dcn1.desktop.import=/path/to/MyDesktopApp \
    -Dcn1.desktop.module=app \
    -Dcn1.desktop.mainClass=com.example.Main
```

`cn1.desktop.module` names the module to import when the project’s root has no sources and more than one of its modules does. `cn1.desktop.mainClass` names the class the application starts through when the project leaves more than one candidate. In both cases the goal stops before it copies

anything and lists the choices.

After that, run and build as you would any Codename One application. The sources are the same for every target:

```
mvn cn1:run                                  # the simulator
mvn cn1:buildIos                             # iOS, on the build server
mvn cn1:buildAndroid                         # Android, on the build server
mvn cn1:buildJavascript                      # the JavaScript port
mvn package -Dcodename1.platform=ios -Dcodename1.buildTarget=ios-source          # an Xcode project
mvn package -Dcodename1.platform=android -Dcodename1.buildTarget=android-source  # an Android Studio project
```

The simulator is the quickest place to see the application, and its skins show it at the size and density of a phone or a tablet. Every target and its options are in the Maven project workflow chapter.

118.2.1. Gradle

A Codename One project built with Gradle (see Chapter 3, *Gradle project workflow*) takes the same sources in the same place, `src/main/desktop`. When that directory exists the Codename One Gradle plugin adds the toolkit layers and runs the same build steps, with no configuration:

```
./gradlew run             # the simulator
./gradlew buildIos        # an iOS build on the build server
./gradlew buildLinuxDevice
```

118.2.2. Placing the sources by hand

The directory mirrors a desktop project's `src/main`:

```
common/src/main/desktop/
    java/        the desktop application's Java sources
    kotlin/      Kotlin sources, if the application has any
    resources/   images, .properties, .fxml and .css files
```

The `common` module's `desktop-compat` profile activates when `src/main/desktop` exists and adds the Swing and JavaFX layers. Only the layer the compiled classes use ships, so a Swing application doesn't carry the JavaFX runtime. A project created before the profile existed gets it from the import goal.

118.3. The entry point

A ported application is an ordinary Codename One application with an ordinary main class: a `Lifecycle` subclass in `common/src/main/java`. The import goal generates it, and its start-up calls the Swing application's `main`, or launches the JavaFX `Application`, on the Codename One event dispatch thread (EDT). That thread is also the Swing event dispatch thread and the JavaFX application thread.

The class is yours. Edit it to pass arguments, to set display properties before the first window opens (Section 118.8.4, “Display properties”), to show a Codename One screen first, or to start the desktop code only for some devices.

118.4. How the build works

Three ideas explain everything the build does:

- **The application is compiled once, against the desktop API, and relinked.** Swing code compiles against the JDK’s own `java.awt` and `javax.swing`, JavaFX code against a `javafx.*` API that ships with Codename One, which is why the sources need no changes. The build then points every reference at Codename One’s implementation. No source is translated and nothing is interpreted: each target compiles the result as it compiles any Codename One application, to native code on iOS and the desktop ports, to Android’s bytecode on Android, to JavaScript in a browser.
- **Only what’s used ships.** A layer is active only when the application’s classes name its API, and the native builds drop every class and method nothing reaches.
- **Nothing is found by reflection at run time.** FXML documents, style sheets, resource lists and resource bundles are compiled into code by the build. That’s what makes the same application run on iOS, and it’s also why it starts fast everywhere.

The JDK API that ordinary application code uses is available on every target: `java.io.File` and `java.nio.file`, regular expressions, the stream API, `java.time`, the executors and concurrent collections, `Optional`, `Properties`, `ResourceBundle`, logging and preferences.

118.5. Unsupported API is a build error

The build checks every reference in the compiled application, so a class, method, constructor or field that a layer doesn’t have stops the build. It never becomes a failure on a user’s device. The message names the API the way the source spells it, with the source file and line:

```
Compliance check failed with 2 forbidden API references.
See /projects/orders/common/target/codenameone/compliance_check.txt for the full report.
First 2 violation(s):
 - com/example/OrdersPanel#restyleTree()V -> javax.swing.JTree.getUI() is not supported by the Codename One Swing
compatibility layer (com/example/OrdersPanel.class) at OrdersPanel.java:48
 - com/example/NotesDialog#printNotes()V -> javax.swing.JTextArea.print() is not supported by the Codename One Swing
compatibility layer (com/example/NotesDialog.class) at NotesDialog.java:31
```

A project with more than a handful of such references gets a summary that groups them by kind and by library, and points at the port report.

118.5.1. The port report

Every build of a project that uses a desktop layer writes `target/codenameone/desktop-port-report.md`, whether the check passes or fails. It says how many of the application’s calls into Swing, AWT and JavaFX are supported, lists what to change source file by source file with a Codename One alternative where one exists, and says what became of each dependency. Set `cn1.desktop.report` to

write it elsewhere:

```
mvn package -Dcn1.desktop.report=port.md       # Maven
./gradlew build -Pcn1.desktop.report=port.md   # Gradle
```

To find out how well an application fits before changing a line of it, import it, build it and read the summary at the top of that report.

118.6. Porting a large application

A small application usually builds after the import. A large one usually needs some work, and widgets are seldom the reason: the user interface calls of a two-hundred-file Swing application, with FlatLaf for its look and a syntax-highlighting editor, built as written. The work is in the libraries and services around the user interface, and it goes in the order below.

118.6.1. Sort out the dependencies

The import keeps every dependency of the project. One that the layer implements itself — the JavaFX modules, SwingX, FlatLaf and RSyntaxTextArea — gets the `provided` scope: the sources compile against the real jar and the layer ships in its place.

Every other dependency is built with the application like any dependency of a Codename One application. Its classes aren't relocated onto a layer, so a library written against Swing, AWT or JavaFX — a layout manager such as MigLayout, an icon library, a component set — fails the check for unsupported API. Replace it with its Codename One equivalent, or bring its source into `src/main/desktop` beside the application's own, where it's relinked and checked like the rest. A library that isn't about user interfaces only has to use API a device has.

118.6.2. Use the Codename One equivalent

Where Codename One has an equivalent, the port report names it next to the finding. The common ones:

Desktop API	Use instead
`java.net.http`, `HttpURLConnection`	`Rest` or `ConnectionRequest`. For code written against `java.net.URL`, `com.codename1.io.URL` has the same shape, with `openConnection` and `openStream`. A REST API maps onto a typed `@RestClient` interface whose code is generated at build time, or onto one generated from its OpenAPI specification (Section B.12, "Generate OpenAPI client (`generate-openapi`)").

Desktop API	Use instead
`ProcessBuilder`, `Runtime.exec`	Supported on the desktop targets through Codename One's process API, `com.codename1.io.ProcessBuilder` and `Process`, which has the JavaSE shape (Chapter 27, *Desktop and Backend Processes*). Phones and the browser have no processes: to open a URL, a file or another application there, use `CN.execute(url)` after `CN.canExecute(url)`, or `Desktop.getDesktop().open(file)` and `browse(uri)` from Swing code.
`java.math.BigDecimal`, `BigInteger`	`com.codename1.util.BigDecimal` and `BigInteger`
`javax.crypto`	The ciphers, MACs and key generators of `com.codename1.security`
`java.sql`	`com.codename1.db.Database`, SQLite on every platform, or the ORM over it (Annotation ORM Section)
Java serialization	`Externalizable` with `Storage`
Reflection over bean properties	`PropertyBusinessObject`. Codename One doesn't support reflection: it defeats ahead-of-time compilation and obfuscation, which both need to see every class and member the code uses. Avoid it in new code.
A JSON library that binds by reflection	`@Mapped` classes with `Mappers.toJson` and `Mappers.fromJson`. The mapping code is generated at build time and uses no reflection, so it's faster and smaller; see Annotation Mapping Section. `JSONParser` reads JSON with no model class at all.
A file watch service	Poll on a background thread with `java.util.Timer`.
JNA, `System.loadLibrary`	A `NativeInterface` with an implementation for each platform
`Runtime.addShutdownHook`	The `stop` and `destroy` methods of the application's main class

118.6.3. Isolate what a phone can't do

What remains is functionality a phone can't provide in the same form. Put it behind an interface the application owns, keep the desktop implementation in the desktop project, and give the Codename One build an implementation that uses the Codename One API, a server, or nothing:

```
/// What the screens ask for. They hold one of these and nothing else.
public interface Tools {
    /// Whether the menu item that opens a terminal should be there at all.
    boolean canOpenTerminal();

    void openTerminal(String directory);

    void showInFileManager(String path);
}

/// The implementation the Codename One build uses. The desktop project
/// keeps its own, written with ProcessBuilder, in a class this build
```

```
/// doesn't compile.
public static class DeviceTools implements Tools {
    @Override
    public boolean canOpenTerminal() {
        return false;
    }

    @Override
    public void openTerminal(String directory) {
        throw new UnsupportedOperationException("No terminal on this device");
    }

    @Override
    public void showInFileManager(String path) {
        String url = path.startsWith("file:") ? path : "file://" + path;
        Boolean can = CN.canExecute(url);
        if (can == null || can.booleanValue()) {
            CN.execute(url);
        }
    }
}
```

This is where most of a large port's time goes. An application whose screens call straight into its services needs that seam before the seam can get a second implementation. An application that already separates its screens from its services has it, and its port is mostly the first two steps.

118.7. Styling and theming

Codename One styles an application with CSS. A `theme.css` file in the project is compiled into a `.res` theme when the application is built, so the device reads a compact binary theme and never parses a style sheet. In the simulator the theme is rebuilt each time the file is saved, and the running application restyles at once. There is no look-and-feel class to write and no skin to subclass: every component has a UIID, and a CSS rule for that UIID styles it on every platform, with native themes for iOS, Android and the desktops underneath. The Chapter 16, *CSS* chapter covers the syntax and Chapter 15, *Native modern themes* the themes it builds on.

This differs from both desktop toolkits. A Swing look and feel is Java code, UI delegates that paint each widget, chosen at run time. JavaFX reads its CSS at run time and applies it to skins. In Codename One the styling is data, settled at build time, and the same for every platform.

A ported application uses this model in three ways.

118.7.1. Swing look and feel becomes a palette

The standard widgets are Codename One components: a `JButton` is a Codename One button, a `JTextField` is the platform's text field with its own keyboard, selection and autocorrection, and the same holds for labels, check boxes, combo boxes, sliders, progress bars and tabs. They take the theme of the platform they run on.

`UIManager.setLookAndFeel` accepts any look and feel, so the usual call at the top of `main` runs unchanged and selects a light or a dark palette: `FlatDarkLaf` and other dark themes select the dark one, `null` or the system look and feel follows the platform's own setting. Switching while windows are open restyles them at once. `UIManager` colors and fonts the application puts are kept and used, and the ones it reads answer from the palette.

FlatLaf's entry points are part of the layer, so an application written against FlatLaf runs without the FlatLaf jar: `setup()`, the dark and light themes, the accent color, style classes and common client properties such as `JTextField.placeholderText`.

On a desktop, the `desktop.themeMode` build hint chooses the theme the packaged application uses, and `native` selects the theme of the machine it runs on:

```
codename1.arg.desktop.themeMode=native
```

The native macOS build reads `macos.themeMode` instead. Both are described under Section 15.3, "Desktop themes".

118.7.2. JavaFX style sheets compile with the application

JavaFX style sheets under `src/main/desktop/resources` are compiled when the application is built, like the application's own CSS, into a compact table that the runtime applies. Type, class, id and pseudo-class selectors, the descendant and child relations, the cascade, inline `setStyle`, looked-up colors and `@font-face` work as in JavaFX:

```
.root {
    -app-accent: #2f6fed;
}

.card {
    -fx-background-color: white;
    -fx-border-color: -app-accent;
    -fx-border-width: 2;
    -fx-border-radius: 8;
    -fx-background-radius: 8;
}

#status {
    -fx-text-fill: -app-accent;
    -fx-font-size: 18;
    -fx-font-weight: bold;
}

.card > .button:hover {
    -fx-opacity: 0.85;
}
```

A property or selector the layer doesn't style is a build warning with the file and line, and the rule is

left out, which is what JavaFX itself does with a property it doesn't know. Redefining a theme color such as `-fx-base` or `-fx-accent` recolors the controls the layer draws itself.

118.7.3. Codename One CSS styles the whole application

The application's `theme.css` styles the Codename One components that the Swing and JavaFX widgets are, so one rule changes a button, a text field or a dialog across the whole application on every platform. Use it for anything that should look the same across screens; use the desktop styling for what's particular to one screen.

118.7.4. Custom painting

A Swing component that overrides `paintComponent` paints as it does on the desktop, through a `Graphics2D` with shapes, strokes, paints, clipping and an affine transform:

```
public class BadgePanel extends JPanel {
    private String initial = "?";

    public void setInitial(String name) {
        initial = name == null || name.length() == 0 ? "?" : name.substring(0, 1);
        repaint();
    }

    @Override
    public Dimension getPreferredSize() {
        return new Dimension(120, 120);
    }

    @Override
    protected void paintComponent(Graphics g) {
        super.paintComponent(g);
        Graphics2D g2 = (Graphics2D) g;
        g2.setRenderingHint(RenderingHints.KEY_ANTIALIASING, RenderingHints.VALUE_ANTIALIAS_ON);
        int size = Math.min(getWidth(), getHeight()) - 16;
        int x = (getWidth() - size) / 2;
        int y = (getHeight() - size) / 2;
        g2.setColor(new Color(0x2f6fed));
        g2.fillOval(x, y, size, size);
        g2.setColor(Color.WHITE);
        g2.setFont(getFont().deriveFont(size / 2f));
        FontMetrics metrics = g2.getFontMetrics();
        g2.drawString(initial, (getWidth() - metrics.stringWidth(initial)) / 2,
                (getHeight() - metrics.getHeight()) / 2 + metrics.getAscent());
    }
}
```

In JavaFX, shapes, `Text`, paths, gradients, transforms and the shadow effects are drawn by the layer, and a `Canvas` replays its drawing calls when it paints, so it stays sharp at any display density.

118.8. On a phone and on the desktop

SwingSet2, the JDK's own Swing demo, and the open source JavaFX 2048 game build without source changes beyond what the importer asks for (SwingSet2's classes moved out of the default package):

The screens below are the Swing and JavaFX scenes from the screenshot test suite, running unmodified on an iPhone. Each is ordinary desktop code: a `JTable` with a custom renderer, JavaFX controls, and an FXML document styled by its own style sheet.

Swing controls

Name: Ada Lovelace

Password: ●●●●●●

☑ Remember me ☐ Work offline

Size: ○ Small ◉ Medium ○ Large

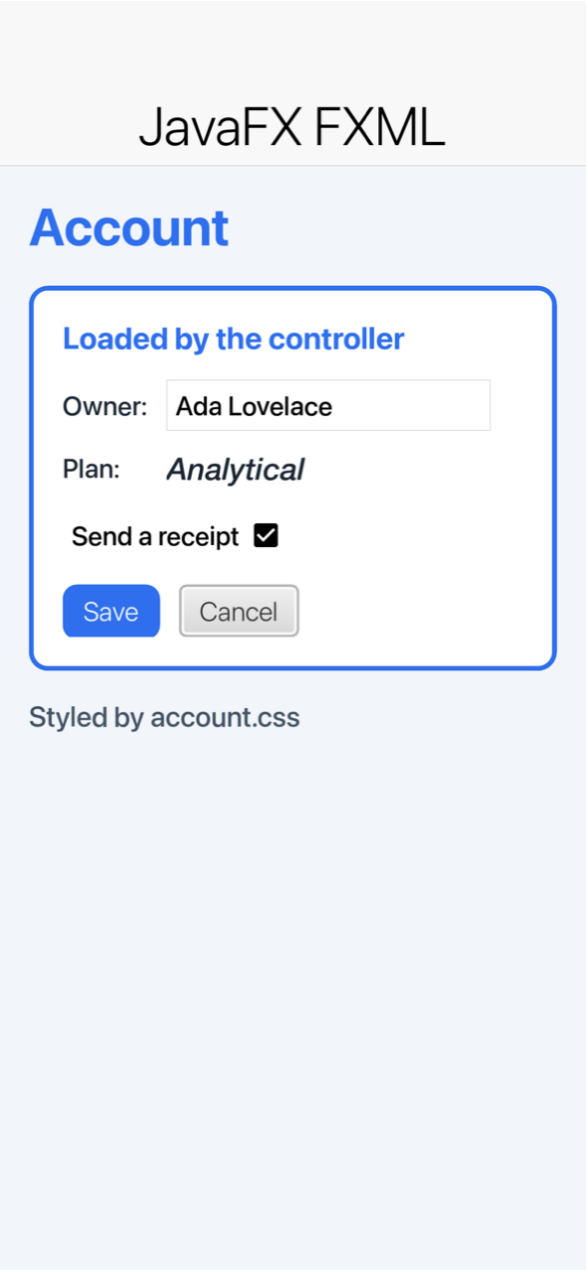
Planet: Earth

Volume:

Progress: 60%

Disabled Cancel OK

Swing tables



JTable, custom renderer

Planet	Moons	Mass
Mercury	0	0.055 M
Venus	0	0.815 M
Earth	1	1.0 M
Mars	2	0.107 M
Jupiter	95	317.8 M
Saturn	146	95.2 M

JXTable, striped

Planet	Moons	Mass
Mercury	0	0.055
Venus	0	0.815
Earth	1	1
Mars	2	0.107
Jupiter	95	317.8
Saturn	146	95.2

118.8.1. Logical pixels

Desktop code sizes things in pixels and assumes about 96 of them to the inch. The layers treat every Swing and JavaFX coordinate as a *logical pixel* of 1/96 inch and scale it to the display, so a 24 pixel row is the same physical height on a phone as on a desktop monitor. A phone is about 400 logical pixels across, so a layout designed for a 1024 pixel window is much wider than the screen. Layout managers and panes that adapt to the available width keep working; fixed sizes and `null` layouts need the attention they would need in a small desktop window.

A window whose content can't shrink to the display keeps its minimum size and the user pans across it with a drag. A `FlowLayout` row and a horizontal `JToolBar` wrap instead of being cut off. A JavaFX scene whose root is a layout pane reflows to the screen as it does when its window is resized.

118.8.2. Windows, dialogs and menus

The first `JFrame` or `Stage` fills the screen. On the desktop ports each further frame or stage is a real window with the size, position and title the application gave it. On a phone or tablet a further frame is a form shown over the one before it, with a back command, and a dialog floats over the current form.

A modal dialog blocks its caller as it does on the desktop. `JOptionPane.showMessageDialog`, a modal `JDialog`, and `showAndWait()` on a JavaFX `Alert` all return after the user answers, while painting and input continue, so code written as a sequence of questions needs no restructuring:

```
import java.awt.BorderLayout;
import java.awt.GridLayout;

import javax.swing.BorderFactory;
import javax.swing.JButton;
import javax.swing.JFrame;
import javax.swing.JLabel;
import javax.swing.JOptionPane;
import javax.swing.JPanel;
import javax.swing.JTextField;
import javax.swing.SwingUtilities;

public class GreeterApp {

    public static void main(String[] args) {
        SwingUtilities.invokeLater(GreeterApp::showFrame);
    }

    private static void showFrame() {
        JFrame frame = new JFrame("Greeter");
        frame.setDefaultCloseOperation(JFrame.EXIT_ON_CLOSE);

        JTextField name = new JTextField(16);
        JPanel form = new JPanel(new GridLayout(0, 2, 8, 8));
        form.setBorder(BorderFactory.createEmptyBorder(12, 12, 12, 12));
        form.add(new JLabel("Name"));
        form.add(name);

        BadgePanel badge = new BadgePanel();
        JButton greet = new JButton("Greet");
        greet.addActionListener(e -> {
            badge.setInitial(name.getText());
            JOptionPane.showMessageDialog(frame, "Hello, " + name.getText() + "!");
        });

        frame.getContentPane().add(form, BorderLayout.NORTH);
        frame.getContentPane().add(badge, BorderLayout.CENTER);
        frame.getContentPane().add(greet, BorderLayout.SOUTH);
        frame.pack();
```

```
        frame.setVisible(true);
    }
}
```

On the desktop a `JMenuBar` is drawn in the window. On a phone its items become commands in the form's overflow menu, and their accelerators become shortcuts.

118.8.3. Mouse, touch and keyboard

The same listeners run on every device:

Input	On a desktop	On a phone or tablet
Press, drag, release	The mouse, with its buttons and modifiers.	A finger, as the primary button.
Secondary click	The secondary button. `JPopupMenu` and `ContextMenu` open on it.	A long press opens the same menus.
Hover and wheel	Follow the pointer and the wheel.	None. Scroll panes follow a drag.
Touch events	None.	JavaFX receives a `TouchEvent` before each mouse event, and a `SwipeEvent` for a quick drag.
Keys	The keyboard.	The on-screen keyboard, typing into the text component being edited.

`CN.isDesktop()` answers which kind of device the application is on, so a feature that lives behind a hover or a key binding can offer a second way in on a phone.

118.8.4. Display properties

Three display properties adjust how a desktop application maps onto a device. Set them with `CN.setProperty` before the first window opens, for example in the generated main class or at the top of `main`:

```
if (!CN.isDesktop()) {
    // Fit a little more of a wide form on a phone.
    CN.setProperty("desktopcompat.scale", "1.6");
    // Keep the menu bar in the window instead of the overflow menu.
    CN.setProperty("desktopcompat.menuBar", "window");
}
// A fixed width font the application ships among its resources.
CN.setProperty("desktopcompat.monospaced", "DejaVu Sans Mono|DejaVuSansMono.ttf");

JFrame frame = new JFrame("Orders");
```

Property	Value	Effect
desktopcompat.scale	A number	The device pixels each logical pixel takes. Without it, the display's density against 96 dots per inch.
desktopcompat.menuBar	window or commands	Draw a JMenuBar in the frame on every device, or turn its items into commands on every device.
desktopcompat.monospaced	Font Name|file.ttf	A fixed-width TrueType font the application ships, used for the Monospaced family.

118.8.5. Threading

The Swing event dispatch thread, the JavaFX application thread and the Codename One EDT are one thread. SwingUtilities.invokeLater, Platform.runLater, javax.swing.Timer and the JavaFX animation classes run there. Long work belongs on another thread, as on the desktop: SwingWorker and a JavaFX Task or Service run their work in the background and deliver results on the EDT:

```
new SwingWorker<List<String>, String>() {
    @Override
    protected List<String> doInBackground() {
        List<String> names = new ArrayList<String>();
        for (String name : new String[] {"Ada", "Grace", "Linus"}) {
            names.add(name);
            publish(name);
        }
        return names;
    }

    @Override
    protected void process(List<String> chunks) {
        for (String name : chunks) {
            model.addElement(name);
        }
    }

    @Override
    protected void done() {
        status.setText(model.getSize() + " names loaded");
    }
}.execute();
```

118.8.6. Resources and libraries

getClass().getResource(…), getResourceAsStream(…) and ResourceBundle.getBundle work: the build packages the files under src/main/desktop/resources and records where each one came from. ImageIcon, ImageIO.read and the JavaFX Image decode PNG and JPEG through the platform.

A library written against Swing or JavaFX, such as MigLayout or a component set, isn't relinked onto the layer from its jar; see Section 118.6, "Porting a large application". The layer itself supplies

FlatLaf and RSyntaxTextArea; keep those two dependencies as they are.

118.9. FXML

FXML documents are compiled when the application is built, into classes that build the same node tree with plain constructors and setters. The application loads a document the way it does on the desktop:

```
@Override
public void start(Stage stage) throws Exception {
    Parent root = FXMLLoader.load(getClass().getResource("greeter.fxml"));
    Scene scene = new Scene(root);
    scene.getStylesheets().add(getClass().getResource("greeter.css").toExternalForm());
    stage.setTitle("Greeter");
    stage.setScene(scene);
    stage.show();
}
```

```
<?import javafx.geometry.Insets?>
<?import javafx.scene.control.Button?>
<?import javafx.scene.control.Label?>
<?import javafx.scene.control.TextField?>
<?import javafx.scene.layout.VBox?>

<VBox xmlns:fx="http://javafx.com/fxml/1" spacing="12" styleClass="card"
      fx:controller="com.codenameone.developerguide.desktopinterop.javafx.GreeterController">
    <padding>
        <Insets top="16" right="16" bottom="16" left="16"/>
    </padding>
    <Label fx:id="status" text="Who is there?"/>
    <TextField fx:id="name" promptText="Name"/>
    <Button fx:id="greet" text="Greet" onAction="#greet"/>
</VBox>
```

The controller's `@FXML` fields and handlers can stay private, and `initialize()` runs after they're set. The build writes direct code for the assignments, so no reflection is involved:

```
import javafx.event.ActionEvent;
import javafx.fxml.FXML;
import javafx.scene.control.Button;
import javafx.scene.control.Label;
import javafx.scene.control.TextField;

public class GreeterController {
    @FXML
    private Label status;

    @FXML
```

```
    private TextField name;

    @FXML
    private Button greet;

    @FXML
    private void initialize() {
        greet.disableProperty().bind(name.textProperty().isEmpty());
    }

    @FXML
    private void greet(ActionEvent event) {
        status.setText("Hello, " + name.getText() + "!");
    }
}
```

Imports, `fx:include`, `fx:define`, `fx:root`, `%key` strings from a resource bundle, `@path` locations and `${…}` bindings to a property all work, and so does an application's own control used as an element. Because every class and property a document names is checked when it compiles, the build reports a typo with the file, line, and column, where the desktop would only find it when loading the document. A JavaFX application that builds its scene in code needs none of this:

```
import javafx.application.Application;
import javafx.beans.binding.Bindings;
import javafx.beans.property.IntegerProperty;
import javafx.beans.property.SimpleIntegerProperty;
import javafx.geometry.Insets;
import javafx.geometry.Pos;
import javafx.scene.Scene;
import javafx.scene.control.Button;
import javafx.scene.control.Label;
import javafx.scene.layout.VBox;
import javafx.stage.Stage;

public class CounterApp extends Application {
    private final IntegerProperty count = new SimpleIntegerProperty();

    @Override
    public void start(Stage stage) {
        Label label = new Label();
        label.textProperty().bind(Bindings.concat("Pressed ", count.asString(), " times"));

        Button press = new Button("Press");
        press.setOnAction(e -> count.set(count.get() + 1));

        VBox root = new VBox(12, label, press);
        root.setAlignment(Pos.CENTER);
        root.setPadding(new Insets(16));

        stage.setTitle("Counter");
        stage.setScene(new Scene(root, 320, 200));
```

```
        stage.show();
    }

    public static void main(String[] args) {
        launch(args);
    }
}
```

118.10. Supported API

The tables list the main classes of each area. The exact answer for an application is in its port report (Section 118.5.1, “The port report”), which counts the calls that are supported.

118.10.1. Swing and AWT

Area	Classes
Windows and dialogs	`JFrame`, `JDialog`, `JWindow`, `JOptionPane`, `JFileChooser`, `JColorChooser`, `ProgressMonitor`, `JRootPane` and `JLayeredPane`
Internal frames	`JDesktopPane` and `JInternalFrame`
Containers	`JPanel`, `JScrollPane`, `JSplitPane`, `JTabbedPane`, `JToolBar` and `Box`
Buttons and labels	`JLabel`, `JButton`, `JToggleButton`, `JCheckBox`, `JRadioButton`, `ButtonGroup` and `ImageIcon`, with simple HTML in their text
Text	`JTextField`, `JPasswordField`, `JFormattedTextField`, `JTextArea`, `JEditorPane`, `JTextPane` with styled documents, document filters and listeners, and `javax.swing.undo`
Lists and values	`JList`, `JComboBox`, `JSpinner`, `JSlider`, `JProgressBar` and `JSeparator`, with their models and renderers
Tables and trees	`JTable` with `javax.swing.table` and `TableRowSorter`; `JTree` with `javax.swing.tree`
Menus and actions	`JMenuBar`, `JMenu`, the menu items, `JPopupMenu`, `Action`, `KeyStroke`, `InputMap` and `ActionMap`
Layout managers	`BorderLayout`, `FlowLayout`, `GridLayout`, `GridBagLayout`, `CardLayout`, `BoxLayout`, `GroupLayout`, `SpringLayout` and `OverlayLayout`
Borders	Every class of `javax.swing.border`, and `BorderFactory`
Painting	`Graphics2D`, `Color`, `Font`, `BasicStroke`, `GradientPaint`, `AlphaComposite`, the shapes and `AffineTransform` of `java.awt.geom`, `BufferedImage` and `ImageIO`
Events	The listeners and events of `java.awt.event` and `javax.swing.event`, key bindings, focus traversal and `java.beans` property change support
Threading	`SwingUtilities`, `EventQueue`, `SwingWorker` and `javax.swing.Timer`
Services	`Toolkit`, `Desktop` (`browse`, `mail` and `open`), the text clipboard, `Cursor`, `UIManager`, dragging and dropping, and `Font.createFont` for a shipped font

118.10.2. SwingX

Area	Classes
Components	`JXTable`, `JXTreeTable`, `JXList`, `JXTree`, `JXDatePicker`, `JXMonthView`, `JXTaskPane`, `JXCollapsiblePane`, `JXTitledPanel`, `JXHeader`, `JXStatusBar`, `JXHyperlink`, `JXBusyLabel`, `JXSearchField`, `JXErrorPane` and the `JX` versions of the basic components
Rendering	Highlighters, the renderer providers, `StringValue` and `IconValue`, and painters
Other	`HorizontalLayout` and `VerticalLayout`, sort controllers, `RowFilters`, `TableColumnExt`, `PromptSupport` and `AbstractBean`

118.10.3. JavaFX

Area	Classes
Application and windows	`Application`, `Platform`, `HostServices`, `Stage`, `Screen` and `FileChooser`
Layout panes	`Pane`, `HBox`, `VBox`, `BorderPane`, `StackPane`, `GridPane`, `FlowPane`, `TilePane`, `AnchorPane` and `Region`
Controls	`Label`, the buttons, `TextField`, `TextArea`, `ComboBox`, `ChoiceBox`, `DatePicker`, `ColorPicker`, `Spinner`, `Slider`, `ProgressBar`, `ScrollPane`, `SplitPane`, `TabPane`, `TitledPane`, `Accordion`, `ToolBar`, `Pagination`, `ListView`, `TableView`, `TreeView` and `Tooltip`
Charts	`LineChart`, `AreaChart`, `BarChart`, `ScatterChart` and `PieChart`
Menus and dialogs	`MenuBar`, `ContextMenu`, `Alert`, `Dialog`, `ChoiceDialog` and `TextInputDialog`
Properties and collections	`javafx.beans.property`, `Bindings`, `ObservableList`, `FXCollections`, `FilteredList` and `SortedList`
Graphics	Shapes, paths, `SVGPath`, `Text`, `TextFlow`, gradients, `DropShadow` and `InnerShadow`, transforms, `Canvas`, `Image`, `WritableImage` and `Node.snapshot`
Animation	`Timeline`, `AnimationTimer` and the transitions
Concurrency	`Task`, `Service` and `Worker`
FXML and styling	`FXMLLoader`, `@FXML`, style classes, inline styles, `PseudoClass` and style sheets

118.11. Calling Codename One from desktop code

The desktop sources compile in the `common` module, next to the Codename One API, so they can call it directly. That's how a ported application adapts to the device it runs on, and how it reaches the camera, the database, push notifications and the rest of Section 118.1, "Motivation":

```
if (!CN.isDesktop() && !CN.isTablet()) {
    // A phone: stack the two halves instead of placing them side by side.
    split.setOrientation(JSplitPane.VERTICAL_SPLIT);
```

```
}
```

Code that uses Codename One classes no longer compiles in the original desktop project. Keep such calls behind a small class of your own if the application must go on building for a desktop JVM too.

118.12. Mixing with Codename One code

A Codename One application can use Swing and JavaFX screens without handing them the whole application. Put the desktop sources in `common/src/main/desktop` as usual, and have the main class show Codename One forms instead of calling the desktop application's `main`.

`SwingInterop.asComponent` wraps a Swing component in a Codename One component that you add to a form like any other:

```
JPanel report = new JPanel(new BorderLayout());
report.add(new JLabel("Orders this week"), BorderLayout.NORTH);
report.add(new JScrollPane(new JTable(new Object[][] {{"Mon", 12}, {"Tue", 9}},
        new Object[] {"Day", "Orders"})), BorderLayout.CENTER);

Form form = new Form("Report", new com.codename1.ui.layouts.BorderLayout());
form.add(com.codename1.ui.layouts.BorderLayout.CENTER, SwingInterop.asComponent(report));
form.show();
```

`FxInterop.asComponent` does the same for the root of a JavaFX scene graph, or for a `Scene` when the screen needs style sheets:

```
VBox root = new VBox(8, new Label("Orders this week"), new Button("Refresh"));
Scene scene = new Scene(root);
scene.getStylesheets().add("/com/example/orders.css");

Form form = new Form("Report", new BorderLayout());
form.add(BorderLayout.CENTER, FxInterop.asComponent(scene));
form.show();
```

Both take an `Object` and throw an `IllegalArgumentException` for anything other than a Swing component, a JavaFX parent or a scene. Call them on the EDT.

Frames, stages and modal dialogs work from Codename One code too. A frame or a stage opens as a form over the current one, and closing it returns there:

```
JFrame frame = new JFrame("Edit order");
frame.setDefaultCloseOperation(JFrame.DISPOSE_ON_CLOSE);
frame.setContentPane(editor);
frame.setVisible(true);   // closing it returns to the form that was showing

int answer = JOptionPane.showConfirmDialog(frame, "Save the order?", "Save",
```

```
        JOptionPane.YES_NO_OPTION);
```

```
Stage stage = new Stage();
stage.setTitle("Edit order");
stage.setScene(new Scene(editor));
stage.show();   // closing it returns to the form that was showing
```

On the desktop ports these windows are real windows. `SwingInterop.setNativeWindows(false)` and `FxInterop.setNativeWindows(false)` keep them inside the application's own window instead, as on a phone.

118.13. Testing a ported application

The application's logic is tested as any Codename One application's is, with `mvn cn1:test` or `./gradlew cn1Test`. Test classes aren't relinked, so a unit test exercises the classes that don't touch the toolkit: models, parsers and the services behind the interfaces of Section 118.6, "Porting a large application". The tests that came with the desktop project stay there and keep running on the JVM.

Then run the application in the simulator with a phone, a tablet and the desktop skin. Most of what a port gets wrong is visible there in a minute: a window that pans because it can't shrink, a table whose columns no longer fit, a feature reachable only from a hover or a key binding.

To prove that the screens respond to a real pointer, the Codename One source tree carries a harness in `maven/integration-tests/desktop-compat-realport`. It starts a built application on the JavaSE port and plays a script of clicks, drags and keys with the display server's own input, and it fails when anything throws or when a step changes nothing on the screen. A script has one step on a line, and a position is a fraction of the application's area:

```
# Wait for the first screen, then keep a picture of it.
sleep 4000
shot start
click 0.061 0.268
type bc
key TAB
drag 0.536 0.573 0.640 0.573 400
# Moving the pointer isn't expected to change anything.
quiet move 0.5 0.5
```

Run it against the `common` module of a built application, under `xvfb-run` on a machine you're working on:

```
# From a checkout of the Codename One sources, against a built application:
xvfb-run -a maven/integration-tests/desktop-compat-realport/run.sh \
    /path/to/MyApp/common /path/to/orders.txt /path/to/output
```

`swing-gallery.txt` and `javafx-gallery.txt` beside the harness are complete scripts to start from.

118.14. Native desktop builds

The same project builds a native executable for Linux, macOS, and Windows. The application, the part of the layers it uses and the part of Codename One it uses are translated to C and compiled into one program with no Java runtime beside it:

```
# Linux: a native executable, built on a Linux machine
mvn package -Dcodename1.platform=linux -Dcodename1.buildTarget=local-linux-device

# macOS: a native .app, built on a Mac with Xcode
mvn package -Dcodename1.platform=ios -Dcodename1.buildTarget=local-mac-device

# Windows: a native .exe, built on Windows or cross-compiled
mvn package -Dcodename1.platform=win -Dcodename1.buildTarget=local-windows-device
```

Each port has a chapter with its toolchain, build hints, signing and packaging: Section 123.3, “Building a native Linux app”, Section 120.2, “Native macOS Build (AppKit)” and Section 122.2, “Building a native Windows app”. A ported application needs nothing beyond what those chapters ask of any application. On these ports a `JMenuBar` is drawn in its frame, the mouse, wheel and keyboard modifiers are reported, and every further `JFrame` and `Stage` is a real window (see Chapter 129, *Desktop Windows*).

118.14.1. Size, memory and start-up

This section measures what the user downloads, how soon the window appears and how much memory the application holds, for the same sources built two ways:

	On a JVM	**Native build**
Sources	The application’s own, unmodified	The same, imported
Runtime	A `jlink` image of exactly the modules `jdeps` names, stripped and compressed	None
Toolkit	The JDK’s Swing, or OpenJFX	Codename One’s Swing or JavaFX layer over the native port

The JVM runs in two configurations. *Default* is the image as built, with its class data sharing archive. *Tuned* is what a developer who cared about start-up and footprint would ship: the serial collector, a smaller thread stack, the first compiler tier only, an application class data sharing archive and the smallest heap the application runs in.

Eight applications were measured: the `swing-gallery` and `javafx-gallery` samples in the Codename One source tree, the JDK’s SwingSet2 and Notepad demos, and four small open-source applications. Every comparison is like for like. Both builds of an application ran on the same machine, and each size compares one architecture with the same architecture: on macOS the native application is measured with the arm64 slice of its executable only, the architecture of the `jlink` runtime it’s

compared with. In each ratio the JVM's figure is divided by the native build's, so a figure above 1 favors the native build.

Size is bytes on disk, and bytes as one zip at the highest deflate level, which is close to what a download costs. **Start-up** is the time from the start of the process to the first painted frame, the median of seven launches. **Memory** is summed over the process tree, ten seconds after the first frame and again after a short script of input. **CPU while idle** is the processor time of an application waiting for input.

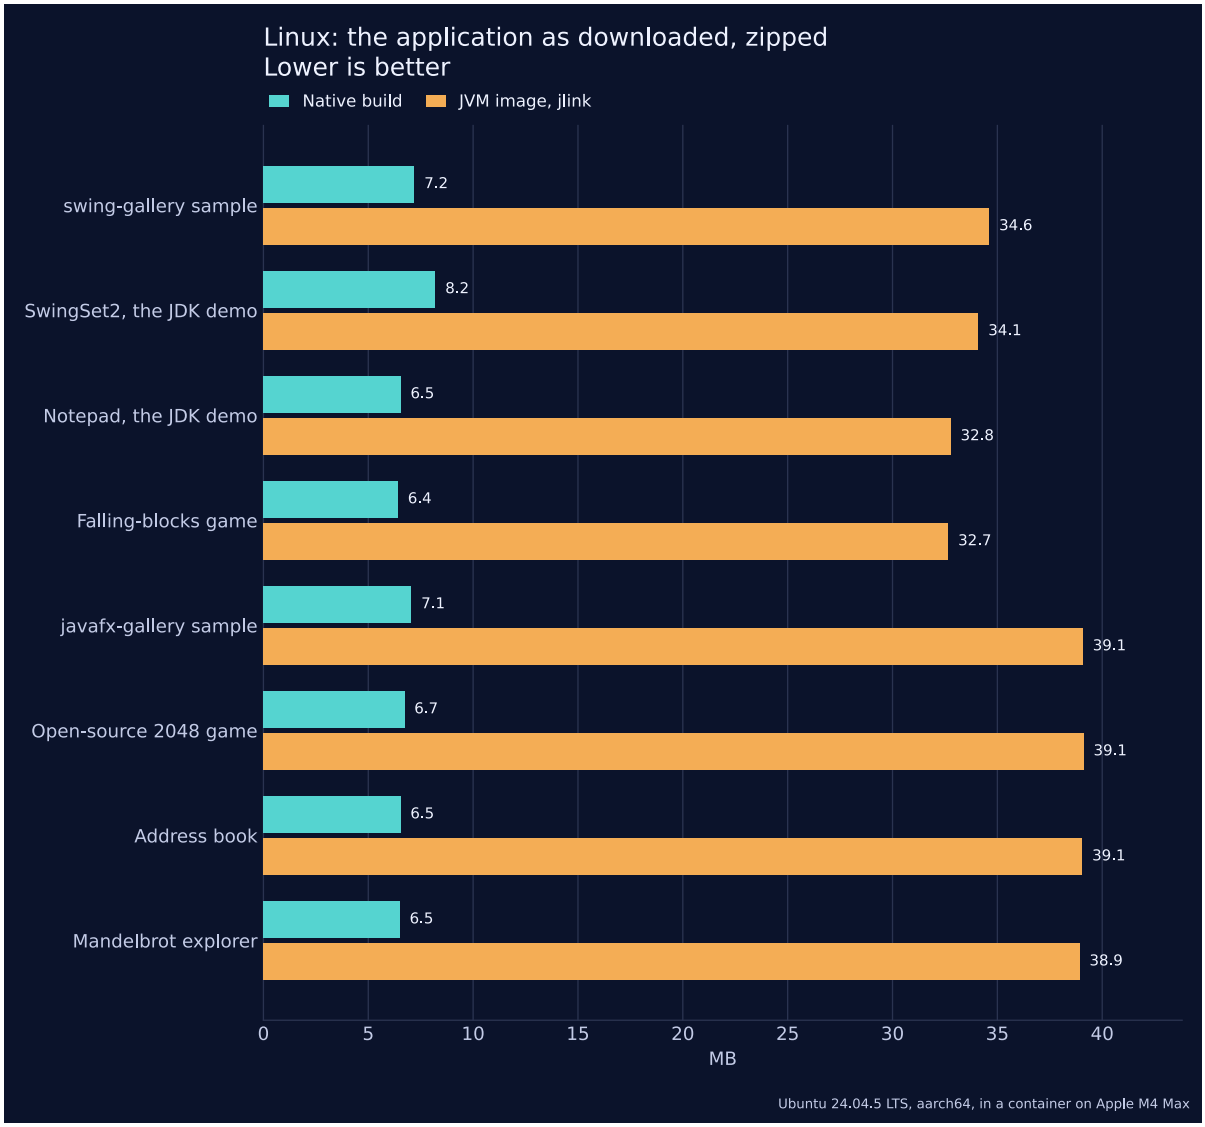


Table 19. Linux: the distributed application (MB)

Application	**Toolkit**	`jlink` **image**	`jlink` **image, zipped**	`jpackage` **image, zipped**	**Native build**	**Native build, zipped**	**JVM image / native build**	**JVM zip / native zip**
`swing-gallery` sample	Swing	56.3	34.6	34.8	19.6	7.2	2.9x	4.8x
SwingSet2, the JDK demo	Swing	55.6	34.1	34.2	20.5	8.2	2.7x	4.2x
Notepad, the JDK demo	Swing	54.3	32.8	32.9	17.7	6.5	3.1x	5.0x
Falling-blocks game	Swing	54.1	32.7	32.8	17.4	6.4	3.1x	5.1x
`javafx-gallery` sample	JavaFX	61.6	39.1	39.2	19.4	7.1	3.2x	5.5x
Open-source 2048 game	JavaFX	61.6	39.1	39.3	18.3	6.7	3.4x	5.8x
Address book	JavaFX	61.5	39.1	39.2	17.8	6.5	3.5x	6.0x
Mandelbrot explorer	JavaFX	61.3	38.9	39.0	17.7	6.5	3.5x	6.0x

The `jlink` image is the application with the smallest Java runtime that runs it: the application's jars and the modules `jlink` found it to need. The native build is one executable file with nothing beside it. Both rely on the desktop libraries of the system, X11 and, for the native build and for JavaFX,

GTK; neither column counts them.

Against the `jlink` image as installed the native build is smaller in 8 applications, of the 8 measured. Its best result is 3.5x for Mandelbrot explorer (17.7 MB against 61.3 MB).

Against the zipped `jlink` image the native build is smaller in 8 applications, of the 8 measured. Its best result is 6.0x for Mandelbrot explorer (6.5 MB against 38.9 MB).

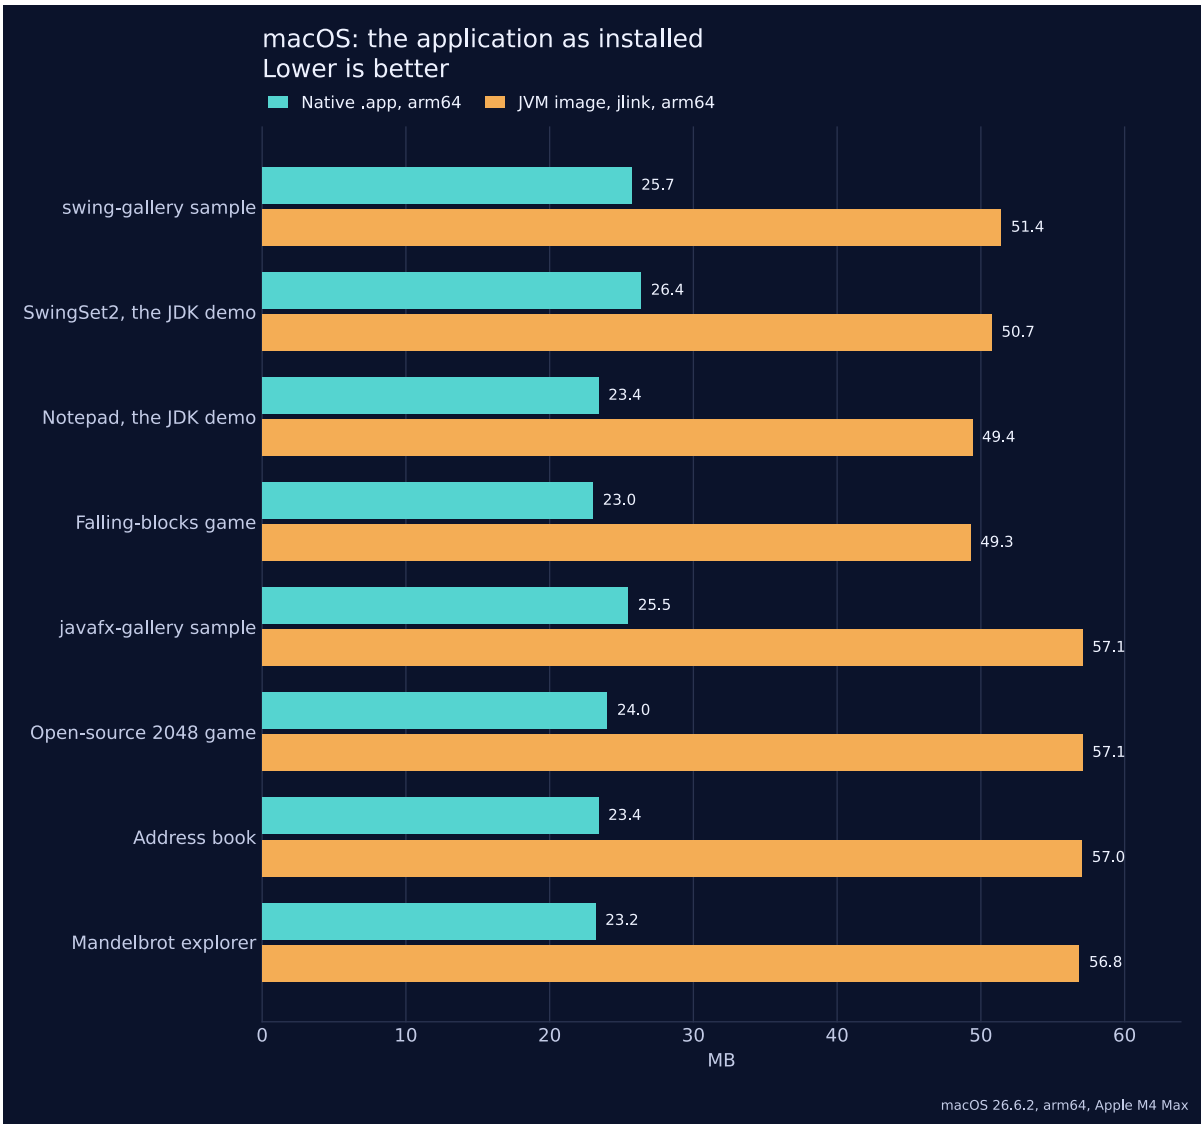

Table 20. macOS: the distributed application (MB)

Application	`jlink` **image, arm64**	`jlink` **image, zipped**	**Native** `.app`**, arm64**	**Native** `.app`**, zipped**	**Universal** `.app`	**JVM image / native** `.app`	**JVM zip / native zip**
`swing-gallery` sample	51.4	32.5	25.7	8.7	49.6	2.0x	3.7x
SwingSet2, the JDK demo	50.7	32.0	26.4	9.8	49.5	1.9x	3.3x
Notepad, the JDK demo	49.4	30.7	23.4	8.0	44.9	2.1x	3.9x
Falling-blocks game	49.3	30.6	23.0	7.8	44.2	2.1x	3.9x
`javafx-gallery` sample	57.1	37.1	25.5	8.6	49.2	2.2x	4.3x

Application	`jlink` image, arm64	`jlink` image, zipped	Native `.app`, arm64	Native `.app`, zipped	Universal `.app`	JVM image / native `.app`	JVM zip / native zip
Open-source 2048 game	57.1	37.1	24.0	8.1	46.0	2.4x	4.6x
Address book	57.0	37.0	23.4	7.9	45.0	2.4x	4.7x
Mandelbrot explorer	56.8	36.9	23.2	7.9	44.6	2.5x	4.7x

Both sides are built for arm64: the `jlink` image holds the arm64 runtime, and the native `.app` is the bundle with the arm64 slice of its executable only. The builder's default output is universal, with an x86_64 slice beside it; its size is in the last size column.

Against the `jlink` image as installed the native build is smaller in 8 applications, of the 8 measured. Its best result is 2.5x for Mandelbrot explorer (23.2 MB against 56.8 MB).

Against the zipped `jlink` image the native build is smaller in 8 applications, of the 8 measured. Its best result is 4.7x for Mandelbrot explorer (7.9 MB against 36.9 MB).

Table 21. iOS and Android: the distributed application (MB)

Application	iOS `.app`	iOS `.app`, zipped	iOS executable, stripped	Android APK	APK, unpacked	Of which dex
`swing-gallery` sample	28.1	9.4	18.2	3.0	5.8	3.9
SwingSet2, the JDK demo	28.7	10.5	17.6	4.4	7.2	3.8
Notepad, the JDK demo	25.6	8.7	16.3	2.9	5.5	3.5
Falling-blocks game	25.1	8.6	16.1	2.8	5.3	3.4
`javafx-gallery` sample	27.8	9.3	18.0	3.1	5.9	4.0
Open-source 2048 game	26.1	8.9	16.7	3.1	6.0	3.8
Address book	25.4	8.6	16.5	3.0	5.8	3.9
Mandelbrot explorer	25.3	8.6	16.3	2.9	5.5	3.6

Table 22. How much of the toolkit layer an application keeps

Application	Toolkit	Classes in the layer	Classes in the native build	Kept
`swing-gallery` sample	Swing and AWT	1039	737	71%

Application	Toolkit	Classes in the layer	Classes in the native build	Kept
SwingSet2, the JDK demo	Swing and AWT	1039	587	56%
Notepad, the JDK demo	Swing and AWT	1039	566	54%
Falling-blocks game	Swing and AWT	1039	538	52%
`javafx-gallery` sample	JavaFX	901	688	76%
Open-source 2048 game	JavaFX	894	413	46%
Address book	JavaFX	896	461	51%
Mandelbrot explorer	JavaFX	896	442	49%

Table 23. Linux: warm start, from process start to the first painted frame (ms, median with the range)

Application	JVM, default	JVM, tuned	Native build	Default / native	Tuned / native
`swing-gallery` sample	326 (316-336)	194 (193-195)	96 (40-104)	3.4x	2.0x
SwingSet2, the JDK demo	220 (205-221)	145 (144-157)	56 (54-84)	3.9x	2.6x
Notepad, the JDK demo	175 (170-187)	123 (107-134)	55 (54-77)	3.2x	2.2x
Falling-blocks game	102 (101-119)	70 (69-72)	74 (54-102)	1.4x	0.9x
`javafx-gallery` sample	603 (589-617)	408 (386-428)	100 (97-110)	6.0x	4.1x
Open-source 2048 game	307 (271-326)	190 (160-205)	77 (44-100)	4.0x	2.5x
Address book	407 (389-452)	238 (233-266)	74 (56-88)	5.5x	3.2x
Mandelbrot explorer	392 (373-424)	214 (202-231)	86 (76-94)	4.6x	2.5x

Against the default JVM the native build is quicker in 8 applications, of the 8 measured. Its best result is 6.0x for `javafx-gallery` sample (100 ms against 603 ms).

Against the tuned JVM the native build is quicker in 7 applications and slower in 1 application, of the 8 measured. Its best result is 4.1x for `javafx-gallery` sample (100 ms against 408 ms). Its worst is 0.9x for Falling-blocks game (74 ms against 70 ms).

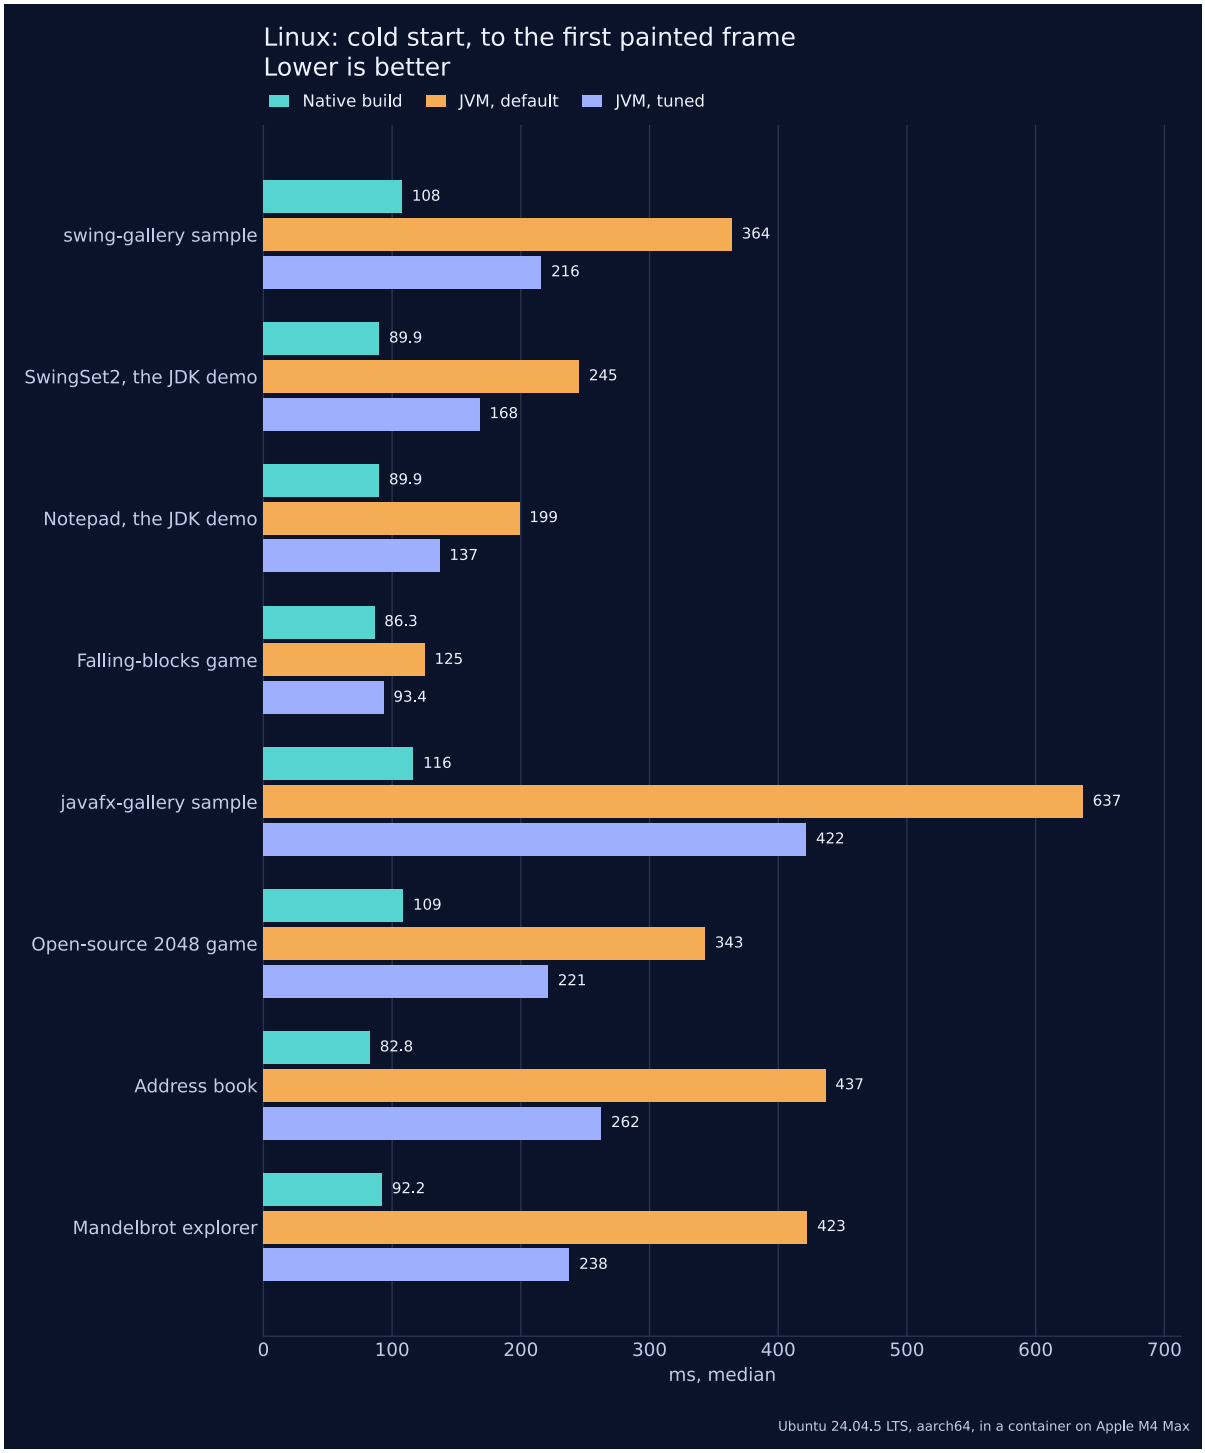

Table 24. Linux: cold start, from process start to the first painted frame (ms, median with the range)

Application	JVM, default	JVM, tuned	Native build	Default / native	Tuned / native
`swing-gallery` sample	364 (358-382)	216 (212-236)	108 (97-117)	3.4x	2.0x
SwingSet2, the JDK demo	245 (229-255)	168 (151-180)	90 (86-95)	2.7x	1.9x
Notepad, the JDK demo	199 (195-210)	137 (126-150)	90 (63-92)	2.2x	1.5x
Falling-blocks game	125 (124-140)	93 (91-99)	86 (65-90)	1.5x	1.1x

Application	JVM, default	JVM, tuned	Native build	Default / native	Tuned / native
`javafx-gallery` sample	637 (631-654)	422 (415-432)	116 (109-120)	5.5x	3.6x
Open-source 2048 game	343 (308-355)	221 (206-226)	109 (107-128)	3.2x	2.0x
Address book	437 (428-477)	262 (258-269)	83 (63-88)	5.3x	3.2x
Mandelbrot explorer	423 (363-428)	238 (196-240)	92 (92-96)	4.6x	2.6x

Against the default JVM the native build is quicker in 8 applications, of the 8 measured. Its best result is 5.5x for `javafx-gallery` sample (116 ms against 637 ms).

Against the tuned JVM the native build is quicker in 8 applications, of the 8 measured. Its best result is 3.6x for `javafx-gallery` sample (116 ms against 422 ms).

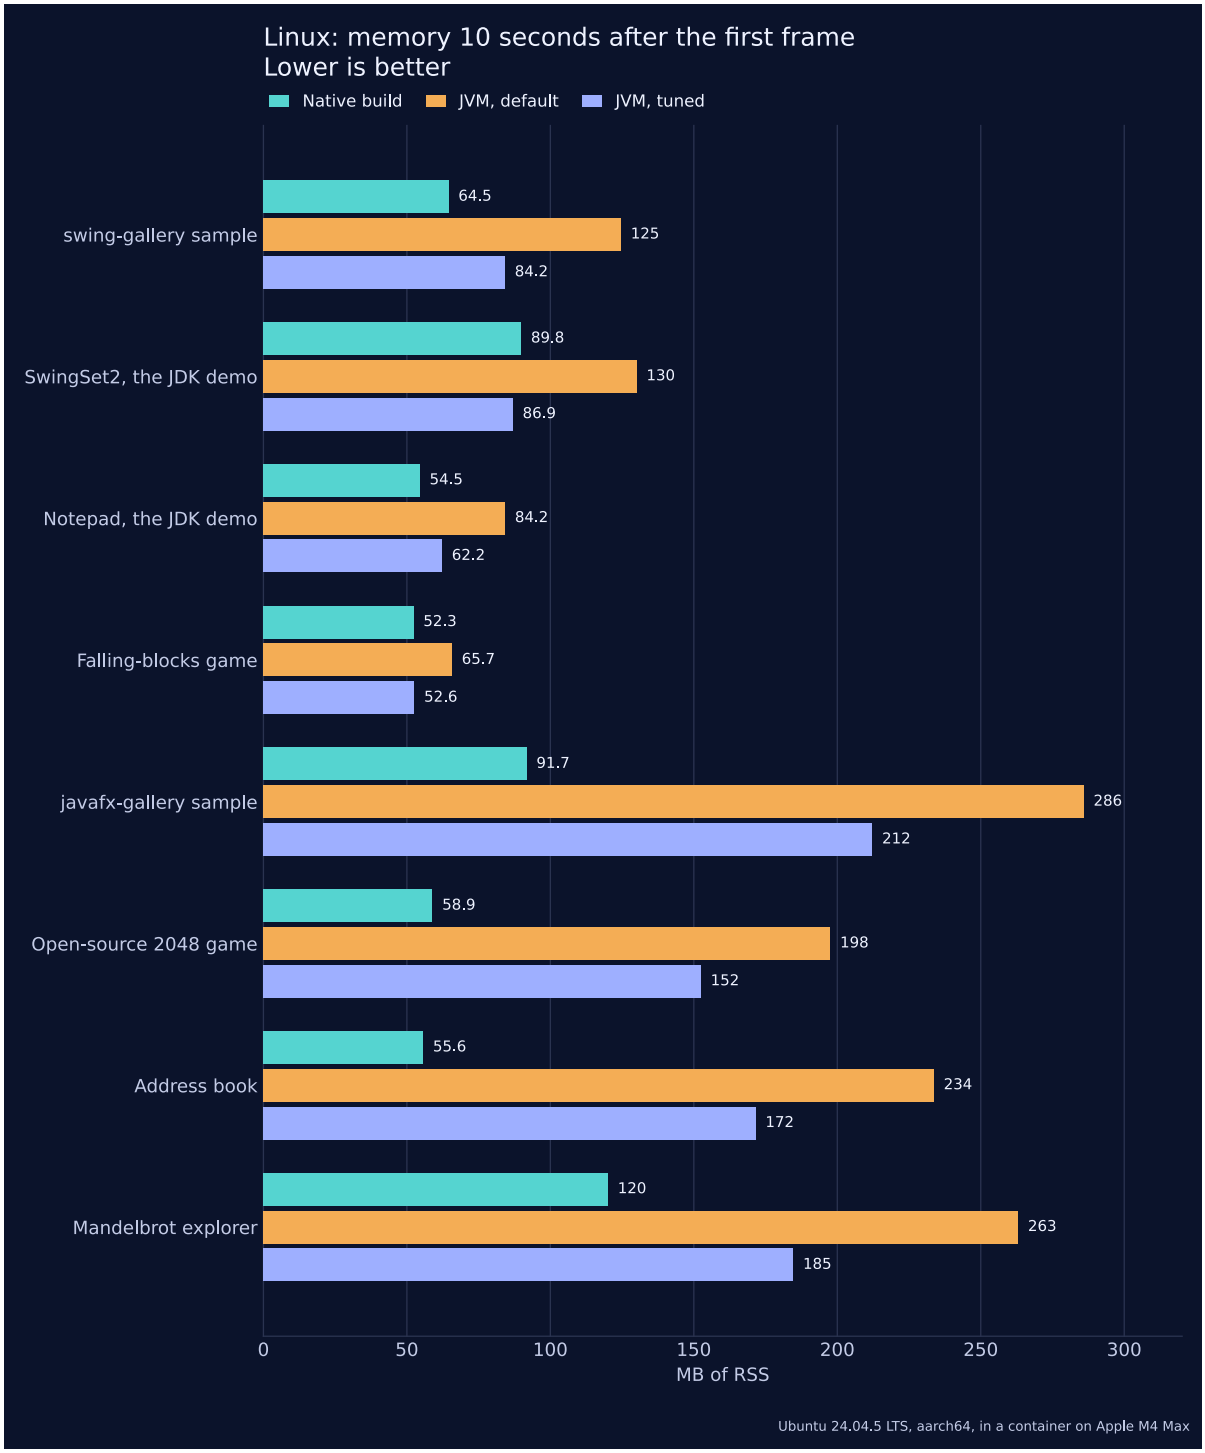

Table 25. Linux: memory 10 seconds after the first frame (MB, RSS / PSS)

Application	JVM, default	JVM, tuned	Native build	Default RSS / native	Tuned RSS / native
`swing-gallery` sample	124.6 / 119.1	84.2 / 78.6	64.5 / 56.4	1.9x	1.3x
SwingSet2, the JDK demo	130.1 / 126.0	86.9 / 82.8	89.8 / 81.3	1.4x	1.0x
Notepad, the JDK demo	84.2 / 80.2	62.2 / 58.2	54.5 / 47.0	1.5x	1.1x
Falling-blocks game	65.7 / 61.8	52.6 / 48.6	52.3 / 45.4	1.3x	1.0x

Application	JVM, default	JVM, tuned	Native build	Default RSS / native	Tuned RSS / native
`javafx-gallery` sample	285.9 / 258.1	212.2 / 184.5	91.7 / 83.3	3.1x	2.3x
Open-source 2048 game	197.5 / 171.7	152.4 / 126.6	58.9 / 51.8	3.4x	2.6x
Address book	233.6 / 207.4	171.5 / 145.2	55.6 / 48.3	4.2x	3.1x
Mandelbrot explorer	263.0 / 236.0	184.6 / 157.6	120.1 / 112.3	2.2x	1.5x

Against the default JVM the native build is smaller in 8 applications, of the 8 measured. Its best result is 4.2x for Address book (55.6 MB against 233.6 MB).

Against the tuned JVM the native build is smaller in 6 applications and within 5% of it in 2 applications, of the 8 measured. Its best result is 3.1x for Address book (55.6 MB against 171.5 MB).

Table 26. Linux: memory after the scripted interaction (MB, RSS / PSS)

Application	JVM, default	JVM, tuned	Native build	Default RSS / native	Tuned RSS / native
`swing-gallery` sample	118.4 / 112.9	86.0 / 80.5	90.8 / 81.8	1.3x	0.9x
SwingSet2, the JDK demo	130.8 / 126.8	87.0 / 83.0	92.8 / 84.3	1.4x	0.9x
Notepad, the JDK demo	91.0 / 87.0	63.5 / 59.4	58.2 / 50.6	1.6x	1.1x
Falling-blocks game	68.3 / 64.4	53.8 / 49.9	54.3 / 47.4	1.3x	1.0x
`javafx-gallery` sample	293.8 / 266.0	213.3 / 185.5	109.4 / 99.7	2.7x	1.9x
Open-source 2048 game	208.3 / 182.4	155.7 / 129.8	100.0 / 93.0	2.1x	1.6x
Address book	245.8 / 219.5	172.6 / 146.3	57.2 / 49.8	4.3x	3.0x
Mandelbrot explorer	293.4 / 266.3	197.6 / 170.6	172.2 / 164.5	1.7x	1.1x

Against the default JVM the native build is smaller in 8 applications, of the 8 measured. Its best result is 4.3x for Address book (57.2 MB against 245.8 MB).

Against the tuned JVM the native build is smaller in 5 applications, larger in 2 applications and within 5% of it in 1 application, of the 8 measured. Its best result is 3.0x for Address book (57.2 MB against 172.6 MB). Its worst is 0.9x for SwingSet2, the JDK demo (92.8 MB against 87.0 MB).

Table 27. Linux: peak RSS over a whole session (MB)

Application	JVM, default	JVM, tuned	Native build	Default / native	Tuned / native	Tuned `-Xmx` (MB)
`swing-gallery` sample	128.5	88.0	90.1	1.4x	1.0x	8
SwingSet2, the JDK demo	130.9	87.2	92.5	1.4x	0.9x	24
Notepad, the JDK demo	92.9	64.0	57.7	1.6x	1.1x	8
Falling-blocks game	70.3	54.2	53.9	1.3x	1.0x	8
`javafx-gallery` sample	296.7	215.8	108.8	2.7x	2.0x	48
Open-source 2048 game	211.5	158.6	125.5	1.7x	1.3x	8
Address book	248.6	175.3	56.7	4.4x	3.1x	48
Mandelbrot explorer	296.1	200.2	340.5	0.9x	0.6x	48

Table 28. Linux: CPU while idle (share of one core)

Application	JVM, default	JVM, tuned	Native build
`swing-gallery` sample	0.0%	0.0%	0.2%
SwingSet2, the JDK demo	0.2%	0.0%	1.6%
Notepad, the JDK demo	0.2%	0.0%	0.0%
Falling-blocks game	1.0%	0.8%	0.6%
`javafx-gallery` sample	25.4%	27.1%	4.7%
Open-source 2048 game	3.9%	2.5%	4.8%
Address book	0.6%	0.4%	0.0%
Mandelbrot explorer	2.2%	1.8%	0.2%

Of the 8 native builds, 5 idle at or under 1% of a core. Above it: SwingSet2, the JDK demo (1.6%), `javafx-gallery` sample (4.7%), Open-source 2048 game (4.8%).

Where the figures were measured

- **Linux**: Ubuntu 24.04.5 LTS, aarch64, 4 CPUs, 7.7 GB of memory, in a container, hosted on Apple M4 Max. The display is a virtual framebuffer, Xvfb, of 1280 by 800 pixels. GTK 3.24.41. Each display has had one GTK program on it before the measured application starts, as a desktop session has: the first GTK program on a display loads a GL driver to choose its visuals, and no later one does. OpenJFX 23.0.2 for the JavaFX baselines.
- **Tuned JVM flags**: `-XX:+UseSerialGC -Xss256k -XX:TieredStopAtLevel=1 -XX:SharedArchiveFile=app.jsa`, and the `-Xmx` of the table above.

- **macOS, iOS and Android sizes**: macOS 26.6.2, Apple M4 Max, Xcode 27.0.

The Linux display is a software framebuffer for both builds, and start-up and memory were measured on Linux only. Figures move with what an application does at start-up, so measure your own.

Measuring your own application

The harness that produced the tables is in the Codename One source tree, under `scripts/desktop-compat-benchmarks`, and takes any Swing or JavaFX project. It builds the application both ways, measures both and writes one `result.json`, which `report.py` turns into tables:

```
scripts/desktop-compat-benchmarks/bench.sh --app /path/to/MyDesktopApp --name myapp \
    --kind swing --main com.example.Main --work /path/to/work
scripts/desktop-compat-benchmarks/report.py /path/to/work/myapp/result.json
```

The `README.md` in that directory lists what it needs. The phone sizes come from a second script, run against the project the first one imported:

```
scripts/desktop-compat-benchmarks/mobile-size.sh --target ios \
    --project /path/to/work/myapp/cn1/app --work /path/to/work/myapp-ios
scripts/desktop-compat-benchmarks/mobile-size.sh --target android \
    --project /path/to/work/myapp/cn1/app --work /path/to/work/myapp-android
```

118.15. Troubleshooting

Each entry is a symptom and what to do about it.

118.15.1. Building

Symptom	What to do
The build names API the Swing or JavaFX layer doesn't support.	Replace the call with one the layer has, or move the feature behind an interface (Section 118.6, "Porting a large application"). The full list is in `common/target/codenameone/compliance_check.txt`.
The message points at a library, not at your code.	If the application doesn't need that part of the library, exclude the library and replace what you used from it.
The build reports `java.awt` or `javax.swing` references and suggests enabling the layer.	The sources that use the toolkit are outside `src/main/desktop`. Move them to `common/src/main/desktop/java`.
The import stops because it can't choose an entry point.	Pass `-Dcn1.desktop.mainClass` to the import goal.
`src/main/desktop` exists but a runtime dependency is missing.	The `common/pom.xml` predates the desktop layers. Run the import goal, which adds the profile.

Symptom	What to do
Kotlin sources under `src/main/desktop/kotlin` aren't compiled.	Create `common/src/main/kotlin`, whose presence switches on the Kotlin build. The import goal does this for you.
Two resources have the same name after packaging.	Rename one of them.
A style sheet warning says a property or selector is ignored.	Style that detail in the application's `theme.css`, or remove the rule.

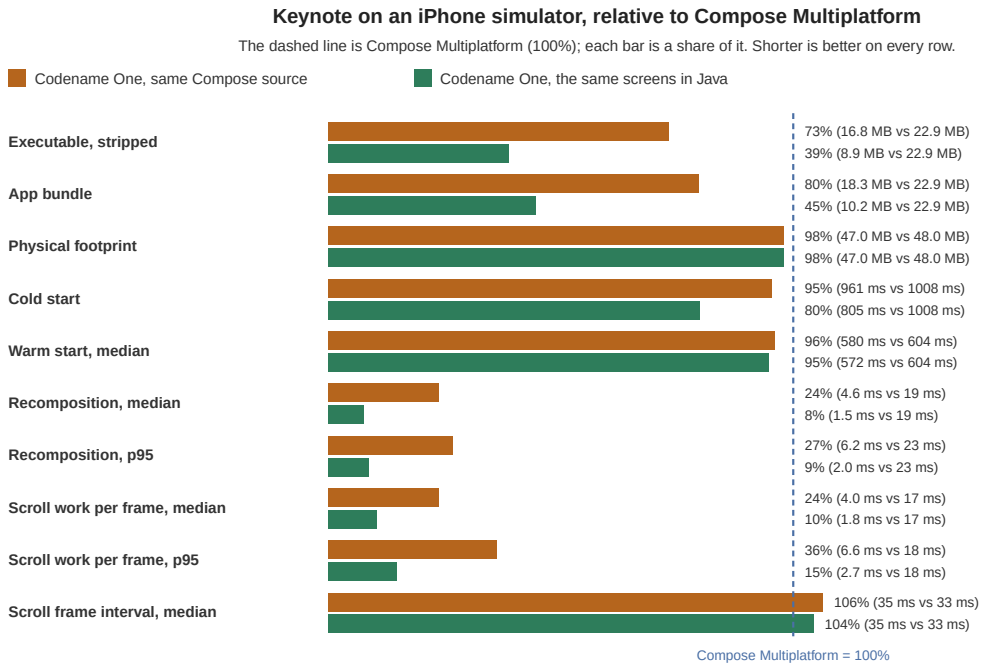
118.15.2. JDK API

Symptom	What to do
`java.lang.reflect`, `Class.getMethod` or a similar call is a build error.	Replace reflection with code: `PropertyBusinessObject` for bean properties, `@Mapped` for JSON, an interface for plugins.
Code that loads classes by name with `Class.forName` fails on Android or in the browser.	Those builds are obfuscated and keep only the classes something references, so a name in a string finds nothing. Reference the class directly, or register it in code.
`ObjectOutputStream` or `ObjectInputStream` is a build error.	Use `Externalizable` with `Storage`, or `@Mapped` JSON.
`HttpURLConnection`, `java.net.http` or sockets are a build error.	Use `Rest`, `ConnectionRequest` or `com.codename1.io.URL`.
Starting a process throws `UnsupportedOperationException` on a phone.	Processes run on the desktop targets. Check `ProcessBuilder.isSupported()` and offer the feature where it answers `true` (Chapter 27, *Desktop and Backend Processes*).
`java.math`, `javax.crypto`, `java.sql` or `java.util.zip.ZipFile` is a build error.	Use the equivalents in Section 118.6, "Porting a large application". The zip and GZIP streams work unchanged.
A relative path or a relative `file:` URL finds nothing.	A device has no working directory. Relative paths resolve inside the application's storage; ship read-only files as resources.
`System.getenv` answers `null`.	A device has no environment. Use display properties or build hints.
`Pattern.compile` throws for an advanced pattern.	Unicode script and block classes beyond the common ones and unbounded look-behind aren't supported. Simplify the pattern.
A `Locale` used as a map key isn't found.	Key the map by the locale's string form.

118.15.3. Running

Symptom	What to do
A method the application overrides is never called.	The layer's class doesn't call it, and the build can't see an override. Find another hook the layer does call, such as a renderer or a listener.
A keyboard shortcut does nothing.	Function keys and Home, End, Page Up, Page Down and Insert aren't reported, and a phone reports no modifiers. Give the action a menu item or a button too.
The window pans sideways on a phone.	Something in it has a minimum width larger than the display. Use a layout that wraps or stacks, put the wide part in a scroll pane, or lower `desktopcompat.scale`.
Text is wider or narrower than on the desktop.	Fonts are the platform's and measure differently. Let a layout manager size the component.
A JavaFX blur or glow isn't drawn.	Use `DropShadow` or `InnerShadow`, which are.
A JavaFX combo box can't be typed into.	`ComboBox` and `ChoiceBox` open the platform's picker. Use a `TextField` where the user types.
An image from a relative `file:` URL is missing.	Load it as a resource. `Image.isError()` says whether it was found.

Chapter 119. Running Kotlin Multiplatform and Compose applications



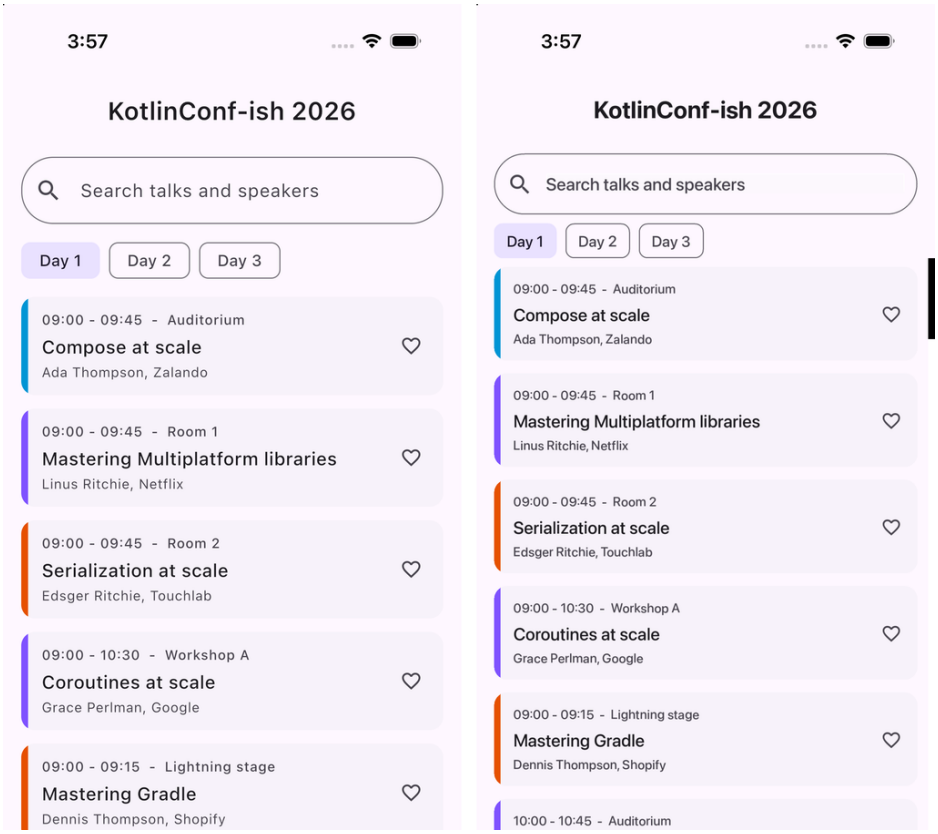
A Kotlin Multiplatform (KMP) module whose user interface is written with Compose Multiplatform builds as a Codename One application. The shared `commonMain` code is compiled unchanged, the composables render as Codename One components, and the result ships to every Codename One target: iOS, Android, the web, macOS, Windows and Linux (as native binaries with no JVM), watchOS and tvOS.

119.1. Motivation

Kotlin Multiplatform with Compose Multiplatform is the toolkit closest to Codename One's own model: one codebase, one declarative UI, logic shared between every client. It's a good way to write an application. Codename One takes that code further — onto more platforms, into a smaller and faster application, and next to a Java API that every target shares.

Compose Multiplatform runs on Kotlin/Native on iOS and links its own drawing engine into the application. Codename One takes the JVM half of a KMP project instead. kotlinc already compiles `commonMain` to ordinary class files for Android and the desktop. Those classes, together with the real Compose runtime and the real `kotlinx.coroutines`, are exactly what Codename One's translator reads. Only the UI layer — `androidx.compose.ui`, `foundation` and `material3` — is replaced, by one written over Codename One components and `Graphics`.

The same application, built from the same `commonMain` both ways and measured on the same iPhone simulator, with Compose Multiplatform as 100%. The second bar is the same screens written in Java against Codename One directly, which the next section explains:



- **The same Compose code runs in a quarter of the CPU time.** A state change is drawn in 4.6 ms against 19.2 ms, and one step of scrolling in 4.0 ms against 17.0 ms. Both keep pace with the

display, so the difference is headroom: for heavier screens, older devices and battery.

- **The executable is 27% smaller** (16.8 MB against 22.9 MB) and the bundle 20% smaller, although the Codename One one carries the whole iOS port.
- **Start-up is faster**, 961 ms against 1008 ms cold and 580 ms against 604 ms warm.
- **Memory is level**, 47 MB of physical footprint against 48 MB.

The benchmark, its method and how to run it are in `scripts/kmp-bench` in the Codename One repository. These are simulator numbers; they show where each runtime spends CPU in identical code, not a device's frame rate.

Beyond size, the composables become real components, so a Compose screen uses the platform's own text input and accessibility, can sit inside a Codename One form next to any other component, and reaches every Codename One API directly — push notifications, in-app purchase, the native maps, the backend — with no `expect/actual` plumbing per platform.

The same build also reaches targets Compose Multiplatform's UI doesn't run on: watchOS, tvOS, and Windows, Linux and macOS as native binaries with no JVM to install. The Codename One backend runs the same Kotlin on the server, so a data class or validation rule in `commonMain` is shared by the app and the service that feeds it.

119.2. Dropping to Java where it pays

A Compose screen and a Codename One screen are the same kind of object at run time — a component in a form — so an application doesn't have to choose one for all its screens. Kotlin calls every Codename One class directly, and a Java class can sit beside the composables in the same module. Compose Multiplatform has no such floor: below `commonMain` there is a different language

and a different UI toolkit on every platform.

The benchmark measures what that floor is worth. `JavaBench.java` in `scripts/kmp-bench/app/java` is the Keynote screens written against Codename One directly, timed by the same steps. Its list is an `InfiniteContainer`, which makes cards a batch at a time as the scroll nears the end — as `LazyColumn` composes only what comes into view — and rebinds a card it has already made instead of building another. It ships no Kotlin standard library, no Compose runtime and no coroutines:

- **A state change is drawn in 1.5 ms**, thirteen times faster than Compose Multiplatform's 19.2 ms and three times faster than the Compose build.
- **A step of scrolling takes 1.8 ms**, against 17.0 ms for Compose Multiplatform.
- **The executable is 8.9 MB**, 39% of Compose Multiplatform's 22.9 MB, and the bundle is 10.2 MB.
- **Memory is level** with both, at 47 MB.

The time gap is mostly the price of the reactive model. A composition records the state it read, compares what it emits against what it emitted last time and applies the difference; an imperative update sets three labels on a card that already exists. The size gap is Kotlin: the Java build carries neither the Kotlin standard library nor the Compose runtime.

Nor does the declarative form buy readability. Here is one session card both ways. The Compose version, from the benchmark:

```
@Composable
fun SessionCard(time: String, title: String, speaker: String,
                favorite: Boolean, onFavorite: () -> Unit) {
    Card(Modifier.fillMaxWidth()) {
        Row(verticalAlignment = Alignment.CenterVertically) {
            Column(Modifier.weight(1f).padding(12.dp)) {
                Text(time, style = MaterialTheme.typography.labelMedium)
                Text(title, style = MaterialTheme.typography.titleMedium)
                Text(speaker, style = MaterialTheme.typography.bodySmall)
            }
            IconButton(onFavorite) {
                Icon(if (favorite) Icons.Default.Favorite else Icons.Default.FavoriteBorder, null)
            }
        }
    }
}
```

And in Codename One, with the look in the theme's CSS where a designer can change it:

```
public class SessionCard extends Container {
    public final Label time = new Label("", "SessionTime");
    public final Label title = new Label("", "SessionTitle");
    public final Label speaker = new Label("", "SessionSpeaker");
    public final Button heart = new Button("", "Favorite");

    public SessionCard(Runnable onFavorite) {
        super(new BorderLayout(), "SessionCard");
```

```
        add(BorderLayout.CENTER, BoxLayout.encloseY(time, title, speaker));
        add(BorderLayout.EAST, heart);
        heart.addActionListener(e -> onFavorite.run());
    }

    public void bind(String when, String talk, String by, boolean favorite) {
        time.setText(when);
        title.setText(talk);
        speaker.setText(by);
        FontImage.setMaterialIcon(heart, favorite
                ? FontImage.MATERIAL_FAVORITE : FontImage.MATERIAL_FAVORITE_BORDER);
    }
}
```

The Java card says what happens and when: the components are made once, `bind` fills them, a tap calls back as `onFavorite` does. Nothing reruns behind the code's back, so a breakpoint in `bind` stops exactly when a card shows a session — the question a recomposition count leaves open.

It tests as directly. A component is an ordinary object, so a unit test makes one, binds it and presses its button, with no test rule, semantics tree or tags kept only for the test:

```
import com.codename1.testing.AbstractTest;
import com.codenameone.developerguide.kmp.SessionCard;

public class SessionCardTest extends AbstractTest {
    @Override
    public boolean runTest() throws Exception {
        int[] taps = {0};
        SessionCard card = new SessionCard(() -> taps[0]++);
        card.bind("09:00  -  Hall A", "Keynote", "A. Speaker, Codename One", false);

        assertEqual("Keynote", card.title.getText());

        card.heart.released();   // a tap
        assertTrue(taps[0] == 1, "the heart reports the tap");
        return true;
    }
}
```

The card's components are public final fields, so the test reads them directly. It runs in the simulator with `mvn cn1:test`, like every other Codename One test.

A hot list, a custom chart or a screen that has to fit a watch is where the imperative path pays first; nothing stops a team writing every screen that way.

119.3. One platform API on every target

The `expect`/`actual` declarations a KMP project writes per platform are mostly calls Codename One

already makes the same everywhere. Composable code calls each of them as an ordinary Kotlin function:

- Push notifications, in-app purchase and subscriptions, and home-screen widgets and live activities.
- Crash protection and App Shield hardening, as build options rather than per-platform SDKs.
- Real-time audio and video and AI and speech.
- Storage, SQLite, networking, the camera, location, sharing and the native maps, with one implementation per platform maintained in Codename One.

The targets go past phones and desktops too: Apple Watch and Wear OS from the same project as the phone application, CarPlay and Android Auto, tvOS, embedded Linux boards with no X11 and no JVM, the browser, and the server-side backend.

119.4. Quick start

Create a Codename One application (for example at https://start.codenameone.com) and import the KMP project into it:

```
mvn cn1:import-kmp-project -Dcn1.kmp.import=/path/to/MyKmpApp
```

The goal copies the module's `commonMain` and its JVM source set (`jvmMain`, else `desktopMain`) into `common/src/main/kmp`, and rewrites the application's main class so that it shows the module's root composable. Two options cover projects it can't decide alone:

`-Dcn1.kmp.module=composeApp`

The module to import, when more than one has a `src/commonMain`.

`-Dcn1.kmp.entry=com.example.App`

The fully qualified root composable, when `commonMain` declares no single `@Composable fun App()`.

The Android and iOS source sets aren't copied. They call those platforms directly, and Codename One supplies both. A JVM file whose `main` opens a desktop window (`application { Window { App() } }`) is left out too: the generated main class starts the application instead.

Then build and run as usual:

```
mvn cn1:run                          # the simulator
mvn cn1:build -Dcodename1.platform=ios   # an iOS build on the build server
```

119.4.1. Gradle

A Gradle application needs the Compose compiler plugin, `id("org.jetbrains.kotlin.plugin.compose")` at the application's Kotlin version, applied next to the Codename One plugin. The build stops with the line to add when it's missing.

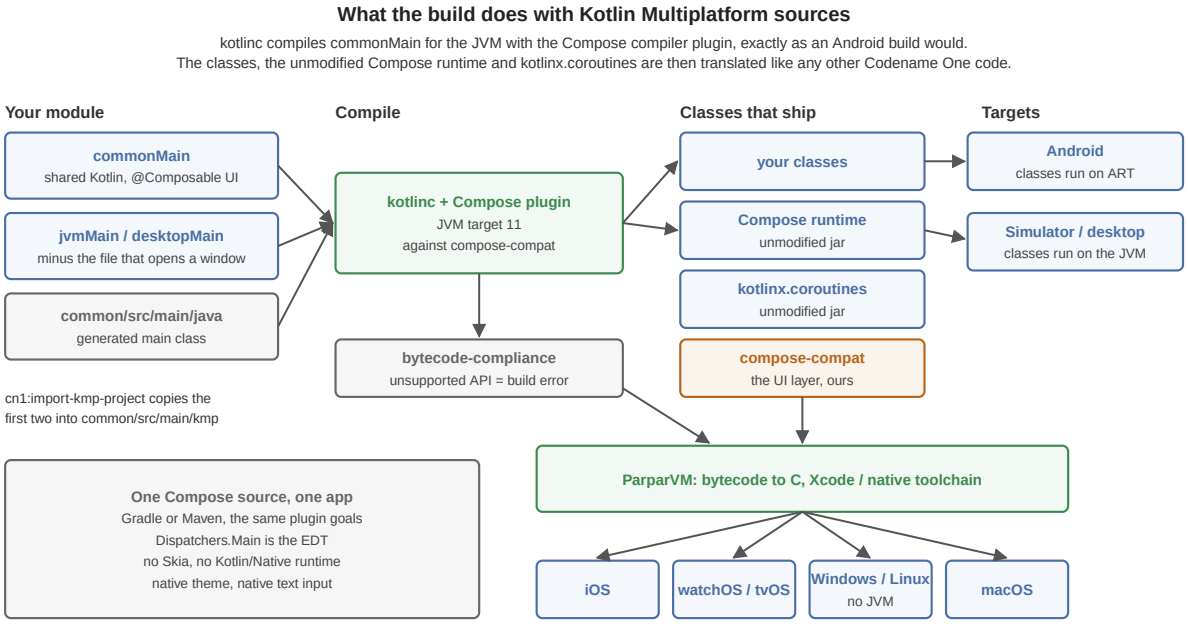
`convert-to-gradle` writes it for you. The Codename One settings plugin adds Google's Maven repository, limited to the `androidx.*` groups, which is where the Compose runtime is published.

119.4.2. Placing the sources by hand

`common/src/main/kmp/commonMain/kotlin` and `common/src/main/kmp/jvmMain/kotlin` are ordinary Kotlin source roots. The archetype's `compose` profile turns on whenever `common/src/main/kmp` exists: it adds `codenameone-compose-compat`, applies the Compose compiler plugin and sets both kotlinc's `jvmTarget` and javac's source and target to 11, because the Compose runtime's inline functions are JVM 11 bytecode. The Compose compiler plugin's version must equal the Kotlin version, which is why both come from one property.

119.5. The entry point

A composition is shown in a `ComposeForm`, or embedded anywhere as a `ComposeView`, which is an ordinary Codename One `Container`:

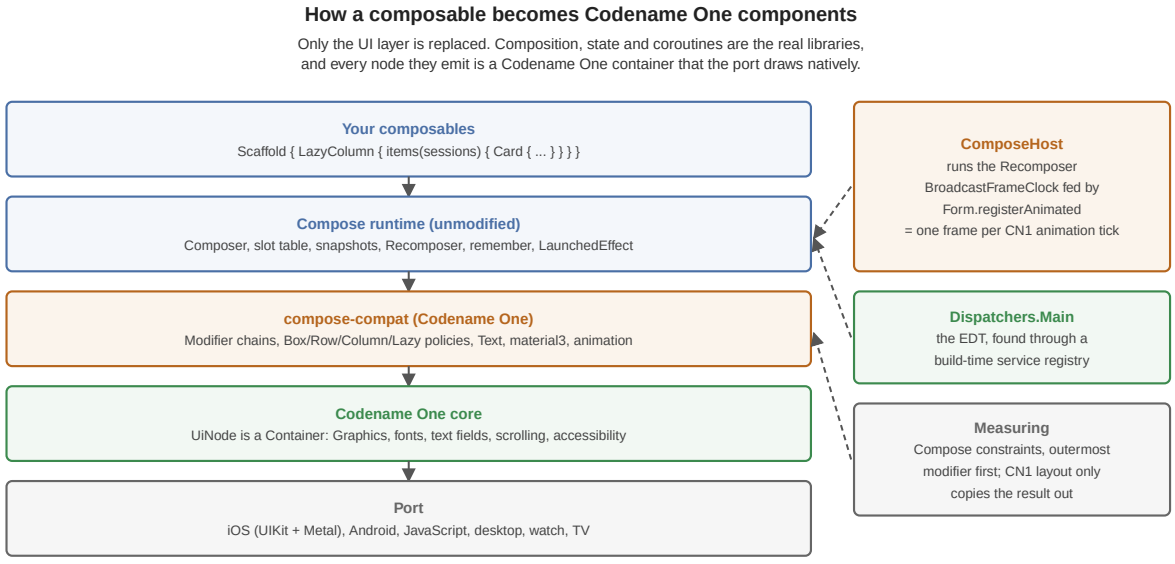


```
class MyApp : Lifecycle() {
    override fun runApp() {
        ComposeForm { LayoutScreen() }.show()
    }
}
```

Or beside other components:

```
val form = Form("Mixed", BorderLayout())
form.add(BorderLayout.NORTH, Label("Codename One"))
form.add(BorderLayout.CENTER, ComposeView { ListScreen() })
form.show()
```

Both live in `com.codename1.compose`. From Java, a `ComposeView` is created by a small Kotlin function that returns one, since a composable lambda can only be written in Kotlin.



119.6. How the build works

There is no transpiler. kotlinc compiles the sources for the JVM, with the Compose compiler plugin, against `compose-compat`. The application's classes, the unmodified Compose runtime, `kotlinx.coroutines` and `compose-compat` are then handled like any other Codename One code: the bytecode compliance check runs over them, and ParparVM translates them to C for iOS, the watch, TV and the native desktop targets. Android runs the classes on ART and the simulator on the JVM.

`androidx/compose/` is never relocated, not even when the Android compatibility layer is active in the same application: the Compose runtime the application was compiled against is the one it runs.

119.7. How a composable becomes components

Composition, snapshots, `remember`, `LaunchedEffect` and recomposition are the real Compose runtime's. What it emits are `UiNode` objects, each a Codename One `Container`:

- **Measuring is Compose's.** A node walks its modifier chain outermost first under Compose constraints (`Box`, `Row`/`Column` and leaf policies). The Codename One layout pass only copies the

result out, so `weight`, `fillMaxWidth`, `wrapContentSize` and intrinsic padding behave as they do in Compose.

- **Frames come from the Codename One animation loop.** `ComposeHost` runs the `Recomposer` with a `BroadcastFrameClock` that `Form.registerAnimated` ticks, so `withFrameNanos`, `animateFloatAsState` and `AnimatedVisibility` run in step with every other Codename One animation, and an idle screen costs nothing.
- **`Dispatchers.Main` is the EDT.** kotlinx.coroutines finds its main dispatcher through a service file. There is no service loader on the device, so the translator compiles that file into a registry at build time.
- **Lazy lists compose what's in view.** `LazyColumn` and `LazyRow` compose each item as its own composition when it comes within a quarter of a view of the window and dispose of it half a view past it. `scrollToItem` works on items that were never measured.
- **The system bars are respected.** `TopAppBar`, `CenterAlignedTopAppBar` and `NavigationBar` pad themselves by the display's safe area, read when they're measured, so a notch or a home indicator that the native view reports late still moves them.

119.8. Supported API

`compose-compat` covers what typical application screens use. Anything else is a build error (see below), never a silent no-op.

Layout

`Box`, `Row`, `Column`, `Spacer`, `LazyColumn`, `LazyRow`, `Arrangement`, `Alignment`, `PaddingValues`, `Canvas`.

Modifiers

`size` (`size`, `width`, `height`, `fillMax*`, `wrapContent*`, `In`, `required`, `defaultMinSize`, `aspectRatio`), `padding`, `offset`, `weight`, `background`, `border`, `clip`, `alpha`, `drawBehind`, `clickable`, `combinedClickable`, `verticalScroll`, `horizontalScroll`, `testTag`.

Text

`Text`, `BasicText`, `TextField`, `OutlinedTextField`, `BasicTextField`, `TextStyle`, `FontWeight`, the Material 3 type scale.

Material 3

`MaterialTheme` and `ColorScheme`, `Scaffold`, `Surface`, `TopAppBar`, `CenterAlignedTopAppBar`, `NavigationBar` and `NavigationBarItem`, `Card`, `ElevatedCard`, `OutlinedCard`, `Button`, `ElevatedButton`, `FilledTonalButton`, `OutlinedButton`, `TextButton`, `IconButton`, `FloatingActionButton`, `ExtendedFloatingActionButton`, `AssistChip`, `FilterChip`, `Checkbox`, `Switch`, the progress indicators, dividers, `Icon` with `Icons.Filled`, `Icons.Outlined` and `Icons.AutoMirrored`.

Animation

`AnimatedVisibility`, `animateFloatAsState`, `animateDpAsState`, `animateColorAsState`, `rememberInfiniteTransition` with `animateFloat`.

Images

`Image` with `ImageVector` and `ContentScale`.

`LazyColumn(reverseLayout = true)` throws: it's not implemented.

119.8.1. Unsupported API is a build error

The bytecode compliance check runs over the compiled classes. A composable or modifier that `compose-compat` doesn't provide is a reference to something that doesn't exist, and the build reports it under its original name with the source line, before anything is translated. Port such a screen by replacing the call, or by writing the missing piece in the application with the supported building blocks — most custom components are a `Box` with a `drawBehind`.

119.9. Testing

Compose screens are tested the way any Codename One screen is: a `ComposeView` is a component, so screenshot tests and the component inspector see it like any other. The Codename One test application (`scripts/hellocodenameone`) carries Compose screens under `common/src/main/kmp` — layout and modifiers, typography and buttons, a `Scaffold` over a `LazyColumn` of cards, and state with `LaunchedEffect` and `AnimatedVisibility` — and its `KmpCompat*` screenshot tests compare them on every platform the test suite runs on.

119.10. Troubleshooting

The Compose compiler plugin reports a Kotlin version mismatch

The plugin and kotlinc are different versions. Take both from one property.

kotlinc or javac reject JVM 11 bytecode or inline functions

The module is compiling below JVM 11. The `compose` profile sets it: check that `common/src/main/kmp` exists and that nothing in the pom overrides `kotlin.compiler.jvmTarget`.

The Gradle build stops asking for `org.jetbrains.kotlin.plugin.compose`

Add the plugin line shown in the Gradle section.

`Incremental compilation failed` after changing the Kotlin version

Kotlin's incremental cache from the old compiler is in `target`. Build once with `clean`.

Chapter 120. Working with macOS

120.1. macOS Desktop Build Options

Launch Codename One Settings from the Maven project root and open **Hints** to configure `desktop.mac.*` build hints such as entitlements and `Info.plist` entries:

```
mvn cn1:settings
```

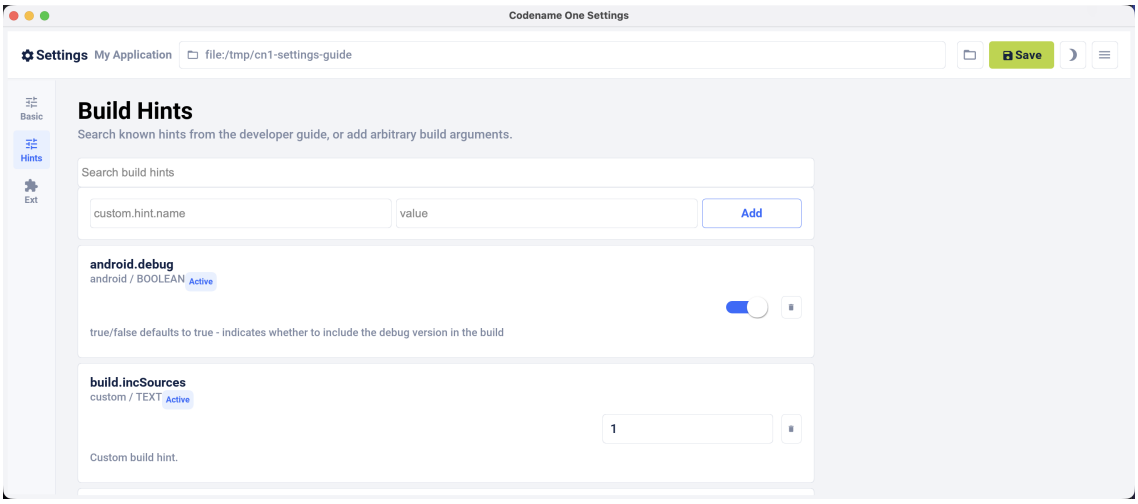


Figure 428. Desktop macOS build hints

Desktop signing values that aren't build hints are top-level entries in `common/codenameone_settings.properties`: `codename1.desktop.mac.certificate` contains the `.p12` path and `codename1.desktop.mac.certificatePassword` contains its password. The Maven desktop macOS build reads these properties together with the `desktop.mac.*` hints.

120.1.1. Bundle Types

Three bundle types dictate what the build server produces for you when you build your project as a Desktop macOS App.

1. **DMG** - Produces a `.DMG` disk image with your app. This is the preferred format for distributing your app outside of the Mac App Store. If you provide a Developer ID Application certificate (see "Understanding Certificates" below), the app will be signed so that users won't receive warnings about "Unidentified developer" when they install your app.
2. **Sandboxed DMG** - Same as **DMG** bundle type except that your app is set up to use the app sandbox. This is typically used to test an app that's being distributed via the App Store, since App Store apps **must** use the sandbox. If you select this bundle type, you're **required** to provide a Mac App Distribution Certificate, and you should also specify entitlements required for your app to function correctly. For more information about the app sandbox, see Apple's documentation on the subject [https://developer.apple.com/app-sandboxing/].
3. **Mac App Store Upload (PKG)** - Produces a `.PKG` file that you can upload to the Mac App Store. This requires that you provide **both** a Mac App Distribution certificate, and a Mac App Installer certificate (see "Understanding Certificates" below). Both of these certificates should be

embedded into a single `.p12` file (See "Exporting Certificates as p12" below).

120.1.2. Understanding Mac Certificates

Currently (as of Jan. 5, 2020) the `mac.desktop-vm` build hint is ignored if you include a certificate with your app. This limitation should be fixed soon.

For the purposes of Mac application distribution, there are 3 types of certificates that you will be interested in. The type(s) of certificate required will depend on the type of bundle you generate. The certificate types are:

1. **Developer ID Application Certificate (Mac applications)**

   This type of certificate is used to sign an app to be distributed **outside** of the Mac App Store as a DMG image. This corresponds to the "DMG" bundle type. You can identify this kind of certificate because its identity will be of the form "Developer ID Application: YOUR COMPANY NAME (SOMECODE)." For example, Developer ID Application: Acme Widgets Corp. (XYSD5YF).

2. **Mac App Distribution Certificate (Mac App Store)**

   This type of certificate is used to sign the.app bundle for an app that's to be distributed in the Mac App Store. This certificate is required for both the "Sandboxed DMG," and "Mac App Store Upload (PKG)" bundle types. You can identify this kind of certificate because its identity will be of the form "3rd Party Mac Developer Application: YOUR COMPANY NAME (SOMECODE)." For example, 3rd Party Mac Developer Application: Acme Widgets Corp. (XYSD5YF).

3. **Mac App Installer Certificate (Mac App Store)**

   This type of certificate is used to sign the.pkg installer for an app that's being submitted to the Mac App Store. This certificate is required for the "Mac App Store Upload (PKG)" bundle type. You can identify this kind of certificate because its identity will be of the form "3rd Party Mac Developer Installer: YOUR COMPANY NAME (SOMECODE)." For example, 3rd Party Mac Developer Installer: Acme Widgets Corp. (XYXD5YF).

120.1.3. Obtaining Certificates

Apple provides documentation on obtaining certificates on its website [https://developer.apple.com/library/content/documentation/IDEs/Conceptual/AppDistributionGuide/MaintainingCertificates/MaintainingCertificates.html#//apple_ref/doc/uid/TP40012582-CH31-SW6] but the process described there involves Xcode. This section describes an alternate process that doesn't require Xcode.

If you have an Apple developer account, you can manage your certificates here [https://developer.apple.com/account/mac/certificate].

Figure 429. Mac Developer portal certificates

The screenshot above shows an account that already has the three kinds of certificates you will require:

1. **Developer ID Application** - Used for the DMG bundle type.
2. **Mac App Distribution** - Used for the Sandboxed DMG and Mac App Store Upload (PKG) bundle types.
3. **Mac App Installer** - Used for the Mac App Store Upload (PKG) bundle type.

If your account doesn't yet have a certificate of the required type, you should begin by pressing the "+" button in the upper right. This will bring you to a page asking "What type of Certificate do you need?" Two options on this page will interest you:

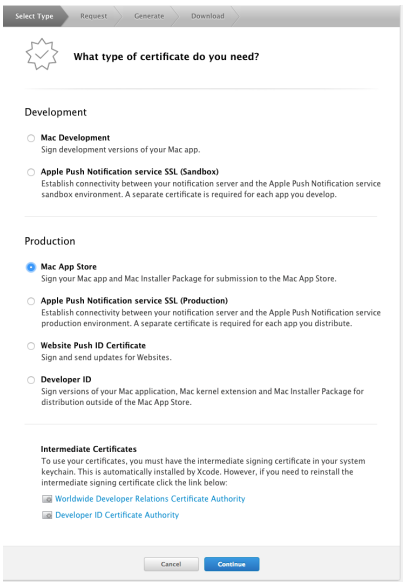

Figure 430. Creating a new certificate

1. **Production** > **Mac App Store** - For both the Mac App Distribution and Mac App Installer certificates.
2. **Production** > **Developer ID** - For the Developer ID Application certificate.

Select the option corresponding to the certificate you wish to generate. In either case, you'll be taken to a form to select whether you want an "Installer" certificate or an "Application" certificate. Select the appropriate type.

You will then be prompted to upload a Certificate Signing Request (CSR) file, and it will provide instructions on how to do this via the Keychain app.

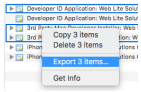
You can reuse the same CSR file for generating all 3 certificates.

After generating the certificates, you should download them to your Mac, and import them into

your keychain. You should be able to accomplish this by simply double-clicking the downloaded ".cer" file, and following the prompts.

120.1.4. Exporting Certificates as P12

The following section requires access to a Mac, and assumes that you've already generated your 3 certificates



Notice that Mac apps may require three different kinds of certificates, yet `codename1.desktop.mac.certificate` accepts a single P12 file. This isn't a mistake. P12 files may contain more than one certificate, and you're expected to include all the certificates that the build server may require inside a single P12. The build server automatically extracts the certificates it needs according to the bundle type.

When building the "DMG" bundle type, the build server will look for a "Developer ID Application Certificate" inside the P12. If one is found, it will be used to sign the app bundle.

The "Sandboxed DMG" target will look for a "Mac App Distribution Certificate" certificate in the P12.

The "Mac App Store Upload (PKG)" target will require both a "Mac App Distribution Certificate" and a "Mac App Installer Certificate" to be included in the P12.

The easiest way to produce a P12 that includes all 3 kinds of certificates is to export them from the Keychain Access app (Requires a Mac). Select all 3 certificates at once (using CMD-click), then right-click and select "Export 3 Items..."

You will then be prompted to select a location to save the `.p12` file, as well as selecting a password for the file.

120.1.5. Entitlements

When distributing apps in the Mac App Store, or when using the "Sandboxed DMG" bundle type, your app is run inside a sandboxed environment, meaning that it doesn't have access to the outside world. It's provided its own "sandboxed" container for file system access, and it doesn't get any network access. If your app requires access to the "outside world," request the required entitlements with `desktop.mac.entitlement. entries in the *Hints` view.

For more information about the app sandbox, and a full list of entitlements, see Apple's documentation on the subject [https://developer.apple.com/library/content/documentation/Miscellaneous/Reference/EntitlementKeyReference/Chapters/EnablingAppSandbox.html].

You can specify entitlements using the build hint `desktop.mac.entitlement.XXXX` where XXX is the entitlement you wish to set. For example, `desktop.mac.entitlement.com.apple.security.network.client=true`

120.1.6. Custom Info.plist Entries

You can add custom entries to the Info.plist file [https://developer.apple.com/library/archive/documentation/General/Reference/InfoPlistKeyReference/Introduction/Introduction.html] using the following build hints:

desktop.mac.plist.KEYNAME

Injects the entry with key `KEYNAME` into the Info.plist file. For example, `desktop.mac.plist.LSApplicationCategoryType=public.app-category.business`

120.2. Native macOS Build (AppKit)

The "macOS Desktop" section above covers the JavaSE bundled-JRE wrapper. The **native macOS build** is a separate, ahead-of-time compiled target: ParparVM translates your bytecode to C and the result is built into a real AppKit application. Its Xcode project targets the macOS SDK, links AppKit and Metal, and carries no UIKit at all. The output is a single signed `.app` bundle suitable for Mac App Store or Developer ID distribution.

This target is a good fit when:

- You need native-speed startup and rendering on the Mac, not a wrapped JVM.
- You want a single `.app` bundle without a JRE inside it.
- You want the Mac conventions your users expect: a real title bar, a real menu bar, and real windows.

Java source is shared with your other targets; no Mac-specific code is required.

This target replaced a Mac Catalyst build, which produced a UIKit application running in macOS's iOS compatibility layer. Existing projects keep building without an edit and simply get the AppKit app instead. If you depend on the previous behavior, see Chapter 121, *Working with Mac Catalyst*.

A few device capabilities have no macOS counterpart and are inert rather than emulated: motion sensors, orientation locking, SMS, and background task scheduling. `Display` reports each of them as unsupported, so an application that checks before using one behaves correctly without a Mac-specific branch.

Accessibility is partly wired. Codename One builds a portable semantics tree for its lightweight components — see Chapter 12, *Accessibility Semantics* — and this port maps `announceForAccessibility()` onto an AppKit announcement, so live messages reach VoiceOver. What it doesn't do yet is publish that tree through `NSAccessibility`, so VoiceOver can't navigate the interface element by element. The tree itself is shared and already consumed by the other ports, so what's missing here is this port's bridge to it rather than the semantics.

Each additional window your application opens through the `Window` API is a real `NSWindow`, with its own GPU surface rather than a raster copied from somewhere else. See Chapter 129, *Desktop Windows*.

120.2.1. Local Build

To generate an Xcode project locally that you can open and run on the Mac:

```
mvn -B -Dcodename1.platform=ios -Dcodename1.buildTarget=mac-source package
```

The output is written to:

```
target/<finalName>-mac-source/<MainClass>.xcodeproj
```

Open the project in Xcode, select the `My Mac` destination, and press Run. The resulting `.app` is identical in shape to one produced by the cloud build server.

120.2.2. Cloud Build

To produce a release-ready signed Mac app on the Codename One build server:

```
mvn -B -Dcodename1.platform=ios -Dcodename1.buildTarget=mac-os-x-native package
```

Mac distribution requires **its own certificates and provisioning profile** — Apple issues separate *Mac App Distribution* (3rd Party Mac Developer Application) and *Developer ID Application* certificates that aren't interchangeable with the *iPhone Distribution* certificate used for iOS App Store builds. Configure them via the parallel `codename1.mac.*` hints:

Hint	Purpose
`codename1.mac.appid`	Mac bundle identifier (the App Store Connect record is distinct from the iOS one).
`codename1.mac.certificate`	Path to the `.p12` containing the Mac signing certificate. Bundle both *Mac App Distribution* and *Developer ID Application* into a single P12 when targeting both channels.
`codename1.mac.certificatePassword`	Password to unlock the P12.
`codename1.mac.provision`	Path to the Mac `.provisionprofile`.

The Apple Developer Team ID itself can stay shared with your iOS build (a single Apple Developer account) — `macos.teamId` falls back to `ios.release.teamId` when not set. The server returns a signed `.app` bundle.

120.2.3. IDE Shortcuts

The IntelliJ workspace template ships two macOS run configurations alongside the iOS ones:

- **Mac Native Project** (Local Builds folder) — equivalent to running `mvn package -Dcodename1.buildTarget=mac-source`. Use this to generate the Xcode project for hands-on

debugging.

- **Mac Native Build** (Build Server folder) — equivalent to `mvn package -Dcodename1.buildTarget=mac-os-x-native`. Use this for cloud builds.

120.2.4. Distribution

The native macOS build supports both Mac App Store and Developer ID distribution. The generated Xcode project includes two `ExportOptions-*-Mac.plist` files in `dist/`:

- `ExportOptions-AppStore-Mac.plist` — App Store distribution (sandboxed, hardened runtime off).
- `ExportOptions-DeveloperID-Mac.plist` — Developer ID distribution (hardened runtime on, sandbox off).

After archiving in Xcode, run:

```
xcodebuild -exportArchive \
  -archivePath build/<MainClass>.xcarchive \
  -exportOptionsPlist dist/ExportOptions-AppStore-Mac.plist \
  -exportPath build/export
```

120.2.5. Entitlements

The native macOS build emits a `<MainClass>.entitlements` plist (or `<MainClass>-AppStore.entitlements` + `<MainClass>-DeveloperID.entitlements` when both channels are configured). The defaults are sensible: App Sandbox on for the App Store channel, hardened runtime on for the Developer ID channel, network client access enabled, user-selected file access enabled. The signing-certificate identity defaults to *Apple Distribution* for the App Store channel and *Developer ID Application* for the Developer ID channel.

120.2.6. Supported Distribution Channels

Channel	Notes
App Store	Sandboxed, hardened runtime off. Signed with *Apple Distribution*; uploaded via App Store Connect.
Developer ID	Hardened runtime on, sandbox off. Signed with *Developer ID Application*; notarized before distribution.

120.3. If You Need the Previous Mac Behavior

Projects that depend on the Mac Catalyst build this target replaced can still build it: set `macNative.enabled=true` and build the iOS target, which is what Catalyst has always been. See Chapter 121, *Working with Mac Catalyst*.

Chapter 121. Working with Mac Catalyst

Mac Catalyst was the previous macOS target. It's superseded by the native macOS build described in Chapter 120, *Working with macOS*, which produces an AppKit application rather than a UIKit one.

Mac Catalyst remains buildable and is still exercised by the compliance suite, so existing projects keep working. New projects should use the native macOS build.

121.1. What Mac Catalyst Is

Mac Catalyst isn't a macOS port. It's a slice of the iOS Xcode project: the same build pipeline, the same UIKit controls, one additional SDK. Apple's compatibility layer runs that UIKit application on macOS.

That's why the behavior differs from a native Mac app in ways no amount of configuration reaches:

- Windows are `UIWindowScene` instances rather than `NSWindow` instances.
- The menu bar is built through `UIMenuBuilder`, and keyboard accelerators are `UIKeyCommand` objects.
- Controls are UIKit's, drawn by the compatibility layer rather than by AppKit.

121.2. Building It

Catalyst has no build target of its own, because it isn't a separate build. It is the iOS build with one hint set, and `IPhoneBuilder` emits the Catalyst slice whenever it sees that hint:

```
codename1.arg.macNative.enabled=true
```

With it in `codenameone_settings.properties`, the ordinary iOS targets produce the Catalyst app — `ios-source` for a local Xcode project, `ios-device` for a build-server build:

```
# Catalyst is an iOS build. Turn it on with the hint, in
# codenameone_settings.properties, and build the iOS project target:
#   codename1.arg.macNative.enabled=true
mvn -B -Dcodename1.platform=ios -Dcodename1.buildTarget=ios-source package
```

```
mvn -B -Dcodename1.platform=ios -Dcodename1.buildTarget=ios-device package
```

Generating the project locally requires Xcode and the Ruby `xcodeproj` gem. The Catalyst path injects its build settings into an already-generated iOS project after the fact, and that gem is what performs the injection; the native macOS build generates a macOS project directly and needs neither.

121.3. Build Hints

Mac Catalyst reads the `macNative.` hint family: `distribution`, `teamId`, `bundleId`, `deriveBundleId`, `minDeploymentTarget`, `iosMinDeploymentTarget`, `appCategory`, `copyright`, the `signingIdentity.` pair and the `notarize.*` group. They're listed in the build-hint reference under Mac Catalyst builds.

`iosMinDeploymentTarget` exists only here. It sets the iOS half of the Catalyst slice, and the native macOS build has no such half.

Deployment floors are macOS 10.15 and Catalyst 13.1.

121.4. Windows

Windows are off by default here, and turning them on isn't recommended. Set `macNative.multiWindow=true` alongside `macNative.enabled=true` if you need them anyway.

They're off because the implementation has limits Catalyst can't lift, listed below, and because enabling them costs the rest of the application a layout shift — see Section 129.16, "Mac Catalyst (legacy)" for the measurement. Neither was worth paying once the native macOS build existed: there, windows are on with no hint at all and every operation on the API is implemented, because AppKit is a multi-window system and Catalyst is an iOS one wearing a Mac frame.

With the hint set, a Codename One `Window` works, with one difference worth knowing: the window's content is rendered into an off-screen raster and presented to the scene's view, rather than the window owning its own GPU surface. Native peer components and native text editing still use the scene's real view hierarchy and behave normally.

Some window controls have no Mac Catalyst equivalent, because AppKit owns the behavior and Catalyst doesn't expose it to a `UIWindowScene`. `setAlwaysOnTop`, `setUtilityWindow`, `minimize`, `restore` and `toggleMaximize` do nothing here, and `setDecorated(false)` is partial: it hides the title bar's title and toolbar but the window frame remains. Modality, minimum window size and resizability all work. The native macOS build implements every one of them.

121.5. Moving to the Native macOS Build

What changes:

- The build target becomes `mac-source` or `mac-os-x-native`.
- The hint family becomes `macos.`. The `macNative.` names are still accepted, so an existing configuration keeps working; `iosMinDeploymentTarget` is ignored with a warning, because it no longer describes anything.
- The deployment floor becomes macOS 11.
- The window chrome becomes AppKit's, so a Mac user gets the title bar, menu bar and window behavior they expect from any other Mac application.

What doesn't change:

- Your Java and Kotlin source.

- Your signing certificates and provisioning profiles.
- Your distribution channels, App Store Connect records and notarization setup.

Chapter 122. Working with the native Windows port

The native Windows port compiles a Codename One app to a real, standalone Win32 executable — a single `.exe` with **no JVM and no runtime dependencies**. It's the Windows analog of the iOS port: the same ParparVM pipeline that turns your Java/ Kotlin bytecode into C and then into a native binary, here targeting Windows with the LLVM toolchain and rendering through Direct2D / DirectWrite.

This is distinct from the long-standing **Windows desktop** build, which packages the app to run on a Java Virtual Machine (see Section 122.8, "Native Windows vs. the desktop (JVM) app vs. the jar" for a practical comparison). The native port needs no JVM on the target machine.

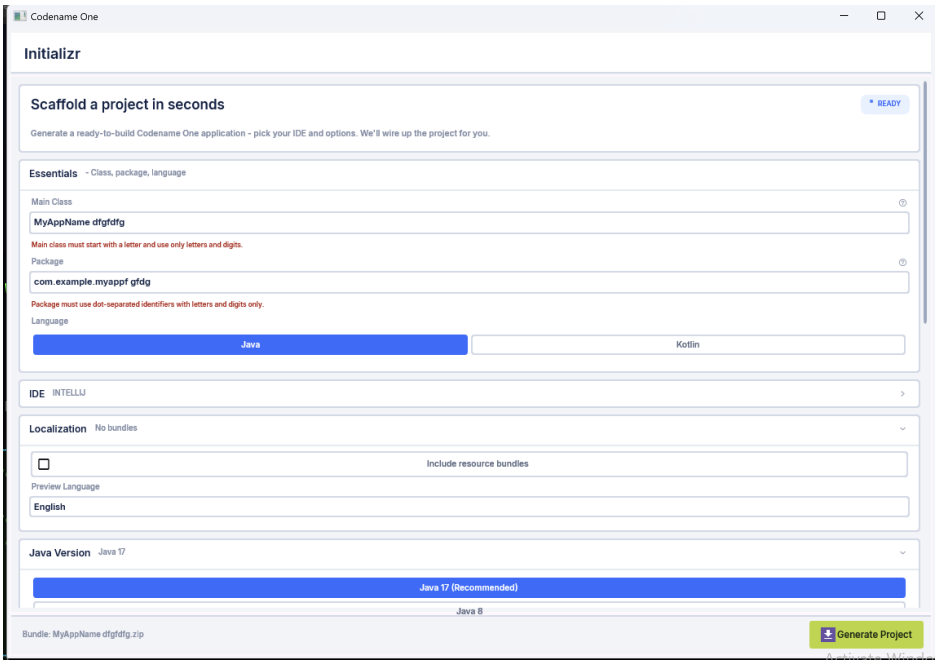


Figure 431. The Codename One Initializr app running as a native Windows `.exe` (ParparVM + Direct2D/DirectWrite, no JVM)

The native Windows port is a young port. It renders, runs and edits text, but several platform services are still being filled in. Treat it as a foundation to build on rather than a feature-complete replacement for the desktop build, and consult the port's `status.md` for the current gap list.

122.1. How it works (the technology stack)

The port reuses Codename One's portable architecture and swaps in a Win32 / Direct2D implementation layer:

- **ParparVM "clean" C target.** The same VM that powers iOS translates your app the Codename One core + the minimal Java runtime to C. A CMake project is generated and compiled with **clang-cl** (LLVM on the MSVC ABI) + **Ninja** into a native `.exe`. There is no bytecode interpreter and no JNI — your code **is** the native binary.

- **Concurrent garbage collector.** ParparVM's non-blocking GC runs natively, the same collector used on iOS.
- **Direct2D + DirectWrite + WIC.** All 2D graphics (primitives, gradients, clipping, affine and perspective transforms, images) go through Direct2D; glyph layout, measurement and rasterization use DirectWrite; image decode/encode uses Windows Imaging Component (WIC). Rendering is GPU-accelerated.
- **Media Foundation** backs `Media` playback, and **WebView2** backs `BrowserComponent` (when the WebView2 SDK is present at build time).
- **WinHTTP** backs networking; raw sockets and WebSockets use Winsock.
- **Single self-contained executable.** There is no `.app`-style bundle directory on Windows, so the app's classpath resources — the theme `.res`, images, localization, the material icon font — are embedded directly into the executable's PE resource section and read back at runtime through `getResourceAsStream`. The result is one file you can copy and run.

122.2. Building a native Windows app

A native Windows build runs through the `codenameone-maven-plugin` like every other target; the project produced by the Codename One Initializr already knows how to build it. The heavy lifting — translate to C, generate the CMake project, configure and build with clang-cl/Ninja, collect the `.exe` — is handled by the builder, so the configuration on your side is trivial.

The build can run two ways, and the builder picks automatically based on the host:

- **On a Windows host** it uses clang-cl + CMake + Ninja inside a Visual Studio developer environment (the CRT and Windows SDK reach the compiler through `vcvarsall`).
- **On any other host — for example a Linux build server** it cross-compiles with clang-cl + lld-link + llvm-rc against a Windows SDK laid out by `xwin` [https://github.com/Jake-Shadle/xwin]. clang is a cross-compiler, so the PE it emits is identical to a Windows-host build. Point the `windows.sdkRoot` build hint (or the `CN1_XWIN_SYSROOT` environment variable) at the `xwin splat` directory. This is how the build cloud produces Windows binaries without a Windows machine.

Both **x64** and **arm64** are produced this way — clang-cl cross-compiles to either architecture from either host; pick the target with the `windows.arch` build hint.

What you **can't** do off Windows is **run** the result: Direct2D/DirectWrite need a real Windows GPU/display stack (emulation such as Wine is too incomplete to trust), so rendering can only be verified on Windows. A Windows 11 VM (Parallels, Hyper-V, …) or a real machine is therefore the place to **test** the app, even when the binary itself was built on Linux.

122.3. Cloud builds (the `win32` target)

On the Codename One build cloud the native Windows build is the **win32** target, and it builds on Linux (the Android/JavaScript build group) using the cross-compile above. Trigger it like any other cloud target:

```
mvn package -Dcodename1.platform=win -Dcodename1.buildTarget=windows-device
```

The convenience goal `mvn cn1:buildWin32`, run from the project root, does the same thing. A regular (release) build returns **two** binaries — x64 and arm64, both stripped release exes. Setting the `windows.debug` build hint instead returns a **single** x64 exe with symbols, for diagnosis. (To build locally on a Windows box, use `-Dcodename1.buildTarget=local-windows-device`.)

122.4. Build hints

The native Windows port adds the build hints below. They use the `windows.` prefix; don't confuse them with the older `win.` hints, which configure the **JVM-based Windows desktop installer** (`win.installDirName`, `win.shortcutName`, …) and have no effect on the native port.

Table 29. Native Windows port build hints

Name	Description
windows.arch	Target CPU architecture for the `.exe`: `x64` (default) or `arm64`. Synonyms `x86_64`/`amd64` and `aarch64` are accepted. clang-cl cross-compiles to the chosen architecture from either host.
windows.debug	`true`/`false` (default `false`). When `false`, the `.exe` is optimized and **stripped** — no PDB, with the linker dead-stripping unreferenced code (`/OPT:REF`) and folding identical functions (`/OPT:ICF`). Set `true` to keep debug symbols (a `.pdb` next to the exe) so a native crash address can be symbolized while you are developing. Optimizations stay on in either case.
windows.embedded	`true`/`false` (default `false`). Builds a kiosk `.exe` for a Windows IoT Enterprise device. See Chapter 125, *Embedded Windows devices*.
windows.xbox	Experimental. `true`/`false` (default `false`). Builds a UWP app for an Xbox in Developer Mode instead of a desktop `.exe`, packaged as an `.msix`. See Section 122.7, "Xbox in Developer Mode". Can't be combined with `windows.msix`.

The full cross-platform build-hints reference is in the Build hints reference chapter [# _build_hints_reference].

122.5. Optimized, with debug info in a separate file

The shipping build is optimized (`/O2`): the linker removes unused functions and folds identical ones (`/OPT:REF` and `/OPT:ICF`), and the debug information isn't embedded in the executable — it's written to a separate `.pdb` companion. The `.exe` therefore stays as small as the translated code allows, while

a faulting address can still be turned back into a function name and source line with `llvm-symbolizer` against the `.pdb`. As a concrete data point, the Codename One Initializr sample builds to an ~8 MB `.exe`; the matching `.pdb` is several times larger but ships beside the binary rather than inside it, and is only needed to symbolize a crash. Setting `windows.debug=true` switches to an unoptimized debug build with full symbols.

122.6. Code signing

Unlike iOS and Android, Windows does **not** require a signature to **run** a desktop exe — an unsigned win32 build launches fine. But an unsigned binary that a user downloads shows **"Unknown publisher"** in the UAC prompt and trips **SmartScreen** ("Windows protected your PC"), so anything you actually distribute should be **Authenticode-signed**. Signing is therefore optional in the port (the default is unsigned) but strongly recommended for release.

The port signs with `osslsigncode` [https://github.com/mtrojnar/osslsigncode], which signs Windows PE files on **any** OS — so signing happens right in the Linux build cloud, no Windows machine needed. Provide a code-signing certificate and the build hints below, and each produced exe (x64 and arm64) is signed and timestamped.

122.6.1. Signing with a PKCS#12 certificate

Put your code-signing certificate and key in a PKCS#12 (`.pfx`/`.p12`) file and point your project settings at it:

```
# codenameone_settings.properties
codename1.windows.signing.certificate=/secure/path/codesign.p12
codename1.windows.signing.password=your-pkcs12-password
# optional signature metadata + timestamping (shown with their defaults):
codename1.arg.windows.signing.name=Acme Corp
codename1.arg.windows.signing.url=https://acme.example
codename1.arg.windows.signing.timestampUrl=http://timestamp.digicert.com
codename1.arg.windows.signing.digest=sha256
```

You configure the certificate once and it's used for **both local and cloud builds** — a cloud build automatically sends it with the build request (the same way the iOS and Android signing certificates are uploaded), so there is nothing extra to do for the build cloud. The signature is **timestamped** (RFC 3161) by default, so it keeps verifying after the certificate expires; set `windows.signing.timestampUrl` empty to turn that off. Set `windows.signing=false` to force an unsigned build even when a certificate is configured.

122.6.2. Hardware-backed and cloud keys

Since June 2023 the CA/Browser Forum requires code-signing private keys to live in a hardware module, so a brand-new OV/EV certificate is no longer a plain `.pfx`. The usual answer is a managed signing service — **Azure Trusted Signing**, **DigiCert KeyLocker**, **eSigner** from SSL.com — which exposes the key through PKCS#11. `osslsigncode` speaks PKCS#11, so the build host points at the service's provider per its docs; the rest of the flow (digest, timestamp, the resulting signed exe) is

identical. Plain `.pfx` signing remains fine for internal/test certificates and for certs issued before the cutoff.

`osslsigncode` must be on the build host's `PATH` (or set `CN1_OSSLSIGNCODE` to its location). If signing is requested but the certificate or tool is missing, the build fails with a clear message rather than shipping an unsigned exe by surprise.

122.7. Xbox in Developer Mode

This target is **experimental**. It's a first step toward gaming consoles (see Appendix F, *Gaming consoles*), and its build hint, behaviour and packaging can change. Continuous integration checks that the package installs and starts on Windows; it hasn't been verified on a console.

An Xbox console switched to Developer Mode runs apps you sideload onto it, with no store submission and no publisher program. The console accepts UWP apps only, so `windows.xbox=true` builds the same native port as a UWP app:

- The app runs inside the Windows app container on a `CoreWindow`, rendering through Direct2D into a Direct3D swap chain. It still runs on a Windows desktop, which is the quickest place to try a build.
- The controller drives the UI. The D-pad and left stick move focus, **A** fires, and **B** is the back key, so `Display.getGameAction()` and the back command work without code for the controller.
- `Display.getDisplaySafeArea()` reports the region the console keeps clear of TV overscan; lay out important content inside it.
- The result is `<MainClass>.msix`, signed. Without a signing certificate the build creates a self-signed development certificate whose subject is the package publisher, and writes it beside the package as `<MainClass>-dev.cer`. Set `windows.msix.publisher` and `windows.msix.pfx` to sign with your own.

```
codename1.arg.windows.xbox=true
```

Features that need a desktop report unsupported in this build: secondary windows, menus, the tray, native widgets and text editors, file dialogs, the clipboard, printing, the camera, audio recording and the share sheet. Files live in the app's local folder, which is the only file system root.

122.7.1. Installing on the console

1. On the console, install the **Dev Home** app and switch to Developer Mode as Microsoft describes, then turn on **Remote Access** (Device Portal) in Dev Home.
2. Open the Device Portal address Dev Home shows (`https://<console address>:11443`) in a browser on the same network.
3. Under **Home**, select **Add** and pick the `.msix`. When asked for a certificate, pick the `.cer` that came with it.

4. The app appears in Dev Home's list and among the console's games and apps; launch it from either.

To try the package on a Windows desktop first, trust the certificate (import the `.cer` into **Local Machine** > **Trusted People**), then install the package with `Add-AppxPackage <MainClass>.msix` in PowerShell, with Developer Mode enabled in Windows settings.

122.8. Native Windows vs. the desktop (JVM) app vs. the jar

Codename One can produce three different Windows artifacts from the same project. They trade off self-containment, size, startup and maturity differently:

	Native Windows `.exe`	**Desktop app (JVM)**	**Executable jar**
Summary	A real Win32 binary (ParparVM → C → native), Direct2D/DirectWrite rendering.	Your app running on a JVM with the Java SE port (Swing-hosted rendering), packaged as a Windows installer.	A runnable `.jar` of your app plus the Codename One jars.
JVM required on the target?	No — fully self-contained.	No if the installer bundles a JRE; otherwise it relies on one.	Yes — a compatible JDK (11–25) must be installed on the machine.
Artifact size	One `.exe`, on the order of 5–10 MB (everything — VM, GC, your code, resources — is inside; ~8 MB for the Initializr sample), plus a separate `.pdb` for crash symbolication.	Largest: app + a bundled JRE (the JRE alone is ~40–70 MB).	Smallest: a few MB (just bytecode); the JVM lives outside it.
Startup	Native process start — no VM warm-up.	JVM start-up cost.	JVM start-up cost.
CPU architecture	Native x64 **and** arm64 binaries (`windows.arch`).	Intel x64 only — it ships with a bundled **Intel Java 8 JRE** (no arm64 build; on an arm64 machine it runs through Windows' x64 emulation).	Whatever the installed JVM supports.

	Native Windows `.exe`	**Desktop app (JVM)**	**Executable jar**
Look & rendering	Direct2D/DirectWrite, GPU-accelerated; the material native theme.	Swing-hosted Codename One rendering (the simulator's pipeline).	Same as the desktop app.
Portability of the artifact	Windows-only, and per-architecture.	Windows-only installer.	Cross-platform — the same jar runs anywhere a supported JVM exists.
Maturity	Young — a foundation, with gaps (see `status.md`).	Mature, battle-tested.	Mature, battle-tested.

In practical terms: reach for the **native `.exe`** when you want to ship a single self-contained, JVM-free, architecture-native Windows app that starts instantly; reach for the **desktop (JVM) app** when you want the mature, fully featured desktop experience and don't mind shipping (or depending on) a JVM; and reach for the **jar** when you want the smallest, most portable artifact for machines that already have a JDK.

Chapter 123. Working with the native Linux port

The native Linux port compiles a Codename One app to a real, standalone Linux executable — a single ELF binary that runs with **no JVM**. It's the Linux analog of the iOS and native Windows ports: the same ParparVM pipeline that turns your Java/Kotlin bytecode into C and then into a native binary, here targeting Linux and rendering through GTK3 / Cairo / Pango.

This is distinct from packaging the app as an executable jar that runs on a Java Virtual Machine on Linux (see Section 123.6, "Native Linux vs. the executable jar" for a practical comparison). The native port needs no JVM on the target machine.

123.1. How it works (the technology stack)

The port reuses Codename One's portable architecture and swaps in a GTK3 / Cairo implementation layer:

- **ParparVM "clean" C target.** The same VM that powers iOS and Windows translates your app + the Codename One core + the minimal Java runtime to C. A CMake project is generated and compiled with `cc`/Clang + **Ninja** into a native ELF. There is no bytecode interpreter and no JNI — your code **is** the native binary.
- **Cairo** + **Pango** + **GdkPixbuf.** All 2D graphics (primitives, gradients, clipping, affine transforms, images) go through Cairo; glyph layout, measurement and rasterization use Pango (with FontConfig/FreeType, so bundled fonts — including the material icon font — register and render); image decode/encode uses GdkPixbuf. Windowing and native peers (text editing, browser, video) are GTK3 widgets layered over the Cairo drawing surface.
- **OpenGL ES (EGL)** backs the portable 3D API (`com.codename1.gpu`); **GStreamer** backs `Media` playback, audio recording and the camera; **WebKitGTK** backs `BrowserComponent`; **libsecret** backs secure storage; **libnotify** backs local notifications; **GeoClue** backs location; **libcurl** and POSIX sockets back networking.
- **Single self-contained executable.** There is no `.app`-style bundle directory, so the app's classpath resources — the theme `.res`, images, localization, the material icon font — are embedded directly into the ELF and read back at runtime through `getResourceAsStream`. The result is one file you copy and run.

123.2. Runs on essentially any Linux desktop

Two choices keep the binary portable, so in practice it just runs:

- **GTK3, dynamically linked.** GTK3 has shipped on every Linux desktop since 2011, so its runtime is already present on virtually any machine with a graphical session, and the binary resolves `libgtk-3`, Cairo and Pango from the system at startup. (GTK4 is newer and not yet universal, so a GTK4 build would be a separate future target.)
- **An old glibc.** The build compiles your app against an old glibc (via `zig cc`), so the resulting ELF needs only an ancient, universally present glibc — in practice around `GLIBC_2.17` (2013) — and

starts on essentially any glibc desktop from the last decade, no matter how new the build machine is.

The result is one small ELF that runs out of the box across mainstream distros. Alpine, which uses musl instead of glibc, is an opt-in target — see the `linux.libc` build hint below.

123.3. Building a native Linux app

A native Linux build runs through the `codenameone-maven-plugin` like every other target. Build it with:

```
mvn -pl common package -Dcodename1.platform=linux -Dcodename1.buildTarget=local-linux-device cn1:build
```

The builder translates the app to C with ParparVM's `linux` app type, generates a CMake project that links the GTK stack via `pkg-config`, builds it with CMake
Ninja, and produces the ELF.

123.3.1. Build-host dependencies

The native compile needs the GTK development stack and the capability libraries the port links. On Debian/Ubuntu:

```
sudo apt-get install -y \
  cmake ninja-build pkg-config \
  libgtk-3-dev libcairo2-dev libpango1.0-dev libgdk-pixbuf-2.0-dev libglib2.0-dev \
  libfontconfig1-dev libfreetype-dev libcurl4-openssl-dev \
  libgstreamer1.0-dev libgstreamer-plugins-base1.0-dev \
  libwebkit2gtk-4.1-dev libsecret-1-dev libnotify-dev libgeoclue-2-dev \
  libepoxy-dev libegl1-mesa-dev libgles2-mesa-dev
```

The `-dev` packages are needed on the *build host. The machine that **runs** the binary only needs the corresponding runtime libraries, which any standard desktop already has.

123.3.2. Architecture and cross-compiling

Both **x64** and **arm64** are supported; pick the target with the `linux.arch` build hint. The build is a **native** compile — it produces a binary for the host architecture by default, so the straightforward way to get both is to build on a machine of each.

You can also **cross-compile** — and you may well want to, for example producing an arm64 binary from a build host that itself runs x64. The translated C is architecture-independent, and the default toolchain (`zig cc`) is itself a cross-compiler, so it can emit a binary for a different CPU from the one it runs on. Point `linux.cc` at a cross `zig cc` wrapper for the target triple (or set `linux.arch` and let the builder generate one) to cross-build.

123.4. Build hints

The native Linux port adds the build hints below (all use the `linux.` prefix).

Table 30. Native Linux port build hints

Name	Description
linux.arch	Target CPU architecture for the ELF: `x64` (default) or `arm64`. The synonyms `x86_64`/`amd64` and `aarch64` are accepted.
linux.debug	`true`/`false` (default `false`). When `false`, the ELF is optimized and **stripped** (no debug info). Set `true` to keep symbols (`RelWithDebInfo`) so a native crash address can be turned back into a function name and source line while developing. Optimizations stay on either way.
linux.libc	`glibc` (default) or `musl`. The default builds with `zig cc` against an old glibc (`-linux-gnu.2.28`), so the binary runs on essentially any mainstream distro. `musl` targets `-linux-musl` for **Alpine** (where the GTK stack is itself musl-built); a musl binary doesn't run on glibc distros and vice versa.
linux.toolchain	Set to `zig` to force the `zig cc` toolchain (the default already uses it for the glibc target). zig is a self-contained cross-compiler, so a single host can build for either `linux.arch` and either `linux.libc`.
linux.cc	Override the C compiler CMake uses (for example a `zig cc` wrapper for a specific target triple, a `musl-gcc`, or a cross `cc`). Takes precedence over `linux.libc`/`linux.toolchain`; also settable through the `CN1_CC` environment variable.

The full cross-platform build-hints reference is in the Build hints reference chapter [# _build_hints_reference].

123.5. Optimized and stripped by default

The shipping build is optimized and stripped: no debug information is embedded, so the single self-contained executable stays as small as the translated code allows. Setting `linux.debug=true` keeps the symbols so a faulting address can be symbolized during development; the build stays optimized either way.

123.6. Native Linux vs. the executable jar

Before the native port, the way to run a Codename One app on Linux was to package it as an executable jar that runs on a JVM. The two differ in what ships and how it runs:

	Native Linux port	**Executable jar**
Needs a JVM on the target?	**No** — a native ELF	Yes (any installed JRE)
What ships	One small ELF + the system GTK libraries	A single `.jar`
Rendering	GTK3 / Cairo / Pango (native)	Java2D on the JVM
Startup / footprint	Native, small	JVM startup
How it's built	ParparVM → C → ELF (CMake/Ninja)	`javase` packaging

The native port is the right choice when you want a true native Linux binary with no JVM dependency; the executable jar remains the convenient path for development and for environments where a JVM is acceptable.

123.7. Blocking native calls and the concurrent GC

ParparVM's garbage collector is concurrent: before it can traverse a lightweight (CN1-created) thread's stack it sets that thread's `threadBlockedByGC` flag and spins until the thread parks itself (clears `threadActive`). A native that parks a CN1 thread in a long blocking syscall — a socket `read`/`write`/`connect`, an `curl_easy_perform`, a `sleep` — **must** drop `threadActive` across the call (`CN1_YIELD_THREAD` / `CN1_RESUME_THREAD`), exactly as every other port does. Forget it on even one path (for example the cn1ss screenshot reader parked in `read()` waiting on the server) and a GC that happens to fire during that window never completes, deadlocking every thread waiting on it. The Linux port wraps all of its blocking I/O this way; keep that invariant when adding new native calls.

Chapter 124. Embedded Linux devices

Codename One runs on embedded Linux boards — Raspberry Pi, NXP i.MX, Rockchip, NVIDIA Jetson, BeagleBoard, RISC-V boards — as the same single native binary the native Linux port builds, with the desktop layer swapped out. There is no X11, no Wayland compositor, no GTK and no JVM on the device: the application takes the screen directly through the kernel, reads touch, keys and rotary encoders straight from the input devices, and starts from boot as a service.

The same source is also the phone, tablet and desktop companion application. A form, a theme, an entity model or a REST client written for the device builds for iOS and Android unchanged, and the simulator runs it on the desktop with a virtual board attached.

124.1. Why use Codename One on a device

- **One native executable.** ParparVM translates the application, Codename One and the Java runtime it uses to C, and the board's compiler builds it. Nothing is interpreted and nothing is compiled at start-up, so the first frame arrives in tens of milliseconds and memory use stays flat.
- **Java or Kotlin for the whole product.** The device UI, the companion application and, with the backend, the server or the headless gateway share one language, one build and one set of classes.
- **A renderer that owns every pixel.** Codename One draws its own components, so the user interface looks the same on a 3.5 inch SPI panel, a 10 inch HMI and a phone, and it needs nothing from the board but a frame buffer.
- **Hardware access in the core API.** GPIO, I2C, SPI, serial ports, PWM, CAN, the watchdog and the backlight are `com.codename1.hardware`, implemented in the port, with virtual devices in the simulator.

124.2. Displays and the software fallback

At start-up the port picks the first display back end that works, in this order, and every board renders through at least the last two:

1. **DRM/KMS** (`/dev/dri/card*`): a mode is set on the first connected output and frames are flipped between two buffers, so there is no tearing. This is the path on Raspberry Pi 4 and 5, i.MX 8, Rockchip and any board with a modern display driver.
2. **fbdev** (`/dev/fb0`): the legacy frame buffer, at 32 or 16 bits per pixel, for SPI panels and older kernels.
3. **Memory**: renders without a display, for tests, screenshots and benchmarks.

Rendering is in software, by a renderer built into the port, which needs no GPU driver and is fast enough for a full-screen HMI at 60 frames per second on a Raspberry Pi class board. Text is drawn with FreeType and images are decoded with libpng and libjpeg; nothing of a desktop stack (X11, GLib, Cairo, Pango or FontConfig) is loaded, so the application starts in a few tens of milliseconds. Images are PNG or JPEG.

Fonts are found by file name, without FontConfig: in the directories listed in `CN1_FONT_PATH`, then in a `fonts` directory beside the executable, then under `/usr/share/fonts` and `/usr/local/share/fonts`. The default face is DejaVu Sans, or Liberation, Noto, FreeFont, Roboto or Open Sans when DejaVu is absent. Fonts an application bundles work the same as on every other platform. The `CN1_DISPLAY` environment variable forces a back end (`drm`, `fbdev`, `memory` or `headless`); the others are listed in the table below.

Table 31. Environment variables read by the embedded port

Variable	Effect
`CN1_DISPLAY`	`drm`, `fbdev`, `memory` or `headless`; by default the first that works
`CN1_DRM_DEVICE`, `CN1_FB_DEVICE`	The device node to use instead of the first found
`CN1_ROTATION`	`0`, `90`, `180` or `270`, for a panel mounted on its side
`CN1_DPI`	The panel's density, when the display doesn't report its size
`CN1_SIZE`	`800x480`: the size of a `memory` display
`CN1_CURSOR`	`1` draws a pointer for a mouse; touch panels have none by default
`CN1_TOUCH_SWAP_XY`, `CN1_TOUCH_INVERT_X`, `CN1_TOUCH_INVERT_Y`	Correct a touch controller mounted differently from its panel
`CN1_INPUT_NO_GRAB`	`1` leaves the input devices shared with other processes
`CN1_FONT_PATH`	Directories, separated by colons, searched for fonts before the system's

Input comes from every `/dev/input/event*` device, including devices plugged in later: multi-touch panels (with pinch), mice, keyboards and rotary encoders, which move the focus like the arrow keys. Text fields open an on-screen keyboard, since a device seldom has a physical one. `SIGTERM` closes the application cleanly and the console is restored on exit.

124.3. GPU rendering

Boards with a dependable OpenGL ES 2 driver can draw through the GPU instead. The same renderer still decides what every operation covers — shapes, clips, glyphs and antialiasing are computed exactly as in software — and the GPU then composites the result: fills, gradients, images and text become textured quads, images are uploaded once and kept on the GPU, and the finished frame is flipped to the display with no copy. The pointer moves on the display's cursor plane. Frames are identical to the software renderer's; the CPU time a frame costs is what drops, which matters most for large images, full-screen animation and high-resolution panels.

The `linux.embedded.renderer` build hint chooses: `gpu` or `software`. Without it, the board profile decides: `gpu` for the Raspberry Pi profiles, `imx8`, `imx6`, `rk3588`, `jetson` and `generic-x64`, and `software` for the rest. A `software` build links no GPU library at all.

A `gpu` build never fails to show a picture for want of a GPU. When the device has no usable driver, or the driver can't draw the window, the application logs the reason and continues with the software renderer. The first log line names the renderer in use (`renderer gpu` or `renderer software`). The device needs Mesa's GBM, EGL and GLES 2 libraries (`libgbm1`, `libegl1`, `libgles2` on Debian and

Raspberry Pi OS), or the board vendor's equivalents.

124.4. Building for a board

One command builds the application for a board on your machine, with no cloud build, installs it on the device and shows its log:

```
mvn cn1:runOnDevice -Dcn1.board=rpi5 -Dcn1.device.host=pi.local -Dcn1.device.user=pi
gradle cn1RunOnDevice -Pcn1.board=rpi5 -Pcn1.device.host=pi.local -Pcn1.device.user=pi
```

The same commands are in the project's `build.sh` and `build.bat` (`./build.sh device`, with `CN1_BOARD` and `CN1_DEVICE_HOST` set). The IDE files a new project carries — IntelliJ IDEA, VS Code, NetBeans and Eclipse — have **Linux Local Build**, **Run on Device** and **Device Logs** entries beside the cloud build. Edit the board and the host in each one once.

Maven goal	Gradle task	What it does
`cn1:buildLinuxLocal`	`buildLinuxLocal`	Builds the native executable on this machine into `linux/target/linux-native`. With `-Dcn1.board=<board>` it's an embedded build for that board.
`cn1:runOnDevice`	`cn1RunOnDevice`	`buildLinuxLocal`, then `deploy-device`, then follows the log.
`cn1:deploy-device`	`cn1DeployDevice`	Installs the last build on the device as a service.
`cn1:device-logs`	`cn1DeviceLogs`	Follows the log of the installed service, without deploying.
`cn1:buildLinuxDevice`	`buildLinuxDevice`	The same executable, built by the cloud build service.

Gradle takes the same properties with `-P` instead of `-D`.

A build for a board of another architecture, an arm64 board from a laptop say, needs a cross-compiler. Install zig [https://ziglang.org/download/] and put it on the `PATH`, or set `CN1_ZIG`. The build then links against an old glibc, so the executable runs on any current distribution. If no cross-compiler is found the build stops and says so. `linux.cc` names any other cross-compiler, and `linux.sysroot` a board SDK (below).

`-Dcn1.board` is a shortcut. To make a project always build for its board, set the `linux.embedded` build hint and name the board in its settings. The builder then picks the architecture, the display defaults and the libraries to link:

```
codename1.arg.linux.embedded=true
codename1.arg.linux.embedded.board=rpi5
```

Table 32. Board profiles

linux.embedded.board	Architecture	Boards
rpi5, rpi4, rpi3, rpi-zero2	arm64	Raspberry Pi 5, 4, 3 and Zero 2 W on a 64-bit OS
rpi-armv7	armv7	Raspberry Pi on a 32-bit OS
rpi-touch7	arm64	Raspberry Pi with the official 7 inch touch display
imx8, imx6	arm64, armv7	NXP i.MX 8 and i.MX 6
rk3588	arm64	Rockchip RK3588 boards (Orange Pi 5, Rock 5)
jetson	arm64	NVIDIA Jetson
beagleplay	arm64	BeagleBoard BeaglePlay
visionfive2	riscv64	StarFive VisionFive 2
generic-arm64, generic-armv7, generic-x64, generic-riscv64	as named	Any other board

`linux.embedded.display`, `linux.embedded.rotation` and `linux.embedded.dpi` set the defaults the binary starts with; the environment variables override them on the device. `linux.sysroot` points a cross build at a Yocto or Buildroot SDK sysroot, so the binary links against exactly the libraries the image carries.

The device needs FreeType, libpng, libjpeg, zlib, a font and, for DRM/KMS, libdrm. OpenSSL 3 and libcurl are loaded only when the application first uses cryptography or the network. Raspberry Pi OS Lite has most of them; the `scripts/embedded/pios/setup-device.sh` script installs the rest and prepares the device to start the application at boot.

124.5. Deploying to a device

The `deploy-device` goal copies the binary to the device over SSH, installs it as a systemd service that starts at boot and restarts if it exits, and restarts it:

```
mvn cn1:deploy-device -Dcn1.device.host=pi.local -Dcn1.device.user=pi
gradle cn1DeployDevice -Pcn1.device.host=pi.local -Pcn1.device.user=pi
```

It uses the system's `ssh`, so keys, agents and `~/.ssh/config` aliases work as they do in a terminal. `cn1.device.env` passes environment variables to the service (`CN1_ROTATION=90,CN1_DISPLAY=fbdev`), and `cn1.device.logs=true` follows its log after the restart. `cn1:device-logs` follows it later, without deploying again.

The service runs as root, with no limit on real-time priority or locked memory, so real-time threads get their scheduling without further setup.

A project's `backend` module can run in the cloud and on a board, and each side usually needs some controllers the other doesn't. The deployed service runs with `CN1_PROFILE=device`, so

`@Profile("device")` beans and `application-device.properties` are active only on the board, and `@Profile("!device")` keeps cloud-only beans off it. `cn1.device.profile` names a different profile, and an empty value sets none.

For a production image, `scripts/embedded/yocto/meta-codenameone` is a Yocto layer and `scripts/embedded/buildroot/package/codenameone-app` a Buildroot package. Both build the translated application with the image's own toolchain and start it at boot.

124.6. Hardware access

`com.codename1.hardware.Hardware` is the entry point. On a device it drives the kernel's own interfaces — the GPIO character device, i2c-dev, spidev, termios, sysfs PWM and backlight, SocketCAN and `/dev/watchdog` — with no extra library. On a phone it reports no support, so the same code runs everywhere:

```
Hardware hw = Hardware.getInstance();
try {
    if (hw.isSupported(Hardware.FEATURE_GPIO)) {
        GpioPin led = hw.openGpioOutput("gpiochip0", 17, false);
        led.setHigh(true);
        GpioPin button = hw.openGpioInput("gpiochip0", 27, GpioPin.BIAS_PULL_UP, GpioPin.EDGE_FALLING);
        button.setListener((pin, rising, nanos) -> {
            try {
                led.setHigh(!led.isHigh());
            } catch (HardwareException e) {
                Log.e(e);
            }
        });
    }
    if (hw.isSupported(Hardware.FEATURE_I2C)) {
        I2cDevice sensor = hw.openI2c(1, 0x48);
        Log.p("Sensor reads " + sensor.readRegister(0));
    }
} catch (HardwareException e) {
    Log.e(e);
}
```

Listeners run on the event dispatch thread. Reads that wait for data — a serial port, a CAN frame — take a timeout and belong off the event dispatch thread.

The simulator attaches a virtual board: `gpiochip0` with 32 lines, a TMP102 temperature sensor at `0x48` and an EEPROM at `0x50` on I2C bus 1, loopback SPI, serial and CAN devices, two PWM channels, a watchdog and a backlight. Hardware code therefore runs, and can be unit tested, before a board is on the desk.

124.6.1. NFC readers

`Nfc.getInstance().readTag(options)` works with a USB contactless reader through PC/SC. The device needs the `pcscd` service and its `libpcsclite` library, which Codename One loads the first time NFC is used; without them `isSupported()` returns `false`. A card on the reader is reported as an ISO-DEP tag whose `getId()` is the UID the reader returns, and `getIsoDep().transceive(apdu)` exchanges APDUs

with it. The connection stays open until the next `readTag` call. Reading NDEF, writing tags and host card emulation aren't available on Linux.

124.7. Headless devices with the backend

A gateway, a sensor hub or a controller with no screen runs the backend instead: a native REST and WebSocket server, built the same way and as small. `Hardware.getInstance()` works there too, through the same kernel code as the UI port, and listener callbacks run on the pin's own thread. The device then serves its API, the phone application is the client, and both share the entity classes.

124.8. Finding each other on the network

Devices, phones and servers on one network find each other over multicast DNS (Bonjour), so nobody types an address. The Linux port implements `BonjourBrowser` and `BonjourPublisher` itself, on a plain UDP socket, so a Buildroot image needs no Avahi. The backend has the same protocol as `com.codename1.backend.Discovery`:

```
Discovery.Advertisement ad = Discovery.advertise("Hall Thermostat", "_thermostat._tcp", 8080,
        Collections.singletonMap("api", "/v1"));
Discovery.browse("_gateway._tcp", new Discovery.Listener() {
    @Override
    public void found(Discovery.Service gateway) {
        System.out.println("Gateway at " + gateway.getHost() + ":" + gateway.getPort());
    }

    @Override
    public void lost(Discovery.Service gateway) {
        System.out.println(gateway.getName() + " went away");
    }
});
```

A phone, a Mac or a Linux desktop sees the device in its own Bonjour browser too. When another device already uses the name, the second one gets a numeric suffix, `Hall Thermostat (2)`. Discovery listeners on the backend run on the discovery thread, because a server has no event dispatch thread.

124.9. Working through a flaky link

A device in a field, a truck or a basement loses its network for minutes or days and has to keep working. `com.codename1.io.outbox.Outbox` is a queue of outgoing messages kept in the application's own database. The device enqueues what it has to report, and the outbox sends it in order once the link is back. The same class works in a UI application and on the backend.

The table sits in the database of the ORM session the outbox was opened on. An `enqueue` inside one of that session's transactions belongs to the transaction, so a reading and the message announcing it commit together or not at all:

```
Outbox outbox = Outbox.open(session, "readings@" + deviceId);

session.beginTransaction();
session.persist(reading);
outbox.enqueue("/v1/readings", body);
session.commitTransaction();

// From a timer, or when the network comes back:
outbox.flush(message -> {
    int status = postToServer(message.getTopic(), message.getKey(), message.getPayload());
    return status < 300 ? Outbox.DELIVERED
            : status < 500 ? Outbox.REJECTED : Outbox.RETRY;
});
```

`postToServer` stands for the application's own request: `Rest` on a client, `Web` on the backend, or anything else that can carry bytes. A message stays at the head of the queue until the transport answers `DELIVERED`. While it's retried, with a backoff that doubles up to five minutes by default, nothing overtakes it. `REJECTED` drops a message the server will never accept.

Delivery is at least once. If the acknowledgement is lost, the same message goes out again with the same `getKey()`, so the server records the keys it has applied and acknowledges a repeat without applying it twice. When many devices report to one server, put the device identity in the outbox name, which is the first half of every key. `setCapacity(limit, true)` bounds a telemetry queue by discarding the oldest readings. `setMaxAttempts` gives up on a message after that many failures.

124.10. Device identity and mutual TLS

A fleet server has to know which device is calling, and a shared password compiled into every unit isn't an answer. Instead, each device generates its own key pair on first boot and asks a certificate authority for a client certificate. The key never leaves the device. The request is a PKCS#10 certificate signing request, which `com.codename1.security.CertificateRequest` builds:

```
KeyPair keys = KeyGenerator.ec(256);
byte[] csr = new CertificateRequest(keys.getPublicKey().getEncoded(), "EC")
        .commonName(deviceId)
        .dnsName(deviceId + ".local")
        .sign(data -> Signature.sign(Signature.SHA256_WITH_ECDSA, keys.getPrivateKey(), data));
String pem = CertificateRequest.toPem(csr);
// Send pem to the enrollment endpoint, store the certificate it returns.
```

From then on the device presents the certificate on every request, and the server identifies it from the TLS handshake:

```
ConnectionRequest request = new ConnectionRequest(fleetUrl + "/v1/readings", true);
request.setClientCertificate(certificatePem, keys.getPrivateKey());
```

`ConnectionRequest.isClientCertificateSupported()` is true on Linux devices, on Android and in the

simulator. A headless device on the backend signs the request with `Crypto.sign` and presents the certificate through `WebClient.setClientCertificate`. Keep the private key in `SecureStorage`, or in a file only the application's user can read on a board without one.

124.11. One project from the phone to the cloud

A connected product is seldom one program: it's a device, the phone application that controls it and often a cloud service that sees every unit. In Codename One all three are targets of one project, laid out like any full-stack application:

- `shared` holds the entities, the DTOs and the API contract that every side compiles against, so a change that breaks the wire format breaks the build.
- `common` is the user interface. It builds for phones and desktops, and for a board with a screen through the Linux target.
- `backend` is the server. It builds for the cloud and for a board, with the `device` profile choosing the controllers that run on the board.

These pieces combine into five common shapes:

1. **A phone controls a device with a screen.** A kiosk or a panel runs the UI and a small backend on the board. The phone finds it with Bonjour and uses its REST API, while the board's own screen talks to the same API locally. A QR code shown on the panel (`com.codename1.qrcode.QrCode`) carries the pairing token.
2. **A phone talks to a headless device.** A gateway runs only the backend and the hardware API, and pushes live readings to the phone over a WebSocket. Where there is no network, Bluetooth LE carries the same messages, and an NFC tag on the case starts the pairing.
3. **A device reports to the cloud.** The device backend writes its readings through the ORM, and an outbox in the same transaction forwards them to the cloud backend when the link is up. Both sides share the entity classes.
4. **A fleet.** Many devices enroll with their own certificates and report to one cloud backend, which knows each one by its TLS handshake. The phone and web dashboards are clients of the cloud, not of the devices. MQTT (`com.codename1.io.mqtt`) suits fleets that already run a broker.
5. **A chain.** The phone talks to the device directly when both are on the same network and through the cloud when they aren't. It tries the address Bonjour found first and falls back to the cloud relay, and the API is the same either way because both backends implement the shared contract.

Each standard is folded into the build only when the application uses it: an application that never browses Bonjour or opens a Bluetooth connection carries none of that code.

124.12. Compared with the alternatives

The same workload ran in each framework: an 800 by 480 pixel gauge (a filled arc that sweeps, a needle and a bold percentage) redrawn for every frame, capped at 60 frames per second, rendered in software into memory (flutter-pi into a virtual display; see below). Each ran three times for ten seconds, from a cold start and then a warm one, in the same Debian bookworm arm64 container on

an Apple Silicon host. The table shows the median. A board is slower than that host and its storage is slower still, so read the columns against each other rather than as a board's figures.

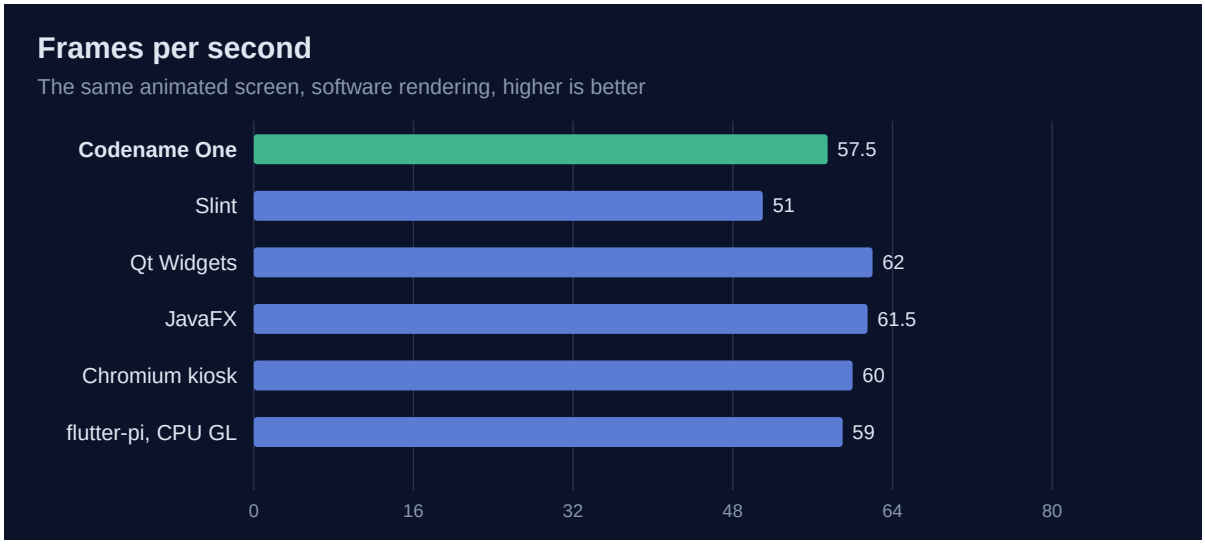

Table 33. The gauge workload, software rendering, 800 by 480 (median of three runs)

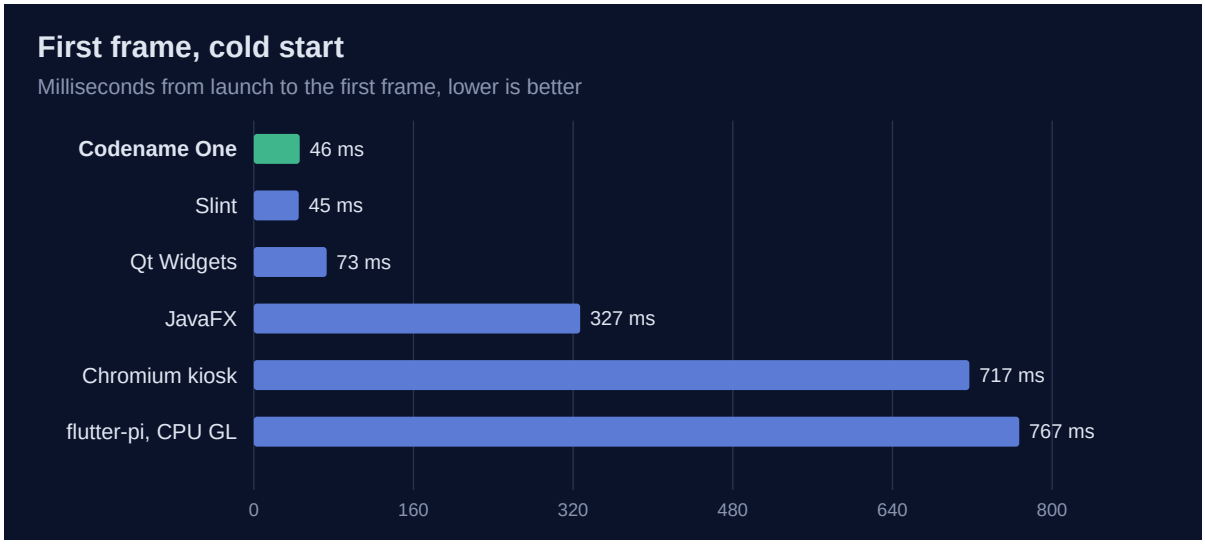
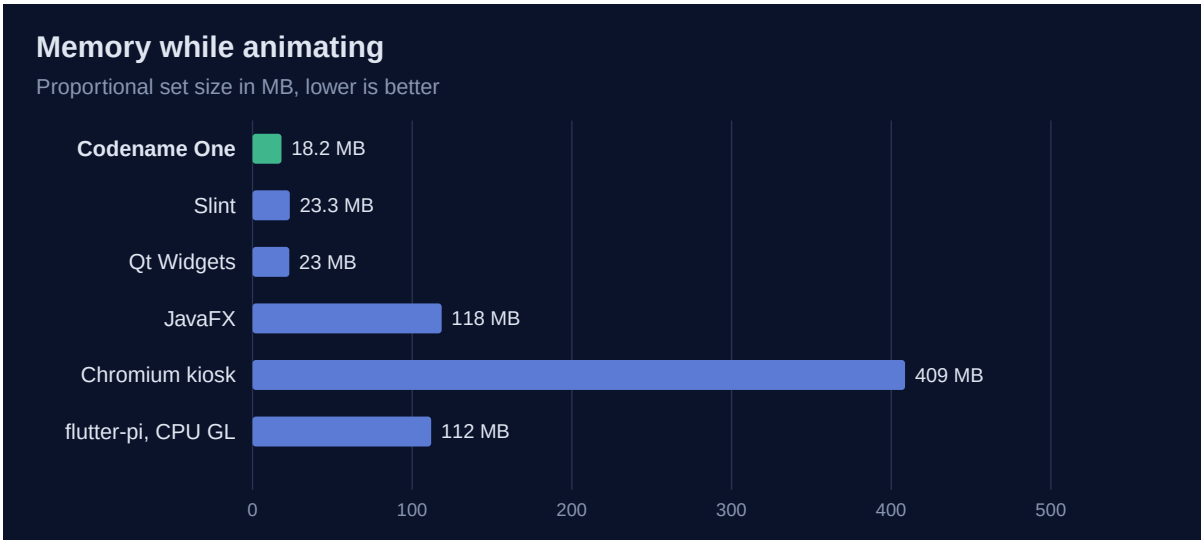


Framework	First frame, cold (ms)	First frame, warm (ms)	Frames per second	CPU (%)	Memory, PSS (MB)	Memory, private (MB)	Files mapped (MB)
Codename One	46	53	57	6	18	17	15 (15 files)
Slint 1.8, software renderer	45	103	51	2	23	22	4.3 (6 files)
Qt 6.4 Widgets, raster engine	73	100	62	6	23	22	73 (51 files)
JavaFX 26, software pipeline	327	468	62	32 to 42	116	115	102 (44 files)
Chromium kiosk, canvas	717	419	60	50 or more	398	224	378 (149 files)
flutter-pi, Mesa software OpenGL	767	541	59	137	112	111	233 (68 files)



- **First frame** is the wall-clock time from starting the process to the end of the first frame drawn. A **cold** start follows dropping the kernel's page cache, so the executable and every library, plugin and font it uses are read from storage again, as on the first start after boot. A **warm** start follows straight after a cold one. Below about 100 ms the two differ by less than the run-to-run noise.
- **Memory, PSS** (proportional set size) counts every page the process maps, shared library pages divided among the processes sharing them, so shared libraries are included. **Private** counts only the pages no other process shares: heap, stacks and written data. Both are read from `/proc/<pid>/smaps_rollup` mid-run, and for Chromium summed over its whole tree of processes.
- **Files mapped** is every distinct file the process has mapped mid-run, counted once at its full size: the executable, every shared library including the C library, plugins loaded at run time, fonts and locale data. That's what has to be on the device for the application to run, whether the board image already carries it. Codename One's executable is 7.7 MB of it; the rest is the C library, FreeType, libpng, libjpeg, libdrm, libepoxy and the font. OpenSSL and libcurl are loaded only when an application first uses them, and this one doesn't. Qt's executable is 0.1 MB of 73; the rest is the Qt Core, GUI and Widgets modules, their dependencies and the platform plugins.
- **Codename One draws more**: its form has a title bar, a button, a slider and a label around the gauge; the others draw only the gauge.
- **JavaFX** runs on a JDK 25 runtime cut down with `jlink` to the modules it uses, with the Headless glass platform JavaFX 26 introduced and Prism's software pipeline. That is the same rendering path as a board without a GPU, minus the display. Gluon does not publish its embedded (Monocle) builds, so this is the closest public build. Its CPU includes the JIT compiler warming up, which is why it varies between runs.

- **Chromium's** CPU covers its start-up as well, an upper bound.
- **Slint** missed frames under the harness's 16 ms pacing loop, not for lack of CPU.
- **flutter-pi** draws only to a DRM/KMS display, so it ran on the kernel's virtual one (`vkms`) instead of into memory, from its own image (`flutter/Containerfile`) on the same base and host. With no GPU, Mesa renders OpenGL ES on the CPU (`llvmpipe` through `kms_swrast`), and flutter-pi starts without being told to. The gauge is a release (AOT) build, made by `flutter/build-bundle.sh` with Flutter 3.35.4 and the matching engine. Its CPU is above 100% because Mesa rasterizes on several threads: it held its frame rate on about 1.4 cores.

Codename One and Slint start fastest, Codename One uses the least memory, Slint needs the least on disk, and the three native toolkits land close together in frame rate and CPU. Codename One and Slint need far less on disk than Qt. JavaFX, the other way to put a Java UI on a board, needs about six times Codename One's memory and seven times its disk, and a kiosk browser about twenty times both. Flutter runs without a GPU only by emulating one on the CPU: it held its frame rate, but on about 1.4 cores against Codename One's 6% of one, in six times the memory and fifteen times the disk.

The table leaves out Android (AOSP), which needs a board support package with a GPU driver and so doesn't run in this harness.

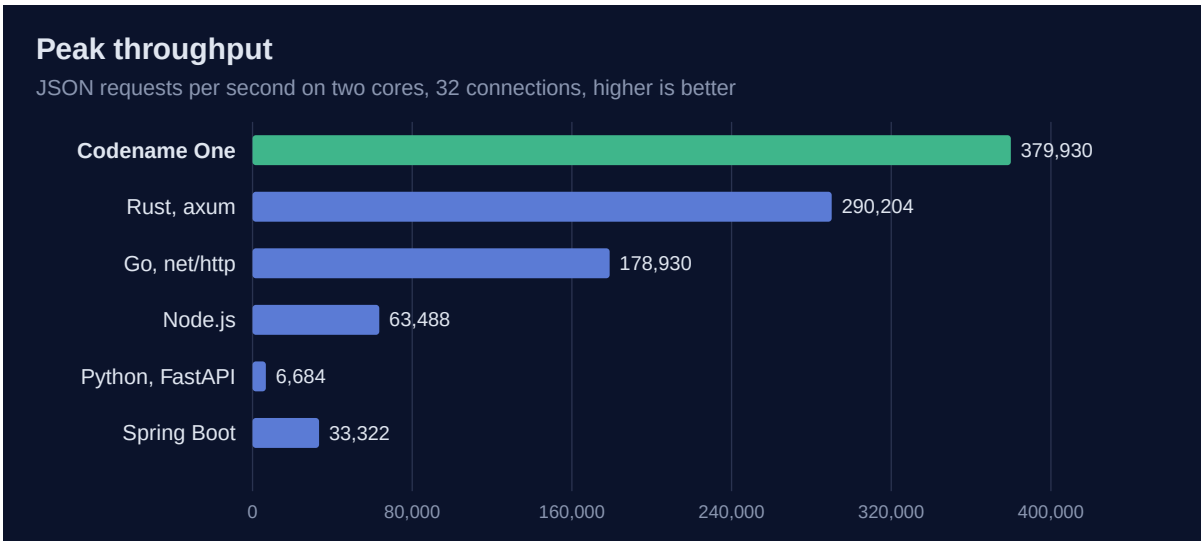
Table 34. What each option offers

	Codename One	**Qt / Boot2Qt**	**Slint**	**flutter-pi**	**Chromium kiosk**	**AOSP**
Language	Java, Kotlin	C++, QML	Rust, C++, JavaScript, Python, `.slint`	Dart	HTML, JavaScript	Java, Kotlin
Runtime on the device	None: one native executable	Qt libraries	Small native library	Flutter engine	Browser	Android runtime
Needs a GPU	No	No (raster), yes for Qt Quick	No	Yes, or Mesa's OpenGL on the CPU at about 1.4 cores	No, but slow without one	Yes
Display without X11 or Wayland	DRM/KMS, fbdev	`eglfs`, `linuxfb`	`linuxkms`	DRM/KMS	Through Ozone	SurfaceFlinger
Same code on iOS and Android	Yes	Yes	Not as a primary target	Yes	As a web application	Android only
GPIO, I2C, SPI, serial, CAN in the API	Yes (`com.codename1.hardware`)	Serial and CAN modules; GPIO through the OS	No	Through plugins	No	Through vendor HALs

	Codename One	Qt / Boot2Qt	Slint	flutter-pi	Chromium kiosk	AOSP
Simulator with virtual hardware	Yes	No	No	No	No	Emulator
Headless server on the same codebase	Yes (the backend)	Qt Core, HTTP server module	No	No	No	No
Yocto and Buildroot integration	Layer and package	Yes (meta-qt6, Boot2Qt)	Yes (meta-slint)	Community recipes	Yes	Not applicable
Licence	GPL 2 with Classpath exception	LGPL 3, GPL or commercial	GPL 3, royalty-free or commercial	BSD 3-clause	BSD 3-clause	Apache 2.0

124.13. Without a display

A gateway or sensor hub has no screen, so the GUI comparison says little about it. The same small JSON service ran in each runtime: `GET /json` answering a short object. The server was pinned to two cores, a small board's share, and the load generator (`oha`) ran on the remaining cores. Each runtime ran four rounds, from a cold start and then a warm one, in the same Debian bookworm arm64 container. The first round pages the container image in and is left out, so the table shows the median of the other six runs.



- **Start** is the time from launch to the first answered request.
- **Idle** is the proportional set size (PSS) two seconds later, with no requests.
- **Steady** is a constant 200 requests per second for ten seconds. It gives the CPU used over that time and the memory at its end.
- **Peak** is as many requests as 32 connections can drive in ten seconds.

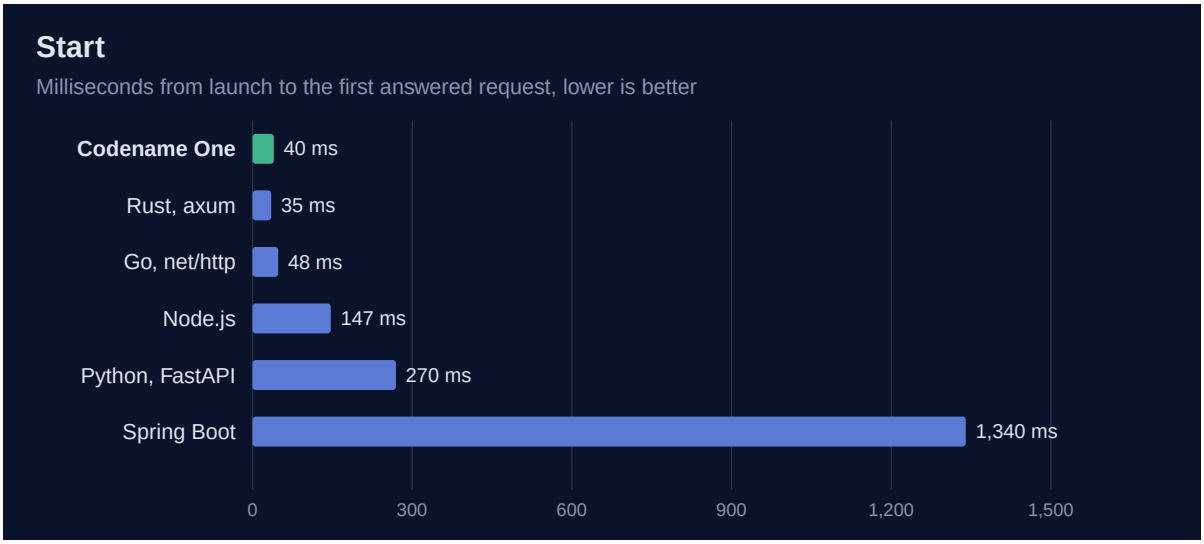


Table 35. A JSON service, two cores (median of six runs)

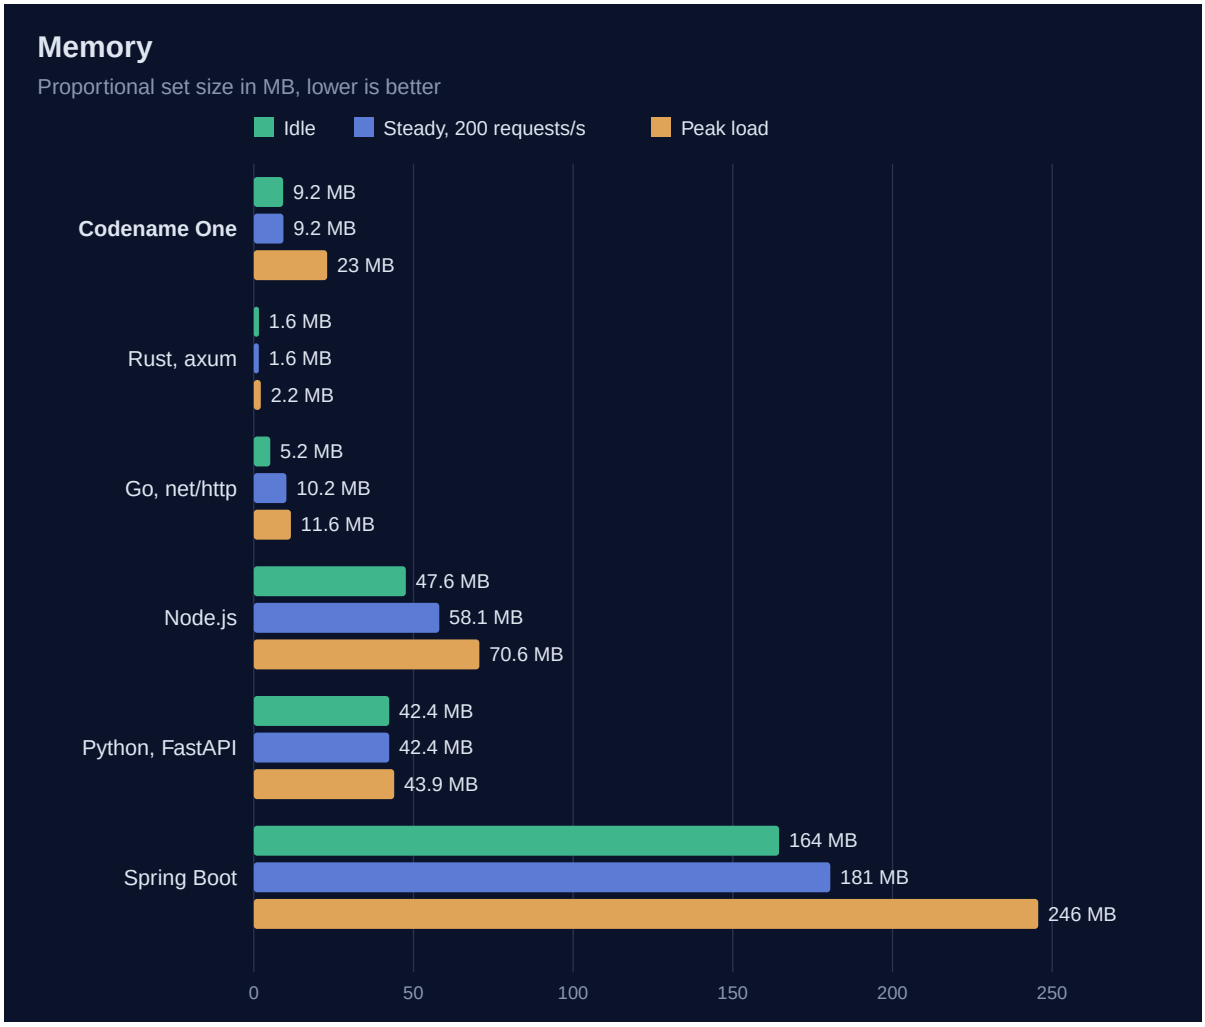

Runtime	Start (ms)	Idle PSS (MB)	Steady CPU (%)	Steady PSS (MB)	Peak (requests /s)	Peak p99 (ms)	Disk mapped (MB)
Codename One backend	40	9.2	3.1	9.2	379,900	0.22	21 (34 files)
Rust, axum	35	1.6	3.2	1.6	290,200	0.25	3.3 (5 files)
Go, net/http	48	5.2	8.3	10.2	178,900	0.59	5.2 (1 file)
Node.js, http	147	48	11	58	63,500	1.1	90 (19 files)

Runtime	Start (ms)	Idle PSS (MB)	Steady CPU (%)	Steady PSS (MB)	Peak (requests /s)	Peak p99 (ms)	Disk mapped (MB)
Python, FastAPI and uvicorn	270	42	22	42	6,700	11	21 (30 files)
Spring Boot 3.5, JDK 21	1,340	164	16	181	33,300	3.3	183 (20 files)

Codename One starts as fast as the compiled runtimes and serves the most requests of any of them: 1.3 times Rust's peak and 2.1 times Go's, at the lowest p99, with a steady-load CPU the same as Rust's. Like Rust's, the server makes two system calls per request, one read and one write, and a request allocates nothing but the object the handler returns. Rust and Go use less memory: a Codename One process grows to about 23 MB at peak load, against Go's 12 MB and Rust's 2 MB. Against the managed runtimes, it starts 33 times faster than Spring Boot, uses an eighteenth of its memory and serves over 11 times its peak.

Every change to the backend runtime or the translator reruns this comparison in continuous integration, against Rust and Go on an arm64 machine. The build fails if Codename One's peak throughput falls below Rust's, if its latency, start or CPU falls too far behind, if its memory passes 12 MB idle or 32 MB at peak, or if a request allocates anything beyond the object its handler returns.

124.14. Control loops with deadlines

A loop that must run at a fixed rate beside the user interface — motor control, sampling, a fieldbus cycle — belongs on a real-time thread. See Real-time threads.

Chapter 125. Embedded Windows devices

Panel PCs, point-of-sale terminals, self-service kiosks and arm64 IoT boards running **Windows 10/11 IoT Enterprise** run Codename One as the same native `.exe` the native Windows port builds. No JVM and no runtime installer go onto the device. Windows still owns the display, the input and the boot, so the embedded build doesn't change how the application draws. It changes what surrounds it: the window fills a screen and keeps it, the shell is the application, and the boards' buses are reachable from Java.

Windows 10 IoT Core isn't a target. It runs UWP applications only and is no longer serviced.

125.1. Building for a device

Two build hints turn a native Windows build into an embedded one:

```
codename1.arg.windows.embedded=true
codename1.arg.windows.embedded.board=imx8
codename1.arg.windows.embedded.rotation=90
```

Table 36. Embedded Windows build hints

Name	Description
windows.embedded	`true`/`false` (default `false`). Builds the kiosk variant described here. Can't be combined with `windows.xbox`.
windows.embedded.board	The device profile: `generic-x64` (default, a touch panel PC), `generic-x64-mouse`, `generic-arm64`, `imx8` or `qualcomm-iot`. The profile sets the defaults below and the CPU architecture, so an arm64 board needs no `windows.arch`.
windows.embedded.rotation	`0`, `90`, `180` or `270`. The display is rotated when the application starts.
windows.embedded.dpi	The density the UI is laid out for. `0` (default) asks Windows.
windows.embedded.monitor	Which monitor the application takes, counting from `0`.
windows.embedded.cursor	`true` shows the mouse pointer. Touch profiles hide it.

Each value can be changed on the device without a rebuild, through the matching environment variable: `CN1_ROTATION`, `CN1_DPI`, `CN1_MONITOR` and `CN1_CURSOR` (`true` or `1` shows the pointer, `false` or `0` hides it).

125.2. What the embedded build does

- The window has no frame, covers the chosen monitor and stays above every other window.
- The Windows key, Alt+Tab, Alt+Esc, Alt+F4 and Ctrl+Esc never reach the system while the application has the screen. Ctrl+Alt+Del is handled by Windows before any application sees it; the Keyboard Filter below blocks it.
- Text is entered through Codename One's own on-screen keyboard, the one the embedded Linux build uses, rather than the Windows touch keyboard, which is unreliable when the application is the shell.
- Standard output and standard error go to the file `CN1_LOG_FILE` names, so a device with no console still keeps a log.

125.3. Deploying to a device

`deploy-device` installs the application over SSH. Windows ships OpenSSH Server as an optional feature; enable it on the device and log in once as an administrator so its key is accepted:

```
mvn cn1:deploy-device -Dcn1.device.host=kiosk.local -Dcn1.device.user=Administrator
gradle cn1DeployDevice -Pcn1.device.host=kiosk.local -Pcn1.device.user=Administrator
```

The goal recognizes a Windows executable, checks that its architecture matches the device and copies it to `C:\ProgramData\CodenameOne`. It then makes the application the device's shell with **Shell Launcher**: it enables the feature if it's missing, restarts the application whenever it exits, and keeps Explorer as the shell for administrators, so the device can still be serviced. Enabling the feature takes a restart, which the goal performs.

Options, as `cn1.device.*` properties:

- `kioskUser` limits the kiosk shell to one account, `kiosk` for instance; other users keep Explorer.
- `keyboardFilter=true` enables the Keyboard Filter and blocks Ctrl+Alt+Del, Ctrl+Shift+Esc, Win+L, the Windows key, Alt+Tab, Ctrl+Esc and Alt+F4.
- `kioskMode=autostart` replaces no shell and starts the application at logon instead, for every account, administrators included. Use it on a development device, or on an edition without Shell Launcher.
- `env` sets machine environment variables, `CN1_ROTATION=90` for instance. Windows reads them at logon, so they apply from the next one.

```
mvn cn1:deploy-device -Dcn1.device.host=kiosk.local -Dcn1.device.user=Administrator \
    -Dcn1.device.kioskUser=kiosk -Dcn1.device.keyboardFilter=true
```

`cn1:device-logs` follows the application's log file over the same connection. As on Linux, the application runs with `CN1_PROFILE=device`, so a backend module's `@Profile("device")` beans are active on the device only.

Assigned Access, the single-app kiosk of the Pro edition, isn't offered: it runs only packaged applications, under a restricted account that can't reach the hardware below.

125.4. Hardware access

`com.codename1.hardware` works on Windows through the device APIs Windows provides:

API	On Windows
Serial ports	Every `COM` port.
GPIO, I2C, SPI, PWM	The `Windows.Devices` APIs. They need a board whose vendor ships the bus drivers, which IoT boards do and most x64 panel PCs don't. Without one, the feature reports that it isn't available. I2C and SPI bus `N` is the board's `N`th controller.
Backlight	The monitor's brightness over DDC/CI, or the built-in panel's through WMI.
CAN, watchdog	Not available: Windows has no standard interface for either. Shell Launcher's restart takes the place of a supervisor.

Chapter 126. Publishing to Steam

Steam reaches Linux desktops, the Steam Deck and the Steam Machine, which all run the same binary. Codename One publishes to it with the native Linux port: one native executable with no JVM, packaged as a Steam **depot** and uploaded with SteamPipe. The same game code builds for iOS, Android and the other targets unchanged.

On top of the build, Codename One adds what a Steam title needs:

- **Controllers.** Every gamepad Steam knows about, the Steam Deck's own controls included, arrives through `com.codename1.gaming.Gamepads`. Forms can be driven with a controller with no code at all.
- **Platform services.** Achievements, stats, cloud saves, rich presence, DLC ownership and the Steam overlay are available through `com.codename1.gaming.GameServices`. The same calls are no-ops on a platform without game services, so the code stays portable.
- **Gaming Mode.** The app starts full screen, and text fields open Steam's on-screen keyboard when the Deck or a TV is in controller mode.

126.1. Controllers

`Gamepads` keeps one `Gamepad` per connected controller, laid out like an Xbox controller: **A**, **B**, **X** and **Y**, the bumpers and triggers, two sticks, the D-pad and the menu buttons.

```
Gamepad pad = Gamepads.getGamepad(0);
if (pad != null && pad.isConnected()) {
    float x = pad.getAxis(Gamepad.AXIS_LEFT_X);   // -1..1, dead zone applied
    boolean jump = pad.isButtonDown(Gamepad.BUTTON_A);
    System.out.println("stick " + x + ", jump " + jump);
}
```

`GameInput` reads the first controller too: `wasGamepadButtonPressed` gives the press of this frame, and `getAxisX`/`getAxisY` fall back to the left stick when the on-screen joystick is idle, so a game written for touch plays with a controller unchanged.

For events rather than polling, add a `GamepadListener`. Return `true` from `gamepadButton` to consume the press.

126.1.1. Navigating forms

With no code, the D-pad and left stick move the focus between components, **A** presses the focused one and **B** runs the form's back command. A game that reads the controller itself calls `Gamepads.setFocusNavigation(false)`.

On Linux the port reads controllers from the kernel's input devices, so nothing needs installing. Under Steam, Steam Input presents every controller as an Xbox pad, and the port skips the devices Steam hides so a controller never appears twice. `Gamepad.rumble()` drives the motors where the

controller has them.

126.2. Game services

```
byte[] saveBytes = "level=3".getBytes();
if (GameServices.isAvailable()) {             // true on Steam
    GameServices.unlockAchievement("FIRST_WIN");
    GameServices.setStat("wins", GameServices.getStatInt("wins", 0) + 1);
    GameServices.commit();
    GameServices.writeSave("slot1", saveBytes);
}
```

- **Achievements and stats** use the API names defined on the Steamworks site. `commit()` sends them to Steam.
- **Cloud saves** use Steam Cloud. Turn on Steam Cloud for the app in Steamworks and give it a byte quota.
- **Presence:** `setPresence(key, value)` sets rich presence, such as `"steam_display"`.
- **Ownership:** `ownsContent("1234")` answers whether the player owns that DLC.
- **Overlay:** `openPlatformUI("achievements")` opens the overlay on a page, and an `http`/`https` target opens the overlay's browser. A `GameServicesListener` is told when the overlay opens and closes, which is the moment to pause.
- `isControllerFirst()` is true on the Deck and in Big Picture mode, where the UI should assume a controller and a TV-distance screen.

The Steamworks library is loaded when the app starts. If it's missing, or Steam isn't running, `isAvailable()` is false and every call does nothing.

126.3. Setting up the app in Steamworks

1. Create the app on the Steamworks partner site [https://partner.steamgames.com] and note its **App ID**. Steamworks creates a depot with the next number.
2. Under **Installation** > **General**, add a launch option with the executable `launch.sh` and the operating system **Linux** + **SteamOS**.
3. Under **SteamPipe** > **Depots**, set the depot's operating system to Linux.
4. Download the Steamworks SDK. The build copies `redistributable_bin/linux64/libsteam_api.so` from it into the depot. Steam allows that library to be redistributed; nothing else from the SDK is used.

126.4. Building

Add the hints to `codenameone_settings.properties`:

```
codename1.arg.steam.appId=480
```

```
codename1.arg.steam.sdkPath=/path/to/steamworks_sdk
```

Then build:

```
mvn cn1:buildSteamLocal       # or ./gradlew buildSteamLocal
```

The SDK path can also come from the `STEAMWORKS_SDK` environment variable. Without an SDK the depot is still built, and `GameServices` reports itself unavailable.

The result is in `linux/target/steam`:

```
content/                  the depot
  MyGame                  the executable
  launch.sh               the launch option
  libsteam_api.so
  steam_appid.txt         for running outside Steam; not uploaded
scripts/
  app_build_480.vdf
  depot_build_481.vdf
```

`content/launch.sh` runs the game outside Steam too, which is the quickest way to test achievements against a running Steam client.

Hint	Default	Meaning
`steam.appId`		The App ID. Required.
`steam.depotId`	App ID + 1	The Linux depot.
`steam.branch`	empty	A beta branch to set the upload live on.
`steam.buildDescription`	name and version	The description shown in Steamworks.
`steam.sdkPath`	`STEAMWORKS_SDK`	The Steamworks SDK directory.
`steam.fullscreen`	`true`	Start full screen.

126.5. Uploading

With SteamCMD installed:

```
mvn cn1:steamUpload -Dsteam.user=my_build_account
```

The first run asks for the password and the Steam Guard code; later runs reuse SteamCMD's saved login.

A cloud build (`mvn cn1:buildSteam`) can be uploaded for you instead. Save the Steam builder account and its `config.vdf` under **Submissions** in the build console, then press **Submit to Steam** on the

finished build, or turn on automatic submission for the Linux target to upload every build that produces a depot.

Valve allows an upload to go live on a **beta branch** only. Set `steam.branch` to test a build on a branch, then make it live on the default branch, and submit it for review, from the Steamworks site.

126.6. Runtime

Steam runs Linux games inside the Steam Linux Runtime, a container with a fixed set of libraries. The native Linux port runs in it as is, with these exceptions:

- `BrowserComponent` is unavailable: the runtime has no WebKitGTK.
- Media playback through GStreamer is unavailable.
- Secure storage is unavailable: the runtime has no libsecret.
- Cryptography uses the runtime's OpenSSL 1.1 when OpenSSL 3 is absent.

Chapter 127. Real-time threads

A control loop has to run at its rate — a motor drive every millisecond, a sensor fusion step every 2.5 — while the user interface, the network and the garbage collector compete for the same processor. `com.codename1.realtime` gives such a loop its own thread. The kernel schedules that thread ahead of everything else, and the collector never stops it.

The target is **firm** real time on a PREEMPT_RT Linux kernel, which mainline Linux includes since 6.12. On such a kernel the latency of a periodic thread is bounded by the kernel and the hardware, not by the virtual machine. That's not a certified hard real-time system: Codename One makes no claim under IEC 61508, ISO 26262 or DO-178C, and a loop whose failure can hurt someone needs an independent safety mechanism, such as a hardware watchdog or an interlock.

127.1. A periodic task

```
class MotorLoop extends RealtimeTask {
    private final double[] samples = new double[64];   ①
    private final double[] gains = new double[64];
    private PwmChannel pwm;
    private boolean failed;

    public void setup() {                              ②
        try {
            pwm = Hardware.getInstance().openPwm(0, 0);
        } catch (HardwareException e) {
            failed = true;
        }
    }

    public void cycle() {                              ③
        if (failed) {
            return;
        }
        double out = 0;
        for (int i = 0; i < samples.length; i++) {
            out += samples[i] * gains[i];
        }
        try {
            pwm.setDutyCycle(out);
        } catch (HardwareException e) {
            failed = true;                             // no allocation on this path
        }
    }

    public void periodsMissed(int count) {             ④
        // the loop overran; hold the output, count it, alarm if it persists
    }
}
```

```
RealtimeThread startLoop() {
    return Realtime.getInstance().start("motor",
            new RealtimeParameters()
                .setPeriodNanos(1000000)    // 1 kHz
                .setPriority(80)            // SCHED_FIFO 1..99
                .setCpu(3),                 // pin to core 3
            new MotorLoop());
}
```

① Everything the loop needs is allocated before it starts.

② `setup()` runs on the real-time thread before the first period. It may allocate.

③ `cycle()` runs once per period, released on an absolute clock, so the period doesn't drift with the execution time.

④ Called instead of skipping without a word when releases were missed.

`getStatistics()` reports the cycles, the missed periods, the release latency (maximum, mean and a histogram with percentiles), the execution time and the allocation violations. Check them on the target board under load: they're the only real evidence that the loop meets its deadline.

127.2. Parameters

Setter	Default	Meaning
`setPeriodNanos(long)`	1 ms	The period. At least 10 microseconds.
`setPriority(int)`	50	The `SCHED_FIFO` priority, 1 to 99. Keep it below the kernel's own interrupt threads (50 on most PREEMPT_RT systems) unless the loop matters more than the devices it reads.
`setCpu(int)`	-1	The core to pin the thread to; -1 leaves it unpinned.
`setIsolateCpu(boolean)`	true	With a CPU given, move the process's other threads off that core.
`setAllocationBudget(int)`	0	Allocations a cycle may make before the thread fails.
`setSchedulingRequired(boolean)`	false	Fail the thread when real-time scheduling can't be applied, instead of running it normally.

127.3. Life cycle

A thread goes through `RealtimeThread.STATE_STARTING`, `STATE_RUNNING` and ends in `STATE_STOPPED` or `STATE_FAILED`; `getState()` reads it.

- `setup()` runs once, on the thread, before the first period.
- `cycle()` runs once per period, and `periodsMissed(n)` before it when `n` releases were missed. The loop then continues from the current time; missed periods aren't run late in a burst.
- `stop()` asks the loop to end after the current cycle, and `join(millis)` waits for it. `stopped()` runs

on the thread last, after a stop and after a failure alike, and may allocate.

- An exception or error from the task, including `RealtimeAllocationError`, ends the thread in `STATE_FAILED`. `failed(Throwable)` receives it on the thread, and `getFailure()` returns it afterward. The default `failed` prints the stack trace.

`isSchedulingApplied()` and `isCpuPinned()` say what the platform actually granted. Check them at start-up and log them: a loop that runs at normal priority looks fine on the bench and misses deadlines in the field.

`getStatistics()` returns a `RealtimeStatistics` snapshot:

- `getCycles()` and `getMissedPeriods()`.
- `getMaxLatencyNanos()` and `getMeanLatencyNanos()`: how late each release woke the thread, against its scheduled time.
- `getMaxExecutionNanos()` and `getMeanExecutionNanos()`: the time from each wake-up to the next wait — `cycle()`, plus `periodsMissed()` when it ran.
- `getAllocationViolations()`.
- `getLatencyHistogram()`: `HISTOGRAM_BUCKETS` (16) counts. Index `i` counts releases less than `2^i` microseconds late. The last bucket holds everything from about 16 milliseconds up.
- `getLatencyPercentileNanos(0.9999)`: a percentile read off the histogram, as the upper bound of its bucket.
- `toString()`: everything above on one line, for a log.

127.4. What the platform supports

`Realtime.getInstance().isSupported(feature)` answers for each part on its own:

Feature	Meaning
`FEATURE_SCHEDULING`	`SCHED_FIFO` priorities can be requested.
`FEATURE_CPU_AFFINITY`	Threads can be pinned to a core.
`FEATURE_MEMORY_LOCK`	`lockMemory()` can lock the process into RAM.
`FEATURE_GC_ISOLATION`	The collector doesn’t stop real-time threads.
`FEATURE_ALLOCATION_CHECK`	Every allocation in a cycle is caught at run time. Without it only allocations that need a new memory page are caught, and the build-time check is the guarantee.
`FEATURE_PREEMPT_RT_KERNEL`	The kernel is PREEMPT_RT.

127.5. The rules a cycle follows

A cycle allocates nothing. In steady state a real-time loop must not create objects. Each allocation adds work for the collector, and an allocating thread can be asked to wait for it. Codename One checks this twice:

- **At build time**, the translator follows every call `cycle()` and `periodsMissed()` can make. It fails the build on `new`, array creation, boxing and string concatenation, and the error names the method and the line. An allocation that's meant to happen, such as in a path that runs only on a fault, is marked with `@AllocationAllowed`.
- **At run time**, an allocation the build couldn't see — through an interface with several implementations, say — stops the thread with a `RealtimeAllocationError` naming the class. The thread's `failed()` method receives it. `setAllocationBudget(n)` allows up to `n` allocations per period for code that can't avoid them yet.

  Catching the error inside `cycle()` doesn't turn the check off. The allocation that failed is counted, and from the next period on the check applies again, so each later allocation fails the same way.

The collector doesn't stop a real-time thread. An ordinary thread pauses for a moment while the collector reads its stack. A real-time thread is released immediately, and its references stay visible to the collector through the write barrier. While any real-time thread runs, the collector also never enters its stop-the-world phases.

Keep the hand-off lock-free. `synchronized` between the real-time thread and the rest of the application works: the virtual machine's monitors use priority-inheriting mutexes on Linux, so a low-priority holder is raised until it releases. The wait is still as long as the holder's critical section. Pass data through preallocated buffers and `java.util.concurrent.atomic` instead.

Avoid the slow paths of the runtime in a cycle. Don't do these in `cycle()`:

- Throw exceptions. Building a stack trace allocates.
- Initialize a class for the first time. Touch it in `setup()`.
- Blocking I/O.
- Use the hardware API calls that return new arrays. Use the variants that fill a buffer you pass.

127.6. Memory and the rest of the system

`Realtime.lockMemory()` locks the process into RAM, so that its memory is never paged out. Each page is locked the first time it's touched (`MCL_ONFAULT`), because the heap is a large address reservation of which only part is used. The real-time thread's stack is touched before its first period. Touch your own buffers in `setup()`, so that no first touch happens in a cycle. Call `lockMemory()` once, early. It needs `CAP_IPC_LOCK` or a `memlock` limit large enough for the process.

`Realtime.setMemoryLimit(bytes)` caps the process's resident memory, on Linux. When the process is over the cap, an allocation in an ordinary thread throws `OutOfMemoryError` at once. Without the cap, the whole process slows down while the collector struggles. Real-time threads are exempt, because they don't allocate. The application decides what to drop and carries on.

The measurement is resident memory, which is what a device runs out of. Two things follow from that:

- It counts memory the heap is holding but hasn't returned to the system yet, so the cap applies to the process's footprint, not its live objects.

- An allocation is refused when a collection ends with the process still over the cap. Without waiting for a collection, it's refused once the process is a quarter over.

Set the cap with headroom over what the application needs at its peak.

The rest of the system gets what the real-time threads leave. With `setIsolateCpu(true)`, which is the default when a CPU is given, every other thread of the process is moved off that core. For a hard split, add `isolcpus=` and `nohz_full=` on the kernel command line, and limit the other services with a cgroup `cpu.max`.

127.7. Building and running on a board

A real-time application is an ordinary Codename One project. Nothing needs to be enabled for it:

- The allocation check runs in every native build that contains a `RealtimeTask`. That covers a local build, a cloud build and the backend's.
- The runtime parts are in every Linux executable.

Build it, install it on the board and watch its log with one command, as for any embedded application (see Building for a board):

```
mvn cn1:runOnDevice -Dcn1.board=rpi5 -Dcn1.device.host=pi.local -Dcn1.device.user=pi
gradle cn1RunOnDevice -Pcn1.board=rpi5 -Pcn1.device.host=pi.local -Pcn1.device.user=pi
```

The service `deploy-device` installs runs as root, with `LimitRTPRIO` and `LimitMEMLOCK` raised, so `SCHED_FIFO` and `lockMemory()` work without further setup. Log the thread's statistics from time to time, for example `getStatistics()` once a minute from an ordinary thread. They then appear in `cn1:device-logs`.

A backend with a real-time loop is built for the board with `cn1:backend-package` (`-Dcn1.backend.target=glibc-arm64` for a 64-bit ARM board). Install it with `cn1:deploy-device -Dcn1.device.binary=<the packaged executable>`.

127.8. Where it runs

Platform	Behaviour
Linux and embedded Linux (PREEMPT_RT)	`SCHED_FIFO` priority, CPU pinning and isolation, memory locking, collector isolation, allocation trap, memory limit. `isSupported(FEATURE_PREEMPT_RT_KERNEL)` tells you whether the kernel is real-time.
Linux (standard kernel)	The same, but latency is the scheduler's best effort.
Backend server (ParparVM)	The same as the Linux port on Linux.
Simulator and other platforms	The loop runs on an ordinary thread at its period, with statistics, so the logic can be developed and tested. No scheduling guarantee.

Real-time scheduling needs the `CAP_SYS_NICE` capability, or an `rtprio` limit in `/etc/security/limits.conf`. Without it the thread runs normally, and `isSchedulingApplied()` returns false. Call `setSchedulingRequired(true)` to make the thread fail instead.

127.9. Measuring

`vm/backend/demo/rtcheck` is the check CI runs. A 1 kHz loop runs while the main thread allocates hard enough to keep the collector busy all the time. It then checks that a cycle allocating through an interface is stopped, and that the memory limit throws. Run it on your board to see the release latency the hardware gives you before you rely on a deadline.

127.10. Porting

A port supplies its implementation by returning a `Realtime` subclass from `CodenameOneImplementation.getRealtime()`; `Display` installs it with `Realtime.install()` when it starts, and the backend installs its own. An application never calls `install()`.

Chapter 128. Desktop Integration

Codename One is mobile-first, but the same app can run on the desktop: as a Java SE “Run as desktop app” / executable jar, and as a native macOS app via the local `mac-source` (native macOS) build target. By default a desktop build looks like a phone app in a window - a mobile-style `Toolbar` at the top of every `Form`, fading touch scrollbars, and commands tucked into a hamburger side menu.

The desktop integration features make a desktop build **feel** like a desktop app:

- A native window title bar that shows the `Form` title (instead of the in-app `Toolbar`).
- A native menu bar populated from your `Command` objects, with per-command placement hints (About, File, Edit, Quit, …).
- Interactive scrollbars - a draggable thumb that highlights on hover and while dragged, click-to-page on the track, a minimum thumb size so it stays easy to grab on long content, a reserved gutter so content isn’t drawn under the bar, and an always-visible (rather than fading) scrollbar.
- Keyboard accelerators on the native menu items (a Save shortcut, a Quit shortcut).
- Native desktop notifications driven by the standard `LocalNotification` API.

These behaviors are **opt-in**. They’re switched on by default for newly generated projects (both the Maven archetype and the start.codenameone.com initializr) and stay completely inert on phones/tablets - all the new behavior is gated on `CN.isDesktop()`, so a mobile build of the same project is unaffected.

Alongside them a desktop build also gets, without asking for anything:

- Keyboard conventions. Tab and Shift-Tab move focus through the form, Enter fires the default command, and Escape fires the back command - or closes a dialog or window that has no back command, the same thing the platform’s own close control does. On a phone none of these keys exist, so every one of them is gated on `CN.isDesktop()`.
- A right-click menu. Give a component its commands with `Component.setContextMenuCommands(Command…)` and one opens on a secondary mouse button, a stylus barrel button or a long press. Where the commands depend on what was clicked, register a `Component.addContextMenuListener(ActionListener)` and call `ContextMenu.show(…)` from it.
- Dialogs in a window of their own, when the installed theme asks for it. The three desktop native themes do; see Section 129.11, “Dialogs in a window of their own”.
- Three controls that only make sense here: `Separator`, `GroupBox` and `Stepper`.

128.1. Title-bar modes

The window chrome is selected by the `desktop.titleBar` setting, which takes one of three values:

`native`	Hide the CN1 `Toolbar`. The `Form` title goes into the OS window title bar and the toolbar's commands are bridged to a native menu bar. This is the default for newly generated apps.
`custom`	Application-drawn title content where the CN1 `Toolbar` acts as the window's title bar: it shows the `Form` title and side menu, dragging it moves the window, and the window is resized by dragging its edges. The commands are bridged to the native menu bar **and** remain in the toolbar's side menu.
`toolbar`	Legacy behavior - the in-app CN1 `Toolbar` is shown exactly as on mobile.

The screenshots below show the same notes app, with File / Edit / View / Help commands, in each mode on macOS.

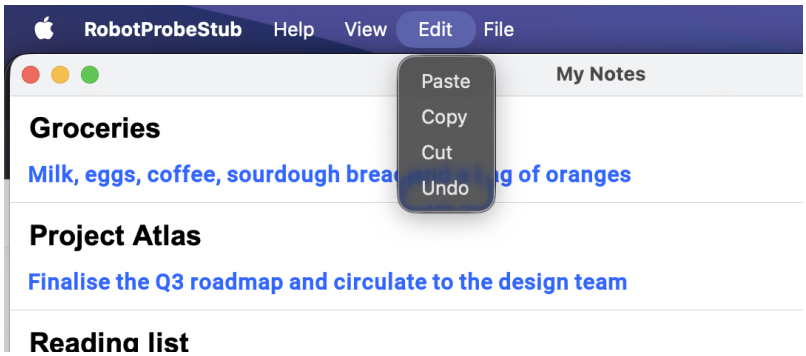

Figure 432. `native` mode: the `Form` title is in the OS window title bar, the commands populate the native menu bar, and there is no in-app `Toolbar`

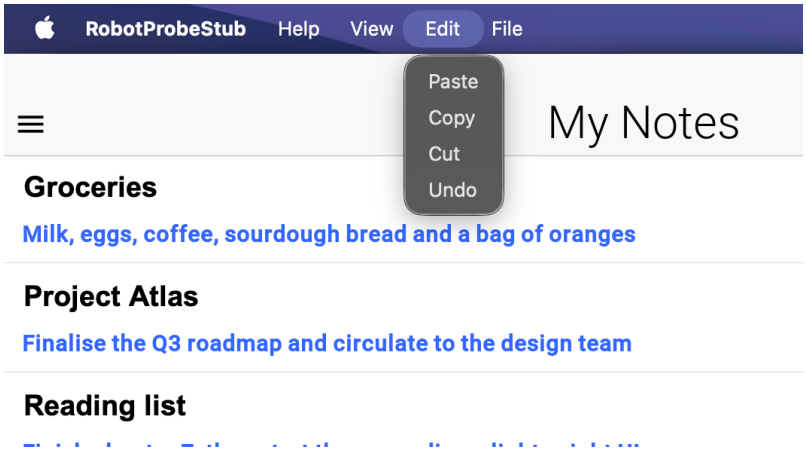

Figure 433. `custom` mode: the window is undecorated and the CN1 `Toolbar` (title + hamburger side menu) is the window's title bar; the commands are also in the native menu bar

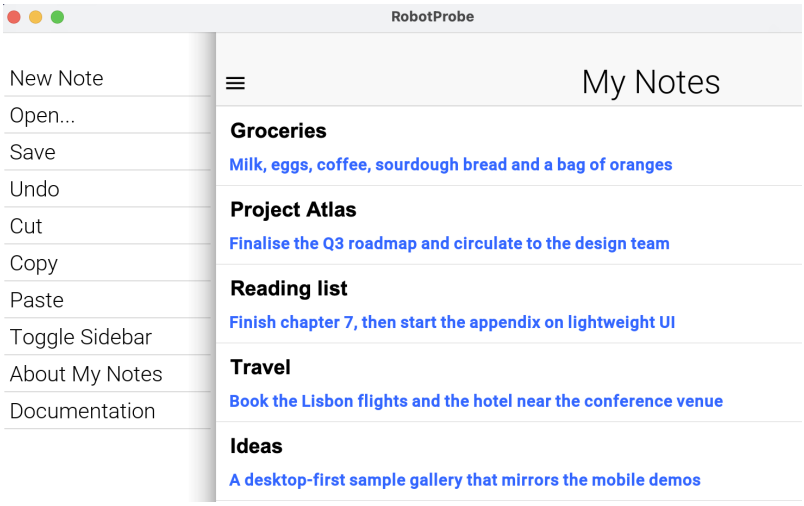

Figure 434. `toolbar` *mode: the legacy look - the in-app* `Toolbar` *sits below a generic OS title bar and the commands live in the hamburger side menu*

128.1.1. Enabling it on the Java SE desktop build

For the desktop (Java SE) target the mode is a build hint that the generated desktop launcher applies for you. In `codenameone_settings.properties`:

```
codename1.arg.desktop.titleBar=native
codename1.arg.desktop.interactiveScrollbars=true
```

Newly generated projects already contain these lines. The generated `<MainName>Stub` reads them at startup, so no code is required. Because the stub is the desktop entry point, the settings only ever take effect on the desktop.

128.1.2. Enabling it on the native macOS build

The local `mac-source` build runs through ParparVM, where the chrome is the application's own `NSWindow` and `NSMenu`. Set `codename1.arg.desktop.titleBar=custom` in `codenameone_settings.properties` to draw title content in the toolbar, or use `native` for the standard OS title bar. The generated launcher applies the build hint before calling the application's `init()` method, so the first toolbar uses the requested mode. Without a hint the installed theme chooses the mode: the bundled Aqua theme requests `native`. If the theme doesn't specify a mode, the port supplies its fallback.

In `custom` mode, macOS retains its native close, minimize and zoom controls and window resizing. Dragging an empty part of the toolbar uses the OS window drag operation. Double-clicking it follows the user's macOS title-bar preference. Buttons (including disabled buttons), editable titles, scrollable regions and other interactive descendants are excluded from the drag area. The toolbar publishes these regions to the native port after layout; applications don't need their own window drag listeners. The native Windows and Linux ports use the same toolbar contract, as described below.

The setting can also be supplied as a runtime property before constructing the first `Form`:

```
Display.getInstance().setProperty("desktop.titleBar", "native");
```

```
Display.getInstance().setProperty("desktop.interactiveScrollbars", "true");
```

On a phone or tablet iOS build these properties are ignored. The legacy Mac Catalyst target also honors them, through `UIWindowScene` and `UIMenuBuilder` rather than AppKit; see Chapter 121, *Working with Mac Catalyst*.

128.1.3. Integrated title content on native desktops

Use `desktop.titleBar=custom` when document actions, a search field, or other application controls belong in the title area. Configure the toolbar with `setTitleComponent()` and the usual left/right bar commands. The framework reserves space for the operating system's window controls; don't add fixed padding for traffic lights or caption buttons. Theme padding is additional application spacing.

```
public static Form createEditor(Command save, Command search) {
    Display.getInstance().setProperty("desktop.titleBar", "custom");
    Toolbar.setGlobalToolbar(true);
    Form editor = new Form("Quarterly report", new BorderLayout());
    Container title = new Container(new BorderLayout());
    title.add(BorderLayout.WEST, new Button(save));
    title.add(BorderLayout.CENTER, new Label("Quarterly report"));
    title.add(BorderLayout.EAST, new Button(search));
    editor.getToolbar().setTitleComponent(title);
    return editor;
}
```

The example belongs in the normal application lifecycle, after Codename One has initialized the display. Applications don't call `Display.init()`. The build hint can select the mode before `init()` runs; a runtime property must be set before constructing the first form.

Native port	Window behavior in `custom` mode
macOS	AppKit retains the real traffic-light buttons, resizable frame and native menu bar. The toolbar occupies the full-size content area. Empty title space uses AppKit dragging and the user's configured double-click action.
Windows	The Desktop Window Manager retains the caption buttons. Native hit testing routes empty title space to caption dragging and routes the edges to resizing. Windows handles maximize, restore, minimize, close and the system menu. Application controls remain client input targets. Caption metrics follow the window DPI; caption appearance follows the system light/dark setting.
Linux	A `GtkHeaderBar` hosts the toolbar's rendered content beside real GTK window controls. GTK chooses their arrangement from the desktop settings and handles title gestures and window commands. The header and document share one Java component tree and rendering surface.

On Windows, the integrated mode omits the separate Win32 menu row, which would overlap the custom caption. Toolbar commands remain available through their application controls and side

menu, and native command accelerators remain registered. Use `native` mode for the traditional Win32 menu bar. On Linux, the native GTK menu row remains below the integrated header. The macOS menu stays in the system menu bar. If an application hides the toolbar's side menu, it must provide another visible way to invoke those commands, such as its ribbon.

Reserved space uses physical left/right edges, independent of a document's text direction. The framework accounts for native controls while measuring and laying out the toolbar, and restores the application's padding values and units afterward. Resize, DPI and native theme changes can change this space. Avoid forcing the toolbar below its preferred height.

Interactive children, including disabled buttons, are excluded from native dragging. Plain `Label` and `Container` instances allow window gestures on their passive backgrounds. Pointer, long-press, context-menu and stylus listeners keep their input. Subclasses and other component types retain input by default, including those that override pointer methods. For a custom component that only draws a title background, call `Toolbar.setTitleBarDragRegion(component, true)` to allow dragging there; interactive children and listeners remain excluded. Passing `false` also excludes a plain label or container. Hiding or removing the toolbar clears its drag regions; the Windows and Linux ports restore their ordinary title area. When DWM composition is unavailable, Windows retains its standard decorated frame instead of removing the user's window controls.

This integration applies to the main application form in native desktop builds. Separate `Window` and dialog peers retain their own native decorations. Phone/tablet UI and browser pages use their existing toolbar behavior: this feature doesn't open browser popup windows or attempt to control browser chrome. The Java SE desktop port retains its existing custom-title behavior.

For port implementers, `getNativeWindowTitleBarInsets(Component)` supplies physical left, right, top and bottom insets followed by the minimum title-band height, all in component pixels. `setNativeWindowTitleBarRegions(Component, int[])` receives the full band followed by interactive exclusion rectangles. An empty array clears the regions. These calls originate on the EDT; ports must copy arrays before asynchronous native work and must not call Java UI code from a synchronous native geometry query. The AppKit port reads a cached geometry snapshot so layout can't deadlock against the native rendering thread.

128.2. Native menu bar and command placement hints

In `native` and `custom` title-bar modes, the commands you add through the `Toolbar` / `Form` command API are bridged to the platform's native menu bar - a Swing `JMenuBar` (which becomes the macOS screen menu) on the Java SE build, and an `NSMenu` on the native macOS build. Selecting a menu item runs the command's `actionPerformed` on the Codename One EDT, exactly as a button press would.

By default every command lands under a single **Commands** menu. To place commands into the conventional desktop menus, tag them with a desktop-menu hint using `Command.setDesktopMenu(String)` and the `Command.DESKTOP_MENU_*` constants:

```
Form hi = new Form("My App", BoxLayout.y());

Command about = new Command("About My App");
about.setDesktopMenu(Command.DESKTOP_MENU_ABOUT);   // application menu
```

```
Command open = new Command("Open File...");
open.setDesktopMenu(Command.DESKTOP_MENU_FILE);     // File menu

Command quit = new Command("Quit");
quit.setDesktopMenu(Command.DESKTOP_MENU_QUIT);     // application menu

hi.addCommand(about);
hi.addCommand(open);
hi.addCommand(quit);
hi.show();
```

The recognized values are (case-insensitive):

`DESKTOP_MENU_APP`	The macOS application menu. Other platforms have none, so these commands go to File.
`DESKTOP_MENU_ABOUT`, `DESKTOP_MENU_PREFERENCES`, `DESKTOP_MENU_QUIT`	The About, Settings and Quit standard commands, placed where each platform keeps them. See Section 128.2.3, “Standard commands”.
`DESKTOP_MENU_FILE`, `DESKTOP_MENU_EDIT`, `DESKTOP_MENU_VIEW`, `DESKTOP_MENU_WINDOW`, `DESKTOP_MENU_HELP`	Placed in the matching standard top-level menu.
Any other string	Becomes a top-level menu with that literal title.
Unset	Grouped under a default **Commands** menu.

Each port maps the hint to its native structure: on the native macOS build the command is inserted into the application’s real `NSMenu` under the application, File, Edit, View, Window and Help submenus; on the Java SE build a top-level `JMenu` is created per hint group.

All four desktop ports have one: a Swing `JMenuBar` on the Java SE build, an `NSMenu` on the native macOS build, a Win32 `HMENU` on the Windows port and a `GtkMenuBar` on the Linux port. The three ParparVM ports encode a command the same way, so one format serves every one.

A port with no native menu bar is handled rather than assumed away. `Form` keeps its Toolbar there instead of hiding it - hiding it would take away the only place the commands are drawn - and `Display.COMMAND_BEHAVIOR_NATIVE` normalizes back to the default rather than dropping every command without a word. Nothing in application code branches on this.

The hint is a plain client property (`Command.DESKTOP_MENU`), so it’s inert on platforms that don’t have a native menu bar - it’s safe to set it unconditionally in shared code.

128.2.1. Keyboard accelerators

Give a command a keyboard accelerator with `Command.setDesktopShortcut(…)`. The shortcut is shown next to the menu item and triggers the command from the keyboard:

```
Command save = new Command("Save");
save.setDesktopMenu(Command.DESKTOP_MENU_FILE);
save.setDesktopShortcut('S');   // Cmd+S on macOS, Ctrl+S on Windows/Linux

Command saveAs = new Command("Save As...");
saveAs.setDesktopMenu(Command.DESKTOP_MENU_FILE);
saveAs.setDesktopShortcut('S',
        Command.DESKTOP_SHORTCUT_MODIFIER_PRIMARY | Command.DESKTOP_SHORTCUT_MODIFIER_SHIFT);
```

The single-argument form uses the platform's **primary** modifier - Command on macOS, Control on Windows/Linux - which is the right default for most menu shortcuts. The two-argument form takes a bit-mask of `Command.DESKTOP_SHORTCUT_MODIFIER_PRIMARY`, `Command.DESKTOP_SHORTCUT_MODIFIER_SHIFT` and `Command.DESKTOP_SHORTCUT_MODIFIER_ALT`. On the Java SE build the accelerator becomes a Swing `KeyStroke`; on the native macOS build it becomes the menu item's `keyEquivalent` and `keyEquivalentModifierMask`. Like the placement hint, the accelerator is inert on platforms without a native menu bar, so it's safe to set unconditionally.

128.2.2. Submenus, separators, check items and icons

The same `Command` carries the rest of a menu item's structure:

`setDesktopMenu("File/Open Recent")`	A path: each `/` nests a submenu, created on demand. The first segment is the placement hint from the table above. Write `//` for a slash that belongs in a title.
`setDesktopMenuGroup(int)`	Orders the items of a menu by group, keeping the order you added them in within a group, and draws a separator wherever the group changes. `Command.createDesktopSeparator(menu)` adds one at an exact spot instead.
`setDesktopChecked(boolean)`	Makes the item a check item. Choosing it flips the state **before** the action runs, so the action reads the new value from `isDesktopChecked()`.
`setDesktopRadioGroup(String)`	Makes the item one of a radio group: checking one unchecks the others.
`setEnabled(boolean)`	A disabled command is greyed out in the menu and can't be chosen.
`setIcon(…)`, `setMaterialIcon(…)`	Shown beside the item where the platform draws menu icons.

```
public static void addViewMenu(Form form) {
    // A check item: the state flips before the action runs.
    Command sidebar = Command.create("Show Sidebar", null, e -> {
        boolean visible = ((Command) e.getSource()).isDesktopChecked();
        System.out.println("Sidebar visible: " + visible);
    });
    sidebar.setDesktopMenu(Command.DESKTOP_MENU_VIEW).setDesktopChecked(true);
```

```
    // A radio group in a submenu, a separator group below the check item.
    String[] zooms = {"50%", "100%", "200%"};
    for (String zoom : zooms) {
        Command c = Command.create(zoom, null, e -> System.out.println("Zoom " + zoom));
        c.setDesktopMenu("View/Zoom").setDesktopMenuGroup(1).setDesktopRadioGroup("zoom");
        c.setDesktopChecked("100%".equals(zoom));
        form.getToolbar().addCommandToOverflowMenu(c);
    }

    // An icon and a separator group of its own.
    Command refresh = Command.createMaterial("Refresh", FontImage.MATERIAL_REFRESH,
            e -> System.out.println("Refresh"));
    refresh.setDesktopMenu(Command.DESKTOP_MENU_VIEW).setDesktopMenuGroup(2);
    refresh.setDesktopShortcut('R');

    form.getToolbar().addCommandToOverflowMenu(sidebar);
    form.getToolbar().addCommandToOverflowMenu(refresh);
}
```

Changing a command's enabled or checked state updates the visible menu. After changing anything else about a published command, such as its name or icon, call `Display.getInstance().refreshNativeMenu()`.

Each platform draws these items in its own style. macOS and Mac Catalyst show a radio item with the same checkmark as a check item, as every Mac application does. Windows draws a bullet. The Windows and Linux menus show no icons: Win32 menu bitmaps need a decoder that port doesn't have, and GTK 3 deprecated menu item images, so no GNOME application shows them.

128.2.3. Standard commands

About, Settings and Quit live in different places on each desktop, under different names. Give such a command a **role** with `Command.setDesktopRole(String)` and the `Command.DESKTOP_ROLE_*` constants, and each platform puts it where its own applications do, with the platform's standard shortcut:

Role	macOS	Windows	Linux
`DESKTOP_ROLE_ABOUT`	Application menu, first	Help, last	Help, last
`DESKTOP_ROLE_SETTINGS`	"Settings…" in the application menu, Cmd+,	"Options" under Tools	"Preferences" at the foot of Edit
`DESKTOP_ROLE_QUIT`	"Quit" in the application menu, Cmd+Q	"Exit" at the foot of File	"Quit" at the foot of File, Ctrl+Q
`DESKTOP_ROLE_HIDE_APP`	Application menu, Cmd+H	Not shown	Not shown

The File roles (`NEW`, `OPEN`, `SAVE`, `SAVE_AS`, `CLOSE`, `PRINT`), the Edit roles (`UNDO`, `REDO`, `CUT`, `COPY`, `PASTE`, `SELECT_ALL`, `FIND`) and `FULL_SCREEN`, `MINIMIZE`, `ZOOM` and `HELP` work the same way. Redo is Cmd+Shift+Z on macOS and Ctrl+Y on Windows, for example. On macOS a role command takes the place of the matching built-in item, so the menu never shows two Quit or Copy items. The browser's in-page

menu follows the Windows layout. It leaves out Quit, Minimize and Zoom, and it drops the shortcuts the browser keeps for itself.

`Command.createDesktopRole(role, listener)` creates the command with the platform's name for it ("Exit" on Windows, "Quit" elsewhere). The resource key `cn1.menu.<role>`, such as `cn1.menu.quit`, translates it. Anything the command sets itself wins over its role: its own menu, group and shortcut. The older `DESKTOP_MENU_ABOUT`, `DESKTOP_MENU_PREFERENCES` and `DESKTOP_MENU_QUIT` hints are read as these roles.

`setDesktopPlatforms("mac", "win", "linux", "web")` limits a command to the native menu bars of the platforms it lists. The application's own menus still show it everywhere.

`Form.setDocumentModified(boolean)`, and the same method on `Window`, shows that the document has unsaved changes. macOS draws a dot in the close button; Windows and Linux put * before the title. A Save command follows that state: it's enabled while there are changes to save. `Command.setDesktopEnabledWhenModified(boolean)` makes any other command follow it too.

```
public static void addStandardCommands(Form form) {
    // Named, placed and given a shortcut the way the running platform does it:
    // "Settings..." in the macOS application menu with Cmd+comma, "Options" under
    // Tools on Windows, "Preferences" at the foot of Edit on Linux.
    Command settings = Command.createDesktopRole(Command.DESKTOP_ROLE_SETTINGS,
            e -> System.out.println("Show settings"));
    // "Quit" on macOS and Linux, "Exit" at the foot of File on Windows.
    Command quit = Command.createDesktopRole(Command.DESKTOP_ROLE_QUIT,
            e -> System.out.println("Quit"));
    // Disabled until the document has unsaved changes.
    Command save = Command.createDesktopRole(Command.DESKTOP_ROLE_SAVE,
            e -> {
                System.out.println("Save");
                form.setDocumentModified(false);
            });
    // Only on the platforms named.
    Command services = new Command("Show Services");
    services.setDesktopMenu(Command.DESKTOP_MENU_HELP).setDesktopPlatforms("mac");

    form.getToolbar().addCommandToOverflowMenu(settings);
    form.getToolbar().addCommandToOverflowMenu(save);
    form.getToolbar().addCommandToOverflowMenu(quit);
    form.getToolbar().addCommandToOverflowMenu(services);

    // A dot in the close button on macOS, "*" before the title elsewhere.
    form.setDocumentModified(true);
}
```

128.3. Interactive scrollbars

Enabling `desktop.interactiveScrollbars` turns the scrollbar from a fading touch indicator into a desktop-style control:

- The thumb can be grabbed and dragged, and it **highlights** while the pointer hovers it and while it's being dragged (the `DesktopScrollThumb` selected / pressed styles).
- Clicking the track pages toward the pointer by about one viewport.
- The thumb has a **minimum size** so it stays easy to grab even when the content is far taller than the viewport. The minimum (in pixels) is the `scrollThumbMinSizeInt` theme constant; when unset it defaults to the equivalent of 4mm.
- A **gutter** is reserved for the scrollbar so content isn't laid out underneath it. The gutter width comes from the `DesktopScroll` / `DesktopHorizontalScroll` UIID padding (see below).
- The scrollbar stays visible rather than fading out.

This is a cross-platform core feature driven by the `interactiveScrollBool` theme constant, which the desktop ports inject only when `CN.isDesktop()` is true. Mouse-wheel scrolling continues to work as before.

128.4. Theme UIIDs

When interactive scrollbars are active, the desktop scrollbar is styled through dedicated UIIDs so the mobile `Scroll` / `ScrollThumb` styling is never affected:

`DesktopScroll`, `DesktopScrollThumb`, `DesktopHorizontalScroll`, `DesktopHorizontalScrollThumb`	The interactive desktop scrollbar track and thumb. The horizontal-/vertical-scroll UIID's padding sets the scrollbar gutter width. The thumb UIID's `.selected` and `.pressed` styles render the hover and drag highlight respectively.

All the native themes ship platform-conventional defaults for these UIIDs, including the `.selected` / `.pressed` thumb highlight states; see Chapter 15, *Native modern themes*. The three desktop themes also turn `interactiveScrollBool` on themselves, so a desktop build using one gets the real scrollbar without setting the build hint. Override the UIIDs in your app's `theme.css` like any other UIID.

The highlight states are `.selected` and `.pressed`, not `.hover`. The interactive thumb reads its selected style while the pointer is over it and its pressed style while it's being dragged, so a `.hover` rule on `DesktopScrollThumb` compiles and is never painted. For the same reason, don't write these UIIDs as `cn1-derive: ScrollThumb`: a derive produces the whole state family by copying the base, so the highlight ends up identical to the resting colour - present in the compiled theme and invisible on screen. The minimum thumb length is the `scrollThumbMinSizeInt` theme constant (pixels). In `custom` mode the title bar is just the regular CN1 `Toolbar`, so it's themed through the usual `Toolbar` / `Title` UIIDs.

128.5. Desktop notifications

The standard `com.codename1.notifications.LocalNotification` API works on the desktop. On the Java SE desktop build a scheduled notification surfaces as a native OS notification through the system tray (Notification Center on macOS, the notification area on Windows/Linux); on the native macOS

build it goes through the same `UNUserNotificationCenter` path as iOS. Clicking the notification delivers it to your app's `LocalNotificationCallback`, exactly as on mobile, so the same scheduling and handling code is shared across phone and desktop:

```
LocalNotification n = new LocalNotification();
n.setId("reminder-1");
n.setAlertTitle("Reminder");
n.setAlertBody("Your export has finished.");

// fire in 5 seconds, no repeat
Display.getInstance().scheduleLocalNotification(
        n, System.currentTimeMillis() + 5000, LocalNotification.REPEAT_NONE);
```

On the Java SE build desktop notifications require an OS with system-tray support (`java.awt.SystemTray`); where it's unavailable the notification is logged and skipped.

Chapter 129. Desktop Windows

A phone application has one window, because the operating system owns the screen and the application fills it. A desktop application usually doesn't: an inspector panel, a preferences window, a second document, a tool palette and a detached console are all ordinary desktop expectations.

`com.codename1.ui.Window` is how you open them. A `Window` is a separate native operating-system window with its own Codename One component hierarchy inside it, its own focus owner, its own animations and its own repaint region. The application's main surface is a `Form` and is unaffected by any of this.

```
if (Desktop.isSupported()) {
    Window inspector = new Window("Inspector", new BorderLayout());
    inspector.add(BorderLayout.CENTER, new Label("Hello from a second window"));
    inspector.setWindowSize(420, 320);
    inspector.centerOnDesktop();
    inspector.show();
}
```

129.1. Where windows exist

Windows are a desktop feature, and the API says so plainly:

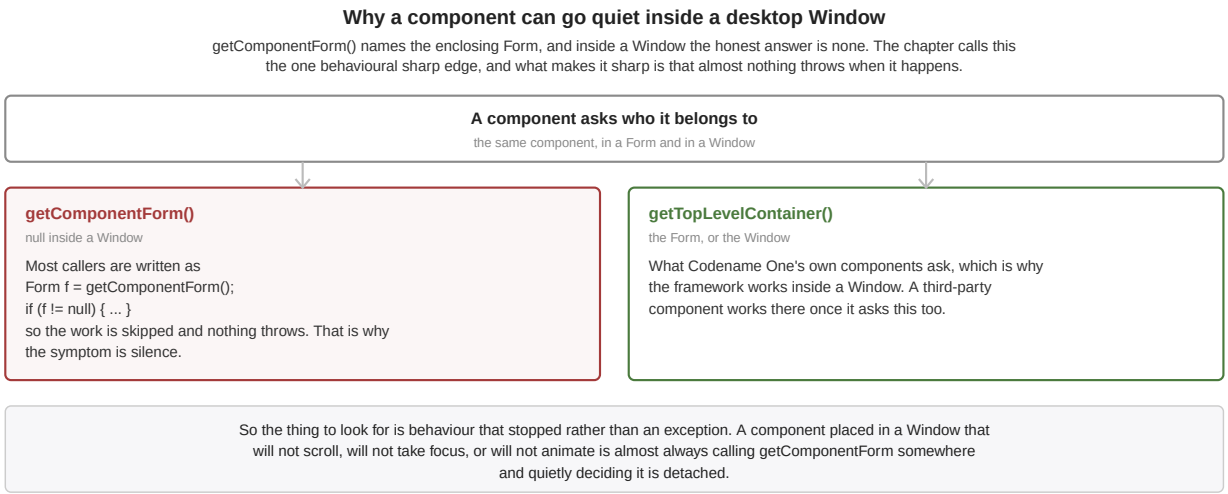
Platform	Windows	Notes
Java SE desktop app	Yes	The packaged desktop build and the simulator in desktop-skin mode.
Java SE simulator with a phone skin	No	A skin simulates one device screen; a real window inside that simulation is incoherent.
Native Windows	Yes	
Native Linux	Yes	
macOS	Yes	Each window is a real `NSWindow`. See Section 129.15, "macOS".
macOS (Mac Catalyst)	Opt-in	Needs `macNative.multiWindow=true`. See Section 129.16, "Mac Catalyst (legacy)".
iOS, Android, JavaScript	No	These platforms have no windowing system.

Always guard with `Desktop.isSupported()` (or the shorthand `CN.isMultiWindowSupported()`). Constructing a `Window` where windows are unsupported throws `UnsupportedOperationException` immediately:

```
Window w = new Window("Tools");   // throws on a phone
w.show();
```

There's no fallback to showing a `Form` instead. A pretend window produces layout and lifecycle bugs that are far harder to find than an exception on the line that asked for it. The exception is thrown by the constructor rather than by `show()`, so a wrong assumption surfaces at the point it was made.

Everything else degrades cleanly. `Desktop.getWindows()` returns an empty array rather than null, `Desktop.getFocusedWindow()` returns null, and `Desktop.getMonitors()` still reports the main display, so portable code that loops over windows or positions against a monitor compiles and runs everywhere.



129.2. Window and Form

`Form` and `Window` are siblings. Both extend `Container`, and both implement the new `TopLevelContainer` interface, which is the contract shared by anything that can sit at the root of a component hierarchy:

```
TopLevelContainer top = component.getTopLevelContainer();
top.getContentPane().add(new Label("works in either"));
top.registerAnimated(component);
Component focused = top.getFocused();
```

`TopLevelContainer` carries only what genuinely applies to both. It has the content pane, the layered panes, the title, commands, animation registration, focus, editing state, the theme manager and the show/size listeners. It does **not** carry `Form`'s mobile surface - form transitions, the back command, `previousForm`, the `Toolbar` or the tint that dims a form behind a dialog - because none of those mean anything for a desktop window, whose title and menus belong to the platform chrome. Members that already exist on `Component` or `Container` are reached through `asContainer()`.

129.2.1. getComponentForm() returns null inside a Window

This is the one behavioral sharp edge, and it's worth stating plainly:

```
Window window = new Window("Inspector", new BorderLayout());
Label l = new Label("hi");
window.add(BorderLayout.CENTER, l);
```

```
l.getTopLevelContainer();   // the Window
l.getComponentForm();       // null -- a Window is not a Form
```

`getComponentForm()` means what it says: it names the enclosing `Form`, and inside a window the honest answer is none. Codename One's own components ask `getTopLevelContainer()` instead, so the framework works inside a window - apart from the handful listed under Section 129.13, "Unsupported inside a window", which depend on something that isn't window-aware rather than on the call itself. A third-party component that calls `getComponentForm()` works inside a window only once it asks `getTopLevelContainer()` too.

The failure mode is usually silence rather than an exception, because most of that code is written as `Form f = getComponentForm(); if (f != null) { … }`. If a component behaves as though it's detached when you put it in a window - it doesn't scroll, doesn't take focus, or doesn't animate - that's almost always the cause.

129.3. Window lifecycle

```
boolean unsavedChanges = hasUnsavedWork();
Window w = new Window("Preferences", new BorderLayout());
w.add(BorderLayout.CENTER, new Label("Preferences"));
w.setWindowSize(500, 400);
w.setCloseOperation(Window.DISPOSE_ON_CLOSE);

w.addCloseListener(evt -> {
    if (unsavedChanges) {
        evt.consume();          // veto the close, then prompt the user to save
    }
});

w.show();
```

`show()` creates the native window the first time it's called and maps it on screen. `hide()` hides the window while keeping it alive, so it can be shown again. `dispose()` destroys the native window and releases everything behind it; calling it twice is harmless.

`setOwnerWindow()` has to be called before the window is shown. Native ownership is established when the window is created — the owner window handle on Windows, the transient parent on GTK, the owner passed to the dialog on Java SE — and no platform lets it be re-pointed once the window exists, so changing it later throws rather than pretending.

`setCloseOperation()` decides what the platform's own close control does:

`DISPOSE_ON_CLOSE`	Destroy the window. The default.
`HIDE_ON_CLOSE`	Hide it, so it can be shown again later.
`DO_NOTHING_ON_CLOSE`	Do nothing; the application calls `dispose()` itself.

Consuming the event in a close listener vetoes the close regardless of the operation, which is how a window asks the user to save first.

That veto isn't available on Mac Catalyst. UIKit hands a scene disconnection over after the scene is already gone, so there is nothing left to refuse: the window is disposed, the close listeners don't run, and `HIDE_ON_CLOSE` and `DO_NOTHING_ON_CLOSE` have no effect for the title-bar control. Don't rely on a save prompt there. An application that has to intervene should drive the close itself: ask the user from its own menu item or button, and call `dispose()` once they've answered.

Note that `dispose()` isn't a close request on any platform. It destroys the window directly and doesn't run the close listeners, so a listener can't veto it - the confirmation belongs in the code that decides to call `dispose()`, not in a listener behind it. Close listeners fire for the platform's own close control, which is exactly the control Catalyst doesn't let anyone refuse.

Every open window is disposed when the application shuts down, so a window can't outlive the event dispatch thread that paints it.

129.4. Window chrome and geometry

```
w.setResizable(false);
w.setDecorated(false);      // no native title bar; draw your own with a Toolbar
w.setAlwaysOnTop(true);     // a floating palette
w.setUtilityWindow(true);   // keep it out of the task bar where the platform allows
w.setMinimumWindowSize(new Dimension(320, 240));
```

Geometry has two coordinate systems and two sets of names, which is deliberate:

- `getWindowBounds()`, `setWindowBounds()`, `setWindowSize()` and `setWindowLocation()` are **native** coordinates and include the platform's own chrome.
- `getWidth()` and `getHeight()`, inherited from `Component`, are the Codename One content size in Codename One pixels.

A size is a **request**. Every window system is free to adjust it — a minimum size, a constraint from the window manager, or a screen too small for what you asked — so read `getWidth()` and `getHeight()` back rather than assuming the request was granted, and listen for `Resized` if it matters.

`centerOnDesktop()` centers the window on the **work area** of the monitor it's on, so it doesn't land under the task bar or the dock. `centerOn(other)` centers it over another top level. `minimize()`, `restore()` and `toggleMaximize()` do what they say, where the platform allows a program to ask.

129.5. Styling

A window is a top level surface, so it starts out with the styles a theme already defines for one: `Form` for the window itself, `ContentPane` for its content pane, `TitleArea` and `Title` for its title. That means every existing theme styles a window correctly without being updated, which is the point — a top level with no style entry paints nothing at all and comes up as an unpainted rectangle.

To make windows look different from forms, give them a UIID of your own and style that:

```
w.setUIID("PaletteWindow");
w.getContentPane().setUIID("PaletteWindowContentPane");
```

129.6. Modal windows

```
Window dialog = new Window("Confirm", new BorderLayout());
dialog.add(BorderLayout.CENTER, new Label("Really delete everything?"));
dialog.setOwnerWindow(mainWindow);
dialog.setModalityType(Window.MODALITY_WINDOW);
dialog.showModal();          // blocks here until the window is disposed
```

`showModal()` parks the calling code until the window is no longer showing, much as a modal `Dialog` does. It doesn't freeze the application: the event dispatch thread keeps running, so every other window carries on painting and animating while the modal is up.

Both `dispose()` and `hide()` end the wait — the window is closed as far as the user is concerned either way, and parking the caller on a window nobody can reach would hang it. That matters when the close operation is `HIDE_ON_CLOSE`, because `showModal()` then returns with the window still live and reusable. Cleanup that only makes sense for a destroyed window should ask `isWindowDisposed()` rather than assume it. Minimizing doesn't end the wait: a minimized window is still up.

Three modality types are available:

`MODALITY_NONE`	Blocks nothing. The default.
`MODALITY_WINDOW`	Blocks input to the window that owns it, and nothing at all when the window has no owner.
`MODALITY_APPLICATION`	Blocks input to every other window and to the main form.

Codename One decides which windows a modal blocks, so modality behaves identically everywhere whether the underlying window system implements its own or not. That decision depends on the whole stack of open modal windows, not just the newest one, which is why it isn't left to the ports: a window modal opened from inside an application modal narrows what **it** blocks without lifting anything the outer one still blocks.

The framework then tells each port which windows to disable natively. That matters beyond appearances, because a blocked window's own title bar is outside the input filter - without it, the close button of a window you've blocked still reaches your application.

129.7. Monitors and per-monitor DPI

`Desktop` is the front door for the display side of a windowing system, alongside `Display` rather than replacing any of it. `Display` answers how big the application's main surface is, which is the only

question a phone has. `Desktop` answers which screens exist and which windows are open.

```
for (Monitor m : Desktop.getInstance().getMonitors()) {
    System.out.println(m.getName()
            + " bounds=" + m.getBounds()
            + " workArea=" + m.getWorkArea()
            + " scale=" + m.getScale()
            + " dpi=" + m.getDotsPerInch()
            + (m.isPrimary() ? " (primary)" : ""));
}

Monitor under = Desktop.getInstance().getMonitorAt(pointerX, pointerY);
Rectangle whole = Desktop.getInstance().getDesktopBounds();   // union of every monitor
```

Prefer `getWorkArea()` over `getBounds()` when placing or maximizing a window: the work area excludes the task bar, the dock and any reserved panels, and the bounds don't.

Note that desktop coordinates span every monitor, so a display placed to the left of or above the primary one legitimately has a negative origin.

129.7.1. A window reports its own monitor's characteristics

On a desktop with mixed displays - a high-resolution laptop panel next to a conventional external monitor is the common case - two windows of the same application can correctly render at different scales:

```
w.getMonitor();     // the Monitor this window currently sits on
w.getScale();       // that monitor's backing scale, e.g. 1.0 or 2.0
w.getDensity();     // that monitor's density bucket
```

These answer for the window's own monitor, not for the global display. When the user drags a window onto a display with a different scale, Codename One re-reads the scale, marks the hierarchy's preferred sizes stale and lays it out again. Skipping that step is what leaves a window blurry or the wrong physical size after a move.

`Display.convertToPixels()` keeps its existing global meaning, the main window's monitor, so no existing application changes behavior.

To react to displays being attached, removed or reconfigured:

```
Desktop.getInstance().addMonitorListener(evt -> {
    // a monitor was added or removed, or one changed resolution
    refreshWindowPlacement();
});
```

129.8. Window events

```
w.addWindowListener(evt -> {
    WindowEvent we = (WindowEvent) evt;
    if (we.getType() == WindowEvent.Type.Resized) {
        rememberWindowGeometry(we.getSource());
    }
});

// Every window, from one place
Desktop.getInstance().addWindowListener(evt -> auditWindowEvent(evt));
```

`Display.addWindowListener()` is unchanged and still reports only the application's main window, so existing code that casts `getSource()` to `Display` keeps working.

Close listeners and window events answer different questions, and the distinction matters when a listener does real work:

- A **close listener** is the user asking to close the window. It runs before anything is destroyed and consuming it vetoes the close, which is how a window prompts the user to save first. It fires once per close attempt.
- `WindowEvent.Type.Disposed` reports that the window is already gone. Nothing can veto it, and it's what to listen for when the work has to happen whether the close came from the user or from a call to `dispose()`.

129.9. Peer components and native text editing

Both work inside a window. A `BrowserComponent`, a video player, a map or a native text field placed in a `Window` is attached to **that** window's native view hierarchy, not to the main window's.

The native macOS port qualifies this for one case. A peer is attached when it's initialized, and a peer already in the window's content when the window is first shown initializes before that window has painted — at which point nothing yet says which window it belongs to, so it lands on the main window's view. Add the peer in response to `WindowEvent.Type.Shown` and it attaches to its own window.

This is worth knowing about because it was the single most common way an early multi-window implementation looks correct and isn't: the peer or the text caret appears on the main window while the content it belongs to is in another one.

129.10. Overlays inside a window

A window has the same layered panes a form does, and that's what an overlay attaches to:

```
Container overlay = w.getFormLayeredPane(MyOverlay.class, true);
overlay.setLayout(new LayeredLayout());
overlay.add(buildOverlayContent());
```

```
w.revalidate();
```

`InteractionDialog` is window-aware. A dialog anchored to a component works with no extra ceremony, because `showPopupDialog(Component)` takes its host from the component you hand it - and it has to, since the rectangle it points at is in that component's coordinate space:

```
dialog.showPopupDialog(buttonInsideTheWindow);
```

A dialog with no anchor can't infer anything, because it isn't attached to the hierarchy at the moment `show()` runs. Tell it which top level to appear on:

```
dialog.setTopLevelHost(window);
dialog.show(top, bottom, left, right);
```

Leave the host unset and the dialog uses the current form, which is the right answer for an application with one window and is what every existing single-window application already relies on.

`Dialog`, `Sheet` and `ToastBar` take the same host. A `Dialog` shown on a window goes into that window's layered pane rather than replacing the main form, and returns the command that was pressed exactly as it always did:

```
Dialog confirm = new Dialog("Confirm");
confirm.setLayout(new BorderLayout());
confirm.add(BorderLayout.CENTER, new Label("Delete the selected document?"));
confirm.setTopLevelHost(window);
Command result = confirm.showDialog();
```

A `Sheet` takes `setTopLevelHost` too, and `Sheet.getCurrentSheet(TopLevelContainer)` answers per surface - with more than one surface, "the current sheet" has no single answer. `ToastBar` gives each window its own instance through `ToastBar.getForTopLevel(TopLevelContainer)`; the singleton keeps following the current form, which is what an application with one surface relies on. The static helpers (`ToastBar.showMessage` and friends) target the window the user is actually in.

A `ComboBox` popup, a `FloatingActionButton` submenu and `InfiniteProgress` are all `Dialog` underneath, so they follow the surface they were opened from with no code change. Tooltips and `HTMLComponent` do too.

Anything you write yourself should resolve its surface with `Component.getTopLevelContainer()` rather than `getComponentForm()`, and measure against that top level rather than against `Display`. For code with no component to start from - a static helper, say - `CN.getCurrentTopLevel()` is the window the user is in, where `CN.getCurrentForm()` only ever names the main surface.

129.11. Dialogs in a window of their own

A dialog can be a real operating system window instead of something drawn inside the application's surface:

```
Dialog confirm = new Dialog("Confirm");
confirm.setLayout(new BorderLayout());
confirm.add(BorderLayout.CENTER, new Label("Delete the selected document?"));

// opens as a real operating system window on the desktop, and as an ordinary
// dialog everywhere else
confirm.setNativeWindowMode(true);
Command result = confirm.showDialog();
```

`Dialog.setDefaultNativeWindowMode(boolean)` sets it for the application, and the theme constant `defaultNativeWindowModeBool` sets it for the theme. The instance setting wins, then the static default, then the theme constant - and all three are subordinate to there being a windowing system at all.

The three desktop native themes declare that constant, so an application using one gets window dialogs by default and doesn't have to ask. An application that wants the old in-surface dialogs back on those themes says so with `Dialog.setDefaultNativeWindowMode(false)`, or per dialog with `setNativeWindowMode(false)`.

On iOS, Android, JavaScript, headless and in the phone-skinned simulator the request is ignored and the dialog shows the ordinary way, so shared code doesn't have to guard it. `InteractionDialog` takes the same setting.

The window is decorated, so the user can move it, close it and find it in the window list. Override `initNativeWindow(Window)` to change that or anything else about it before it appears. Closing it with the platform's own close control dispatches the back command, or disposes the dialog when there isn't one, so it means the same thing as Cancel. `getNativeWindow()` returns the window while the dialog is showing.

Commands split by what they already are: buttons stay buttons inside the dialog, and commands added with `addCommand` are published to the window so the platform can put them wherever it shows a window's commands.

These are ignored in this mode, because they describe a dialog drawn inside another surface: the margin arguments to `show(top, bottom, left, right)`, the position argument to `showPacked` and `showStretched`, the tint and `setBlurBackgroundRadius`, transitions, `setDisposeWhenPointerOutOfBounds` and `disposeOnRotation`. `Display.getCurrent()` also keeps naming the main form rather than the dialog.

An anchored popup - `showPopupDialog(Component)`, `showPopupDialog(Rectangle)`, and so the `ComboBox`, `Picker` and `ContextMenu` popups with them - never opens a window even with the option on for the whole application. The rectangle it points at is in its host's coordinate space, nothing exposes where a window's drawable begins on the desktop, a separate window would never receive the click meant to dismiss it, and it would steal focus from its opener every time it appeared.

129.12. Transitions in a window

A `Form` transition into or out of a window isn't supported, and won't be. A transition paints both screens into one `Graphics` covering one surface; two operating system windows are composited by the window server, on monitors that need not even share a scale factor, so there is no shared context to draw an in-between frame into. That's the same reason `Window.capture()` exists rather than `Display.screenshot()`. A window's own appear and disappear animation belongs to the platform.

Moving between screens **inside** a window is an ordinary transition:

```
window.setContent(nextScreen,
        CommonTransitions.createSlide(CommonTransitions.SLIDE_HORIZONTAL, true, 300));
```

`replace`, `replaceAndWait`, `animateLayout`, `animateHierarchy` and their fade variants all work on a window as they do on a form.

129.13. Unsupported inside a window

- A `Picker` in a window always uses its lightweight popup, even on a platform with a native one, because every native picker attaches to the main surface and would open over the wrong window.
- `Form` transitions into or out of a window - see Section 129.12, "Transitions in a window" for why, and for what to use instead.
- A `Toolbar` on a window. `Toolbar` is installed through `Form.setToolbar` and is bound to a form throughout, so there is no supported way to put one on a window yet. Window commands go to the platform through `addCommand`.

`Display.getDisplayWidth()` and `getDisplayHeight()` continue to report the **main** window. Components inside a window should size against their own top level, and `CN.getCurrentTopLevel()` is the surface the user is in where `CN.getCurrentForm()` only ever names the main one.

129.14. Capturing a window

`Display.screenshot()` can only see the application's main surface, so a second operating-system window is simply not in it. `Window.capture()` exists for that and returns an image of the window itself.

Most desktop ports read the window's own pixels back, so what you get is what the window is showing — native peers and editors included. The JavaSE simulator, Mac Catalyst and native Linux read their rasters directly. Native Windows takes a different route to the same place: a secondary window renders into a Direct2D `HWND` target, which Direct2D gives no readback for, so the port asks the window to render itself into a device context with `PrintWindow`. That's a real readback of the client area rather than a re-render of the hierarchy.

The native macOS port is the exception to the peers-included half of that. It reads back the

window's own Metal texture, so the image holds everything Codename One drew, but the native peer views AppKit composites above that texture aren't in it: a `BrowserComponent`, a video player or a map inside the window is missing from the result. Everything else the window shows is captured normally.

`Window.capture()` falls back to re-rendering the component tree if a port returns nothing. That fallback draws what the window **should** be showing: it never contains a peer or a native editor, and it can't reveal a disagreement between a window's raster and its component hierarchy. Because a plausible image of the right size is exactly what a silent fallback looks like, the Windows port logs when it happens rather than letting a re-render pass for a readback.

129.15. macOS

Windows work on the native macOS build with no configuration and no build hint. Each one is a real `NSWindow`: it has the standard title bar and its close, minimize and zoom buttons, it takes part in Mission Control and the Window menu, and it owns its own GPU surface rather than displaying a raster rendered elsewhere.

`Desktop.getMonitors()` reports the real display list from `NSScreen`, including each screen's backing scale, so a window restored onto a Retina display and one restored onto a non-Retina display each get the right density. Dragging a window between them updates it.

Every operation on the windowing API is implemented. That's worth saying explicitly because the Mac Catalyst target below can't implement several of them — which is why windows are off by default there and on by default here.

129.16. Mac Catalyst (legacy)

Windows are opt-in on the macOS (Mac Catalyst) target. Set the `macNative.multiWindow` build hint to `true` alongside `macNative.enabled`:

```
macNative.enabled=true
macNative.multiWindow=true
```

A second Codename One window is a second `UIWindowScene`, which needs the `UIApplicationSupportsMultipleScenes` key in `Info.plist`. The builder emits that key only for a Catalyst build that asked for windows, and for no other target, so iPhone and iPad apps are unaffected either way.

The opt-in exists because that key has a cost the rest of the app pays. It puts the process on the UIScene lifecycle, under which a Catalyst window opens four points shorter: the conformance suite measures 685 points of content height without the key and 681 with it. Every layout in the app shifts slightly. That's a fair trade when you want windows and an unpleasant surprise when you don't, so an app that doesn't ask for them keeps the bundle it has always had.

`Desktop.isSupported()` reads the key back out of the running bundle rather than trusting a build flag, so the API and the `Info.plist` can never disagree — including in a project that was generated

once and then hand-edited.

System sheets follow the focused window. Sharing (`ShareButton` and `Display.share()`), camera capture, the photo gallery, the file chooser and the full-screen video player are presented from the scene the user is actually in, and the share popover anchors against that window's own coordinates and screen scale rather than the main scene's. Invoking one from a secondary window opens it over that window, where it belongs.

Catalyst differs in one implementation detail worth knowing: a window's Codename One content is rendered into an off-screen raster and presented to the scene's view, rather than the window owning a second GPU surface. The native macOS build doesn't do this. Native peers and text editing still use the scene's real view hierarchy, so they behave normally.

Some window controls have no Mac Catalyst equivalent, because AppKit owns the behaviour and Catalyst doesn't expose it to a `UIWindowScene`. `setAlwaysOnTop`, `setUtilityWindow`, `minimize`, `restore` and `toggleMaximize` do nothing there; the getters keep reporting whatever the application set, so treat them as requests the platform may decline. `setDecorated(false)` is partial: it hides the title bar's title and toolbar — which is what an application supplying its own chrome needs — but the window frame itself stays. Modality, the minimum window size and resizability all work.

Scenes also arrive asynchronously. `show()` asks the system to activate one and is handed it back later, so a window exists for a moment before its scene does, and a closed window's scene is kept for the next one rather than destroyed — asking for a scene while a destruction is still in flight is refused by the system.

129.17. Threading

Everything runs on the event dispatch thread, as usual. Showing, moving and disposing a window are all EDT operations; calling them from a background thread is marshalled for you the same way `Form.show()` is.

Constructing one is the exception, because a constructor has to return its object and so can't be deferred. `new Window(…)` runs on the thread that calls it, and that's safe from any thread — but the window doesn't exist for the framework until it's shown.

There is one event dispatch thread for the whole application no matter how many windows are open. A window that animates keeps the thread awake; a minimized or hidden window does no work at all.

Chapter 130. Wearables (Apple Watch and Wear OS)

Codename One builds a watch app from the same project as your phone app, on both Apple Watch and Wear OS. This chapter covers the whole picture: how one project produces two apps, how you run the pair while you develop, how the two apps exchange information, and how to put a complication on a watch face.

130.1. One Project, Two Apps

Declaring a watch lifecycle class next to your phone main class is the entire opt-in:

```
codename1.mainName=MyApp
codename1.watchMain=com.mycompany.myapp.MyWatchMain
```

There are no wearable build hints. The watch bundle identifier, deployment target, signing team and display name are all derived from settings your project already has, and one declaration builds the watch app on both platforms.

Note the asymmetry: `codename1.mainName` is a simple class name resolved against `codename1.packageName`, while `codename1.watchMain` is fully qualified.

What the two apps share is the code base: your classes, your resources, your theme and your CSS. What they don't share is anything at runtime. They're two apps, on two devices, in two sandboxes, with separate lifecycles. In particular `Storage`, `Preferences` and the SQLite database are **per device**: writing on the phone doesn't make the value appear on the watch. Moving information between them is what Section 130.6, "Sharing Data Between the Phone and the Watch" is for.

The two platforms get there by different routes, which is why their supported feature sets differ:

- **Wear OS is Android.** A Wear OS app is an ordinary Android app that declares the watch hardware feature. The existing Codename One Android port renders the UI through exactly the same pipeline it uses on phones and tablets, so almost everything that works on Android works on the watch.
- **watchOS isn't iOS.** watchOS has no UIKit view hierarchy, no OpenGL ES and no Metal. The Codename One watchOS port therefore ships a dedicated **Core Graphics** rendering backend and a separate watch application target that hosts the Codename One runtime (the ParparVM-translated app) inside a SwiftUI shell. The graphics-heavy, GPU-bound and UIKit-peer APIs that have no watchOS equivalent are unavailable on the watch (see Section 130.8.3, "Supported and Unsupported APIs on watchOS").

Without a watch main class the build is byte-for-byte what it was, so adding one never changes a phone build you already ship.

130.2. Companion or Standalone

By default the watch app is a **companion**: on Apple Watch it ships inside the phone app and the pair installs together. If the watch app is the product and there is no phone app to pair with, declare it standalone:

```
codename1.watchStandalone=true
```

Both platforms support both forms. On Apple a companion build embeds the watch app inside the iOS app so the pair installs together; on Android it produces a second artifact, `<yourapp>-wear.apk`, beside the phone one. A standalone build on either platform ships the watch app on its own.

On Android a standalone build turns the single APK into the Wear OS app, and that is what ships. On Apple the watch target is built standalone — detached from the phone app rather than embedded in it — but the archive step still targets the phone scheme, so submission needs one manual step in Xcode. See Section 130.8.1, “What the Watch App Runs Today” before you archive.

130.3. Running the Pair While You Develop

The simulator can run both halves. Choose a watch skin (Apple Watch 41mm or 45mm, Wear round or Wear square) to develop the watch UI on its own, or pick **Watch → Launch Watch App** to start the watch app beside the phone app.

The watch app runs in its own process rather than in another window of the same one, because that’s what it becomes on a device — a second app with its own sandbox. The two processes find each other, so `sendMessage` and `putData` genuinely round-trip on your desktop and you can develop the conversation between the two apps without deploying anything.

Check your layout against the **Wear round** skin. A round face is where a design that assumes a rectangle falls apart, and its safe area is inset accordingly.

130.4. Detecting the Watch Form Factor

Use `CN.isWatch()` (or `Display.getInstance().isWatch()`) to branch your UI for the watch at runtime. This is the wearable analog of the existing `isTablet()` and `isDesktop()` checks:

```
Form f = new Form(BoxLayout.y());
if (CN.isWatch()) {
    // Compact, single-column layout suited to a small round/square screen
    f.add(new Label("Hi Watch"));
    f.getToolbar().setVisible(false);
} else {
    // Full phone/tablet layout
    f.add(new SpanLabel("Welcome to the full size application"));
}
f.show();
```

On Android `isWatch()` is derived from `PackageManager.FEATURE_WATCH` (`android.hardware.type.watch`); on iOS it's reported natively by the watchOS runtime. On every other platform it returns `false`.

`isWatch()` describes the device form factor, not the screen shape. A Wear OS device can be round or square; query the display safe-area insets (see Section 130.5, "Designing for the Watch") rather than assuming a rectangle.

130.5. Designing for the Watch

A watch screen is small and is frequently round. A few practical guidelines:

- Prefer a single vertical column (`BoxLayout.y()` inside a `Form` that scrolls on the Y axis). The Digital Crown on Apple Watch and the rotary input on Wear OS scroll the focused scrollable container.
- Keep interactive targets large and few. There is little room for a `Toolbar`, side menu or tabs — hide the title area when you don't need it.
- On round screens, keep content away from the corners. Use the form's safe-area insets so important content isn't clipped by the rounded bezel.
- Use the "`watch`" theme/constant overrides if you want a distinct watch look without forking your code (the override layer activates on watch devices the same way platform overrides do elsewhere).

130.6. Sharing Data Between the Phone and the Watch

The two apps share no storage. `Storage`, `Preferences` and the SQLite database are per device, and there's no container that spans the pair, so a value written on the phone is simply not on the watch. `com.codename1.wearable` is the channel between them, and it's the same API on Apple Watch and Wear OS.

The platforms offer three transports because they answer three different questions. Choosing the wrong one is the usual reason a watch app "never gets the update":

You need	Use	Delivered
An answer, now, while both apps are awake	`WearableConnection.sendMessage`	Immediately, or it fails
The peer to end up with the latest value, whenever it next looks	`WearableConnection.putData`	Eventually, survives sleep and relaunch
To move a file or a large blob	`WearableConnection.transferFile`	In the background, possibly much later
Data the watch needs with no phone involved at all	Ordinary `Storage` plus the network	As usual
Something rendered while your app isn't running	`com.codename1.surfaces` (see Section 130.7, "Complications and Tiles")	By the system, from a published timeline

A message is a phone call: it only connects if someone picks up. Replicated data is a noticeboard: you pin the current value at a path, and the peer reads it whenever it wakes. Reach for data by default and for messages only when you genuinely need an answer now.

130.6.1. Replicating State

Publish on one side:

```
// On the phone: publish the value the watch should show whenever it next wakes.
WearableConnection.putData(new WearableMessage("/steps")
        .put("count", stepCount)
        .put("goalReached", stepCount >= 10000));
```

React on the other:

```
// On the watch: react to it. Register from init(), not from a form -- a value that
// arrived while the app was starting is replayed only to listeners that exist by then.
WearableConnection.addDataListener(new WearableDataListener() {
    public void dataChanged(WearableMessage data) {
        stepsLabel.setText("" + data.getInt("count", 0));
    }

    public void dataRemoved(String path) {
        stepsLabel.setText("--");
    }
});
```

Each path holds one value, so this replicates state rather than queueing events: two rapid updates to the same path may reach the peer as one. That's what makes it the right default — the peer always converges on the latest value, however long it was away.

Register listeners from your app's `init()`. The platform starts an app purely to hand it a payload, so what arrives may well be the thing that launched you. Codename One queues those deliveries and replays them on the EDT, but only to listeners that exist by the time it does.

130.6.2. Asking a Question

When you need an answer rather than a value, send a message and handle the reply:

```
// Ask the phone something and use the answer. Only works while both apps are awake,
// so check first and fall back to what you already replicated.
if (WearableConnection.isReachable()) {
    WearableConnection.sendMessage(new WearableMessage("/workout/start"),
            new WearableReplyHandler() {
                public void replyReceived(WearableMessage reply) {
                    showWorkout(reply.getString("id", null));
```

```
                }

                public void replyFailed(String message) {
                    Log.p("Could not start the workout: " + message);
                }
            });
}
```

Then answer it on the other side:

```
// Answer the watch. Reply quickly and do slow work afterwards -- the sender is waiting.
WearableConnection.addMessageListener(new WearableMessageListener() {
    public WearableMessage messageReceived(WearableMessage message, boolean expectsReply) {
        if ("/workout/start".equals(message.getPath())) {
            return new WearableMessage("/workout/start").put("id", beginWorkout());
        }
        return null;
    }
});
```

A reply is never guaranteed: the peer may be asleep, out of range, or running a version of your app that doesn't know the path. `replyFailed` is the normal case, not the exceptional one.

130.6.3. Knowing What's There

`isSupported()` asks whether the platform provides the link, not whether a watch is there. It's false on a desktop build and on any platform with no wearable API, and every call is then a harmless no-op, so this API needs no platform conditionals around it — but an iPhone with no paired watch still answers true, because Apple's API is present either way.

Ask the other three about the counterpart. `isPaired()`, `isCompanionAppInstalled()` and `isReachable()` distinguish the cases worth telling a user about: no watch, a watch without your watch app installed, and a sleeping watch.

Don't decide your UI from one call at startup. These answers come from state queried asynchronously, so the first calls in a cold process can report false for a device that's paired — nothing is known until the first query lands. Register a `WearableStateListener` and react when the answer changes.

One Android limit is worth knowing. The Data Layer exposes pairing only through the nodes it knows about, so a paired watch that has never run your watch app appears in no list and `isPaired()` reports false until it runs once. Treat false as "no counterpart known" rather than proof there is none, and prefer showing setup guidance to hiding it. Apple's API answers pairing directly and has no such gap. Gate a wearable feature on those rather than on `isSupported()`, or you will offer it to someone holding a phone and nothing else. Add a `WearableStateListener` rather than polling.

130.7. Complications and Tiles

A complication — the small live readout on a watch face — is the same idea as a home-screen widget: content-driven, rendered while your app isn't running, fed by a timeline. Codename One models it as such, so a complication is a watch **family** of `com.codename1.surfaces` rather than an API of its own:

```
// A complication is a widget in a watch family, published from the same timeline.
WidgetKind steps = new WidgetKind("steps")
        .setDisplayName("Steps")
        .addSupportedSize(WidgetSize.WATCH_CIRCULAR)
        .addSupportedSize(WidgetSize.WATCH_RECTANGULAR);
```

Everything you already know about surfaces applies: the same node catalog, the same `${key}` state interpolation, the same timeline that lets the OS advance content on its own clock with no app wake-ups. `SurfaceVector` is especially at home here, because most complications are a gauge, a dial or a ring.

Family	Apple Watch	Wear OS
`WATCH_CIRCULAR`	`accessoryCircular`	Ranged-value or monochromatic-image complication
`WATCH_RECTANGULAR`	`accessoryRectangular`	Long-text complication, or a Tile for a richer layout
`WATCH_INLINE`	`accessoryInline`	Short-text complication. Text only — anything else is dropped
`WATCH_CORNER`	`accessoryCorner`	Renders as circular; Wear OS has no corner slot

Design for a glance. A complication is a few dozen pixels someone reads in under a second, so one number or one gauge beats any layout that has to be read.

130.7.1. What a Watch Face Actually Shows

This is the part that surprises people, so it's worth stating plainly: **a complication isn't a small widget.** A watch face asks your data source for one typed value — a short string, a long string, a ranged value, a monochrome glyph — and composes it into its own design. There is no layout to honour.

The node tree you publish is therefore flattened and **mined for content** rather than rendered. On Wear OS your kind supplies at most two text nodes and one image; containers, padding, background, corner radius, alignment, weight, per-node colour, and every action except the root, all belong to the face. Everything dropped is reported once per render, so `adb logcat -s CN1Surfaces` tells you what a face is showing and what it leaves out.

Apple is less lossy, because a WidgetKit accessory family renders your SwiftUI tree — but the slot is

still tiny and monochrome, and the same design advice applies.

A Tile is the exception. It renders the node tree in full, and two things come out **better** there than on a phone widget:

- **Circular progress renders natively.** The Android home-screen widget has to degrade a circular bar to a linear one; a Tile doesn't.
- **Per-node tap actions work.** A small iOS widget honors only the root action.

The Tile's own limitation is time: a `SurfaceDynamicText` countdown ticks natively on both phone platforms, but freezes on a Tile and refreshes when your timeline says the value changes. ProtoLayout can animate one, but only on some Wear releases — a frozen value that's always right beats a ticking one that works on some watches.

Preview the watch families in the simulator (**Widgets** > **Widgets Preview**) before you build to a device. It renders the node tree at the right size and clips the round families the way a face does — which is worth seeing, because a watch face shows nothing a circular complication draws into its corners. It can't show you the per-platform lowering, though, so a layout that looks right there can still arrive on Wear OS as one number.

`WATCH_RECTANGULAR` and `LOCKSCREEN` share a family on Apple. If you publish both, each surface gets the layout you designed for it; if you publish only one, it's used for both.

Declaring a watch family is all it takes. On Apple the build adds a second WidgetKit extension, `CN1WatchWidgets`, embedded in the watch app; on Wear OS it generates a complication data source per kind, plus a Tile for the rectangular family. Both are additive: an app that declares no watch family carries neither.

A kind that declares **only** watch families no longer produces a home-screen widget on Android. It never produced an iPhone one, and rendering a complication as a home-screen widget puts a surface in front of the user that the manifest never asked for. Declare a phone family alongside the watch ones if you want both.

The one thing to know before you design: **what a watch face shows isn't what you laid out**. See Section 130.7.1, "What a Watch Face Actually Shows".

130.8. Apple Watch (watchOS)

The watchOS build adds a second Xcode target to the generated project. It compiles the shared, translated application sources for the watch architecture (`arm64_32` on device), renders through the Core Graphics backend, and — in the default *companion* distribution — embeds the watch app inside your iOS app so the pair installs together. The watch app is rooted in a generated SwiftUI `@main` shell that hosts the Codename One frames and forwards Digital Crown and tap input into the runtime.

Figure 435. Codename One UI rendered on the watchOS simulator via the Core Graphics backend

130.8.1. What the Watch App Runs Today

`codename1.watchMain` is the watch app's entry point on both platforms. The watchOS build writes a stub of its own for that class and runs a second translation rooted there, so the watch binary starts your watch lifecycle class and carries what that class reaches rather than everything the phone reaches. On Wear OS the declared class is the watch launcher. Put the watch UI in the class you declared.

One case differs by design: naming the phone's own main class as `codename1.watchMain` keeps a single translation, because both entry points reach the same code and translating twice would produce the same binary twice. There the watch starts the phone lifecycle, and `CN.isWatch()` is how you decide what the watch shows. That check is still worth keeping in shared code, but it's no longer what selects the watch UI when the two entry points differ.

One rough edge is left at archive time. Under manual signing the embedded watch target has no provisioning profile of its own, since the host app's profile is the one installed, so give the watch bundle id — `<your.package>.watchkitapp` — its own profile before you submit. That applies to `codename1.watchStandalone` too, where the watch bundle is the only one being signed.

The watch app's icon is generated for you, scaled from the project icon into the watch target's own asset catalog, so there's nothing to add by hand. Replace that set in the generated project if you want the watch to carry different artwork from the phone.

None of this affects building, running or testing on the simulator or a device.

130.8.2. Native Code and the Watch Slice

Your Objective-C is compiled for the watch as well as the phone. The translator copies native sources through to every slice it produces, so a `.m` that imports UIKit, or an iOS-only SDK, is a build error on watchOS even when no watch code calls it.

Guard it the way the framework guards its own — there are several hundred such guards across the iOS port:

```
#if !TARGET_OS_WATCH
```

```
#import <UIKit/UIKit.h>
// ... the iOS-only implementation
#endif
```

The same applies in reverse to a native interface only the watch uses. There is no build hint for this and no attempt to infer it: which of your native sources can compile for watchOS is a question about that source, and the preprocessor is where it's answered.

130.8.3. Supported and Unsupported APIs on watchOS

Because watchOS lacks UIKit views, GPU rendering and several iOS frameworks, the APIs that depend on them aren't available on the watch slice. They're guarded so that the shared sources still link, and they degrade rather than crash:

- **Unavailable:** `BrowserComponent` / web view, camera capture, `MediaPlayer` video, inline native text editors (text input routes through the watch text input controller), `MapComponent` native maps, and StoreKit in-app purchase.
- **Available:** the full Codename One UI and layout system, drawing and `Graphics` (rendered via Core Graphics, including gradients, transforms, clipping and Gaussian blur via Accelerate/vImage), `FontImage`/material icons, images and mutable images, networking and storage, JSON/XML, and the property and binding frameworks.

The watch slice runs the same garbage-collected ParparVM runtime as the iOS app. Memory and CPU budgets on the watch are far smaller than on the phone, so keep watch screens light.

130.8.4. Building and Debugging

A companion build produces an iOS `.ipa` that carries the embedded watch app. A standalone build generates the watch target, but the archive step still targets the phone scheme, so the artifact handed back is the iOS app: open the generated project and archive the watch scheme yourself to produce the watch application. The build logs this. The generated project is a standard Xcode project, so you can open it and debug or profile the watch target with the native Xcode tools as usual. Cloud builds generate the watch target through the same iOS build — declare the watch main class and build for iOS — and the same applies there, so a standalone cloud build returns the iOS archive.

130.9. Android (Wear OS)

A Wear OS app is a regular Android app. The Codename One Android port renders the UI with the same pipeline it uses on phones, so no special rendering backend is required. The same `codename1.watchMain` declaration drives both platforms.

What it produces differs from Apple, though, and that difference is worth stating precisely. Set `codename1.watchStandalone` and the Android build **is** the watch app: one APK that installs and runs on the watch. Leave it unset and you get two artifacts — `<yourapp>.apk` for the phone and `<yourapp>-wear.apk` for the watch — because a Wear companion is a separate product published to the same

Play listing, where an Apple one is embedded inside the phone app.

The Wear artifact carries a higher version code than the phone's. On a watch Play picks among the APKs the device supports by version code, so the wear one has to outrank it; on a phone the required watch feature filters the wear APK out entirely. The default is the phone's code plus 100,000,000, which sounds extravagant and isn't: the gap has to be wide enough that the phone's own next release never catches up to a watch code it already published, and plus one is consumed by the next phone build. `android.watchVersionCodeOffset` changes the gap and `android.watchVersionCode` sets the watch code outright.

Set `android.watchModule=false` if you want the wearable link but no watch app of your own — your phone build is then exactly what it was.

A standalone Wear app declares the watch hardware feature in the manifest:

```
<uses-feature android:name="android.hardware.type.watch" android:required="true" />
```

It also marks itself standalone, so it installs and runs directly on the watch without a paired phone app:

```
<meta-data android:name="com.google.android.wearable.standalone" android:value="true" />
```

A standalone Wear build also raises the minimum SDK to API 23, the Wear OS 2.0 standalone baseline, if your project requests a lower level.

130.9.1. Wear OS Input and Screen Shape

Two things behave differently on a watch and are handled for you:

- **Rotary input.** The rotating side button or bezel scrolls the focused scrollable container, exactly as the Digital Crown does on Apple Watch. It arrives on its own input source rather than the mouse-wheel axes, and is scaled by the device's own scroll factor.
- **Round screens.** A circular face reports no display cutout, so a layout drawn to the full rectangle would have its corners eaten by the bezel. The safe area is inset to the largest rectangle that fits inside the circle — about 15% a side — so honoring the form's safe-area insets is enough.

Because a Wear OS app is an ordinary Android app, you can also declare any additional manifest features and permissions with the generic `android.uses_feature.<name>` and `android.uses_permission.<name>` hints.

Referencing `com.codename1.wearable` adds the `play-services-wearable` dependency and the listener service automatically. The `android.playService.wearable` hint remains for apps that want to call the Data Layer APIs directly.

130.10. Feeding a Complication from the Phone

A watch app has its own storage. Nothing the phone writes is visible there, on either platform — on Apple the App Group identifier is the same string but resolves to a watch-local container, and on Wear OS the two apps are separate installs. That's the single most counter-intuitive fact here, and it's got one consequence: **a complication is fed by the watch's own `Surfaces.publish()`.**

Which is often inconvenient, because the data usually lives on the phone. A phone-side publish of a watch-bearing kind is therefore mirrored to the watch for you, over the same link `com.codename1.wearable` uses. You write the same `Surfaces.publish(…)` you always did.

The mirror is best-effort by design, and always runs **after** the local publish has succeeded — nothing it does can leave your phone widget wrong:

- **Apple** uses the one WatchConnectivity API that wakes the watch app in the background to refresh a complication. It's budgeted at about fifty transfers a day. When the user has placed no complication, or the budget is spent, the update is queued instead and applied when the watch app next runs.
- **Wear OS** replicates the descriptor over the Data Layer, which starts the watch app's process to deliver it. Imagery travels as a file transfer.
- **Size** is capped — 48KB on Apple, and on Wear OS 64KB for the descriptor with its own cap on imagery. Over the cap the imagery is dropped first, on the grounds that a complication rendering its numbers with a missing glyph beats one that never updates; over the cap even then, the watch keeps its previous timeline.

Every refusal is logged once. Nothing throws.

The mirror is applied on the watch without starting your application: it writes the descriptor and asks the watch face to re-read. The wake exists to refresh a complication, not to bring a UI forward the user didn't ask for.

The reserved path `/cn1surface/<kindId>` belongs to the framework on Wear OS — don't publish your own data there.

Declaring a watch family on Android adds `play-services-wearable` to your **phone** APK, because that's what carries the mirror. An app that wants complications fed only by the watch itself can avoid that by not declaring watch families on kinds the phone publishes.

130.11. Summary

	Apple Watch (watchOS)	Wear OS (Android)
Enable	`codename1.watchMain`	`codename1.watchMain`
Rendering	Dedicated Core Graphics backend + separate watch target	Standard Android rendering pipeline

	Apple Watch (watchOS)	Wear OS (Android)
Distribution	Companion (embedded in the phone app) or standalone	Companion (a second `-wear` artifact) or standalone
Runtime detection	`CN.isWatch()`	`CN.isWatch()`
Talking to the phone app	`com.codename1.wearable` over WatchConnectivity	`com.codename1.wearable` over the Wearable Data Layer
Complications	A WidgetKit extension embedded in the watch app	A complication data source per kind, plus a Tile for the rectangular family

Declare a `WATCH_*` family on a surface kind and the build generates whatever that platform needs. What a watch face then **shows** is narrower than what you laid out, on Wear OS especially — see Section 130.7.1, “What a Watch Face Actually Shows” before you design one.

The wearable build is additive on both platforms: without a watch main class, your phone builds are unchanged.

Chapter 131. Television (Apple TV and Android TV)

Codename One can build and run your application UI on the living-room TV platforms: Apple TV (tvOS) and Android TV / Google TV. As with the phone and wearable targets, the same Java/Kotlin code base drives the TV app — you write Codename One UI as usual and the build pipeline produces the appropriate TV artifact for each platform.

The two platforms reach the TV through different mechanisms:

- **Android TV / Google TV is Android.** An Android TV app is an ordinary Android app (the **same APK**) that adds a small amount of manifest metadata: a Leanback launcher category so the app appears on the TV home screen, the `android.software.leanback` feature, and an optional banner. The existing Codename One Android port renders the UI through exactly the same pipeline it uses on phones and tablets.
- **Apple TV runs tvOS.** tvOS is a UIKit relative of iOS reached through the same ParparVM (Java bytecode → C → native) pipeline used for iPhone/iPad, built against the `appletvos` SDK with a tvOS application target. tvOS has no touchscreen — navigation is driven by the Siri remote and the focus engine.

In both cases the build is **additive**: with the TV hints turned off your phone/tablet build is unchanged.

131.1. Detecting the TV Form Factor

Use `CN.isTV()` (or `Display.getInstance().isTV()`) to branch your UI for the TV at runtime. This is the living-room analog of the existing `isTablet()`, `isDesktop()` and `isWatch()` checks:

```
Form f = new Form(BoxLayout.y());
if (CN.isTV()) {
    // 10-foot UI: larger fonts, generous spacing, focus-driven navigation
    f.add(new Label("Hello TV"));
} else {
    // Full phone/tablet layout
    f.add(new Label("Hello"));
}
f.show();
```

Codename One's existing D-pad/arrow focus traversal (the same mechanism that powers `GAME_UP`/`GAME_DOWN`/`GAME_LEFT`/`GAME_RIGHT` and component focus) drives remote navigation on the TV, so focusable components such as `Button` are navigable with the remote out of the box.

131.2. Adapting Styling with CSS Media Queries

The TV (and watch) form factors integrate with the CSS `@media` device-type mechanism. Rules inside a `device-tv` (or `device-watch`) media block are selected at runtime when `Display.isTV()` (respectively

`isWatch()`) returns `true` — exactly the way `device-tablet` / `device-desktop` already work:

```
Label {
    color: black;
}

@media device-tv {
    Label {
        /* Larger type for the 10-foot UI */
        font-size: 3mm;
        color: white;
    }
}
```

131.3. Building for Android TV / Google TV

Enable the Android TV manifest metadata with a single build hint in `codenameone_settings.properties`:

```
codename1.arg.android.tv=true
```

This makes the build:

- add `<category android:name="android.intent.category.LEANBACK_LAUNCHER"/>` to the launcher activity so the app appears on the Android TV home screen;
- declare `<uses-feature android:name="android.software.leanback" android:required="false"/>` and make `android.hardware.touchscreen` optional so the app installs on touchless TVs;
- generate a 320×180 launcher banner (`@drawable/tv_banner`) from the app icon.

The resulting APK still installs and runs on phones and tablets.

131.3.1. Android TV Build Hints

Build hint	Default	Description
`android.tv`	`false`	Mark the build as an Android TV / Google TV app: adds the `LEANBACK_LAUNCHER` intent category, declares the `android.software.leanback` feature, makes `android.hardware.touchscreen` optional, and generates the 320×180 launcher banner. The same APK still runs on phones and tablets.

131.4. Building for Apple TV (tvOS)

Enable the tvOS application target with the `tvNative.*` build hints (the Apple Watch build is enabled by declaring a `codename1.watchMain` instead — see the wearables chapter):

```
codename1.arg.tvNative.enabled=true
```

The tvOS build produces a standalone Apple TV app. Because tvOS uses a separate App ID and provisioning profile from your iOS app, you supply tvOS signing material the same way you do for the other Apple targets.

`codename1.tvMain` (and `tvNative.enabled`) only add the tvOS target; the iPhone/iPad build is unchanged.

131.4.1. tvOS Build Hints

Build hint	Default	Description
`tvNative.enabled`	`false`	Force the tvOS target on even without a distinct `tvMain`.
`codename1.tvMain` (a.k.a. `tvMain` / `tvNative.mainClass`)	*(none)*	Fully-qualified tvOS lifecycle entry class. Setting it also turns on the tvOS build. When omitted (with `tvNative.enabled=true`) the tvOS app reuses your phone main class.
`tvNative.bundleId`	`<package>.tvos`	Bundle identifier of the tvOS app.
`tvNative.minDeploymentTarget`	`13.0`	`TVOS_DEPLOYMENT_TARGET` for the tvOS target.
`tvNative.displayName`	*(app display name)*	The tvOS app name shown on Apple TV.
`tvNative.teamId`	*(falls back to the iOS team id)*	Apple Developer Team ID used to sign the tvOS target.

Under the hood

Chapter 132. Advanced topics/under the hood

For build arguments, annotations, and the complete build-hints table, see Chapter 110, *Build hints reference*.

132.1. Versioned builds

By default a cloud build always uses the current Codename One release. With a *versioned build* you can instead pin the build to a specific previously released framework version, so you get reproducible output over time. This helps when stabilizing a release, supporting an older app, or isolating a regression: if an app that built correctly in the past starts failing, rebuilding against the last known good version tells you whether the change came from your code or from the framework and build server.

Set the `build.cn1Version` build hint to the version you want to target. Versions use the standard Maven release scheme, for example `7.0.182`:

```
codename1.arg.build.cn1Version=7.0.182
```

The build server fetches that version's framework artifacts from the Codename One Maven repository and builds against them, falling back to Maven Central for releases published before the move. To keep your simulator and local compile classpath aligned with the same release, set the matching `cn1.version` in your project `pom.xml`.

Versioned builds are a Pro and Enterprise feature, and how far back you can target depends on the subscription tier:

Tier	Versions you can target
Pro	Any version released within the last two months
Enterprise	Any version released within the last six months

If you request a version older than your tier's window, a version that was never published, or you aren't on a Pro or Enterprise plan, the build fails with an explanatory message instead of falling back to the current release.

132.1.1. Building against master

Set `build.cn1Version` to `master` to build against the current development head (the latest `master` of the Codename One repository) instead of a released version:

```
codename1.arg.build.cn1Version=master
```

Every push to `master` publishes a fresh set of framework artifacts and the build server always grabs

the latest, so this is the quickest way to verify an unreleased fix or feature end to end on a device. Because `master` tracks active development it can be less stable than a release, so use it for verification rather than for shipping production builds. Building against `master` is available to Pro and Enterprise subscribers.

132.2. Android permissions

One of the annoying tasks when programming native Android applications is tuning all the required permissions to match your codes requirements, Codename One aims to simplify this. The build server automatically introspects the classes sent to it as part of the build and injects the right set of permissions required by the app.

For example, sometimes developers might find the permissions that come up a bit confusing and might not understand why a specific permission came up. This maps Android permissions to the methods/classes in Codename One that would trigger them. Notice that this list isn't exhaustive as the API is rather large:

`android.permission.WRITE_EXTERNAL_STORAGE` - included by default (up to Android 13) so file APIs continue to work unless you block it with `android.blockExternalStoragePermission=true`.

`android.permission.INTERNET` - always requested because the networking stack depends on it even for offline features like local web views.

`android.permission.CAMERA` & `android.permission.RECORD_AUDIO` - required when capturing photos, video, or audio. The builder injects them automatically and the Android port prompts the user the first time the API is used.

`android.permission.READ_PHONE_STATE` - used by telephony-aware APIs like `Display.getMsisdn()` and by media integration so audio pauses on calls.

`android.permission.ACCESS_FINE_LOCATION` & `android.permission.ACCESS_COARSE_LOCATION` - requested when using `com.codename1.location` or embedded maps so location fixes can be delivered.

`android.permission.ACCESS_BACKGROUND_LOCATION` - added when background geofencing or fetch tasks are enabled; the Android port verifies the permission on Android 10+.

`android.permission.POST_NOTIFICATIONS` - prompted on Android 13+ for both push registration and local notifications.

`package.permission.C2D_MESSAGE`, `com.google.android.c2dm.permission.RECEIVE`, and `android.permission.RECEIVE_BOOT_COMPLETED` - bundled with the push subsystem so Firebase Cloud Messaging can wake the app after device restarts.

`android.permission.READ_CONTACTS` - requested when accessing the device address book through `Display.getAllContacts()` and related APIs.

`android.permission.READ_MEDIA_VIDEO` & `android.permission.READ_MEDIA_AUDIO` - added on API 33 and above when the app plays a URI through `MediaManager.createMedia(String, boolean)` or `createMediaAsync(String, boolean, Runnable)`, since that URI can point at the shared media store. The `InputStream` overloads don't add them: the Android port copies the stream into app private

storage and reads nothing shared. Block them with `android.blockReadMediaPermissions=true`.

`android.permission.READ_MEDIA_IMAGES` - never added by media playback, because no Codename One API requests it at runtime. Declaring it alongside `READ_MEDIA_VIDEO` places the app under Google Play's Photo and Video Permissions policy, so ask for it only when you need it, with `android.requestReadMediaPermissions=true`.

132.2.1. Permissions under Marshmallow (Android 6+)

Starting with Marshmallow (Android 6+ API level 23) Android shifted to a permissions system that prompts users for permission the first time an API is used for example: when accessing contacts the user will receive a prompt whether to allow contacts access.

Permission can be denied and a user can later on revoke/grant a permission through external settings UI

This is great as it allows apps to be installed with a single click and no permission prompt during install which can increase conversion rates!

Enabling permissions

By default, Codename One's Gradle 8 based Android builder uses the highest Android SDK you've installed, with a minimum of API 36, for both the compile and target SDK versions. If you override the target through the `android.targetSDKVersion` build hint, the builder honors it while keeping the compile SDK at least as high as the target SDK. Lowering the target may disable some compatibility libraries. Keeping the target current is strongly recommended for Play Store compliance.

Permission prompts

To test this API see the following simple contacts app:

```
Form f = new Form("Contacts", BoxLayout.y());
f.add(new InfiniteProgress());
Display.getInstance().invokeAndBlock(() -> {
    Contact[] ct = Display.getInstance().getAllContacts(true, true, false, true, true, false);
    Display.getInstance().callSerially(() -> {
        f.removeAll();
        for (Contact c : ct) {
            MultiButton mb = new MultiButton(c.getDisplayName());
            mb.setTextLine2(c.getPrimaryPhoneNumber());
            f.add(mb);
        }
        f.revalidate();
    });
});

f.show();
```

If you explicitly lower the target SDK (for example: `android.targetSDKVersion=21`) and install this app on an Android 6 device you will still see the legacy install prompt with all permissions listed up

front:

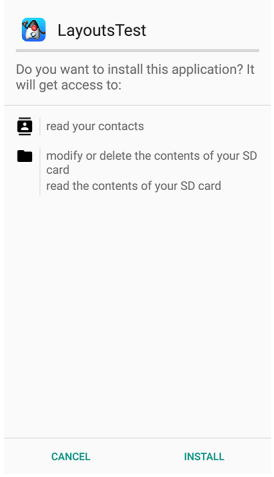


Figure 436. Install UI when using the old permissions system

When you keep the default target (API 36+) the installer defers to the runtime permission flow and the installation UI looks like this instead:

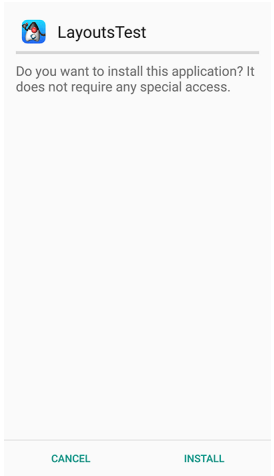

Figure 437. Install UI when using the new permissions system

When you launch the UI under the old permissions system you see the contacts instantly. In the new system you're presented with this UI:

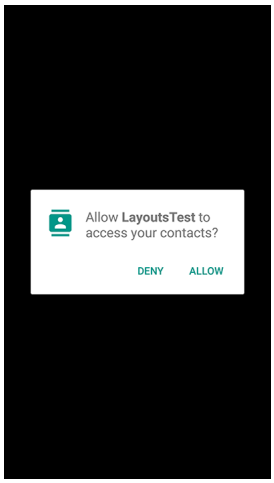

Figure 438. Native permission prompt first time

If you accept and allow all is good and the app loads as usual but if you deny then Codename One

provides the user another chance to request the permission. Notice that in this case you can customize the prompt string as explained below.

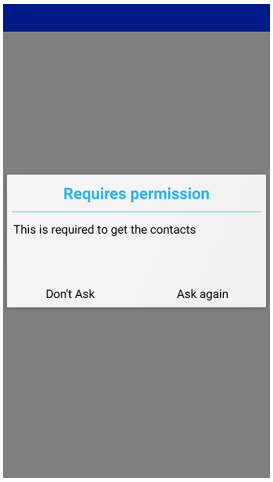

Figure 439. Codename One permission prompt

If you select don't ask then you will get a blank screen since the contacts will return as a 0 length array. This makes sense as the user is aware he denied permission and the app will still function as expected on a device where no contacts are available. For example, if the user realizes his mistake he can double back and ask to re-prompt for permission in which case he will see this native prompt:

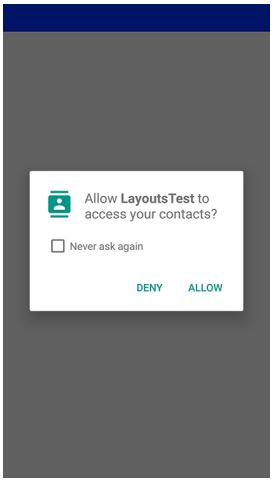

Figure 440. Native permission prompt second time

Notice that denying this second request won't trigger another Codename One prompt.

Code changes

No explicit code changes needed for this functionality to "work." The respective APIs will work like they always worked and will prompt the user seamlessly for permissions.

Some behaviors that never occurred on Android but were legal in the past might start occurring with the switch to the new API. For example: the location manager might be null and your app must always be ready to deal with such a situation

When permission is requested a user will be seamlessly prompted/warned. You can customize the permission text through `Display` properties. For example: to customize the rationale text of the

contacts permission:

```
Display.getInstance().setProperty(
        "android.permission.READ_CONTACTS",
        "MyCoolChatApp needs access to your contacts so we can show you which of your friends already have MyCoolChatApp
installed");
```

The Android port also checks `UIManager.localize()` for localized values before falling back to `Display` properties. You can provide localized strings for the permission body and dialog buttons/title using keys based on the permission name:

```
com.codename1.ui.plaf.UIManager.getInstance().setBundle(new java.util.Hashtable<String, String>() {{
    put("android.permission.READ_CONTACTS", "Localized rationale for contacts");
    put("android.permission.READ_CONTACTS.title", "Localized permission title");
    put("android.permission.READ_CONTACTS.askAgain", "Localized ask again");
    put("android.permission.READ_CONTACTS.dontAsk", "Localized don't ask");
}});
```

For example, if the permission key is `android.permission.READ_CONTACTS`, you can localize these keys:

- `android.permission.READ_CONTACTS` (dialog body)
- `android.permission.READ_CONTACTS.title`
- `android.permission.READ_CONTACTS.askAgain`
- `android.permission.READ_CONTACTS.dontAsk`

The same pattern applies to other permissions. `android.permission.ACCESS_BACKGROUND_LOCATION` also supports: `android.permission.ACCESS_BACKGROUND_LOCATION.settings`, `android.permission.ACCESS_BACKGROUND_LOCATION.cancel`, `android.permission.ACCESS_BACKGROUND_LOCATION.explanation_title`, `android.permission.ACCESS_BACKGROUND_LOCATION.explanation_body`, and `android.permission.ACCESS_BACKGROUND_LOCATION.ok`.

This is optional as there is a default value defined. You can define this once in the `init(Object)` method but for some extreme cases permission might be needed for different things for example: you might ask for this permission with one reason at one point in the app and with a different reason at another point in the app.

Simulating prompts

You can simulate permission prompts by checking that option in the simulator menu.

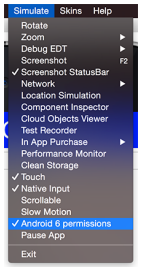

Figure 441. Simulate permission prompts menu item in the simulator

This will produce a dialog to the user whenever this happens in Android and will try to act in a similar way to the device. Notice that you can test it in the iOS simulator too.

AndroidNativeUtil's checkForPermission

If you write Android native code using native interfaces you're probably familiar with the `AndroidNativeUtil` class from the `com.codename1.impl.android` package.

This class provides access to many low-level capabilities you would need as a developer writing native code. Since native code might need to request a permission Codename One uses the same underlying logic, namely: `checkForPermission`.

To get a permission you can use this code as such:

```
if (!AndroidNativeUtil.checkForPermission(
        android.Manifest.permission.READ_PHONE_STATE,
        "This should be the description shown to the user...")) {
    // you didn't get the permission, you might want to return here
}
// you have the permission, do what you need
```

This will prompt the user with the native UI and later on with the fallback option as described above. Notice that the `checkForPermission` method is a blocking method and it will return when there is a final conclusion on the subject. It uses `invokeAndBlock` and can be invoked on the event dispatch thread without concern.

By default, fallback prompts are displayed using Codename One's `Dialog.show(…)`. If you're writing native Android code and need to use your own prompt implementation, you can install a custom callback:

```
AndroidNativeUtil.setPermissionPromptCallback(new PermissionPromptCallback() {
    @Override
    public boolean showPermissionPrompt(String permission, String title, String body, String positiveButtonText, String
negativeButtonText) {
        return com.codename1.ui.Dialog.show(title, body, positiveButtonText, negativeButtonText);
    }

    @Override
    public void showPermissionMessage(String permission, String title, String body, String okButtonText) {
        com.codename1.ui.Dialog.show(title, body, okButtonText, null);
    }
});
```

Pass `null` to `AndroidNativeUtil.setPermissionPromptCallback()` to restore the default behavior.

132.3. On device debugging

On-device debugging now has two dedicated chapters, one per platform:

- Chapter 107, *On-Device Debugging (iOS)* covers attaching a standard Java debugger (IntelliJ, jdb,

VS Code) to an iOS app running on a device or in the native iOS simulator, as well as debugging the generated Xcode project natively.

- Chapter 108, *On-Device Debugging (Android)* covers the equivalent adb/JDWP-based flow for Android devices and emulators, including wireless debugging and debugging the generated Gradle project from Android Studio.

132.4. Native interfaces

Sometimes you may wish to use an API that's unsupported by Codename One or integrate with a 3rd party library/framework that isn't supported. These are achievable tasks when writing native code and Codename One lets you encapsulate such native code using native interfaces.

132.4.1. Introduction

Notice that when you say "native" you don't mean C/C++ always but rather the platforms "native" environment. For Android, Java or Kotlin code can be invoked with full access to the Android API. In case of iOS, Objective-C or Swift code can be invoked and so forth.

You can still access C code under Android either by using JNI from the Android native code or by using a library

Native interfaces are designed to allow primitive types, Strings, arrays of primitive types (single dimension) & PeerComponent [https://www.codenameone.com/javadoc/com/codename1/ui/PeerComponent.html] values. Any other kind of parameter/return type is prohibited. For example, once in the native layer the native code can act and query the Java layer for more information.

The reason for the limits is the disparity between the platforms. Mapping a Java `Object` to an Objective-C `NSObject` is possible but leads to odd edge cases and complexity for example: GC vs. ARC in a disparate object graph

Furthermore, native methods should avoid features such as overloading, varargs (or any Java 5+ feature for that matter) to allow portability for languages that don't support such features.

Don't rely on pass by reference/value behavior since they vary between platforms

The shape is always the same, whether you are reaching one platform API or wrapping a whole third party SDK. Portable Java sits on one side, your per-platform implementation class on the other, and between them a narrow interface carrying only the types listed above: primitives, strings, single dimension primitive arrays and `PeerComponent` values. Nothing calls the vendor's SDK except that implementation class.

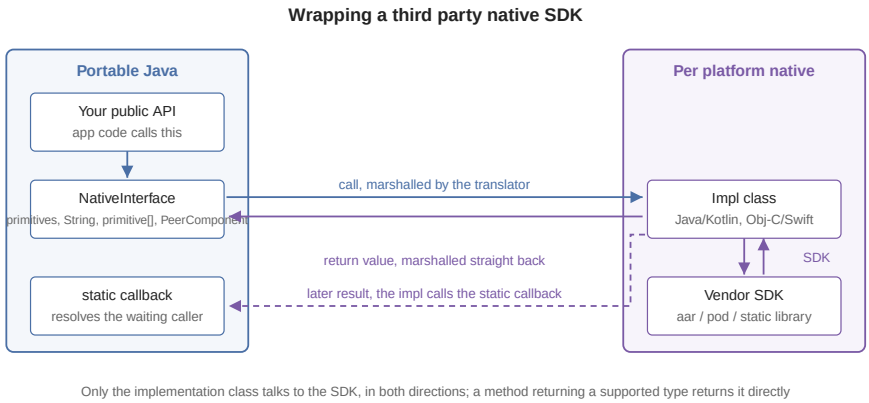

Figure 442. The native interface round trip

A method that returns one of those types returns it directly — the value is marshalled back the same way the arguments went out. The return path only gets interesting when the work finishes later: a native SDK that answers through its own callback has nothing to return by then, so it calls a `static` method on the Java class instead, and that method resolves whatever the caller was waiting on. Section 132.6, “Integrating Android 3rd party libraries & JNI” covers bundling the vendor binary on Android, `ios.pods` does the same for iOS, and Section 132.5, “Libraries - cn1lib” covers shipping the result as a library.

Implementing a native layer effectively means:

1. Creating an interface that extends NativeInterface [https://www.codenameone.com/javadoc/com/codename1/system/NativeInterface.html] and defines methods with the arguments/return values declared in the previous paragraph.
2. Creating the proper native implementation hierarchy based on the call conventions for every platform, in each platform module’s own source directory

For example: to create a simple hello world interface do something like:

```
public interface MyNative extends NativeInterface {
    String helloWorld(String hi);
}
```

You now need to right-click the class in the IDE and select the `Generate Native Access` menu item:

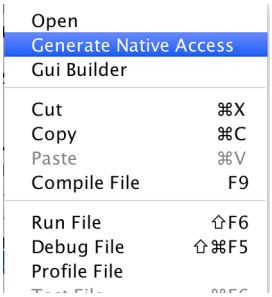

Figure 443. Generating the native code

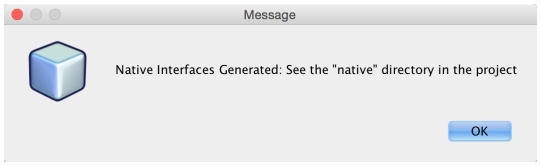

Figure 444. Once generated you're prompted that the native code is in the "native" directory

You can now look int the `native` directory in the project root (in NetBeans you can see that in the `Files` tab) and you can see something that looks like this:

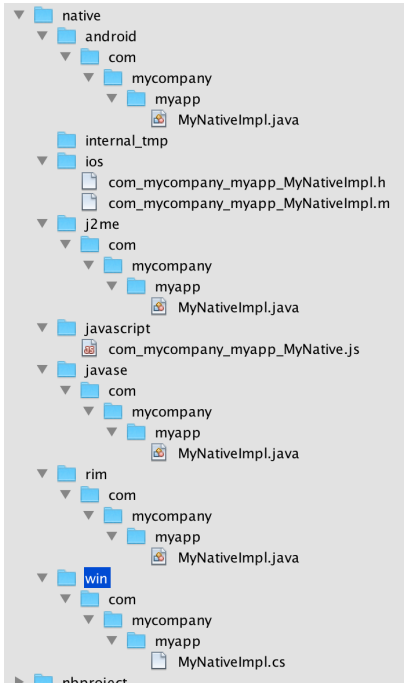

Figure 445. Native directory structure containing stubs for the various platforms

These are effectively stubs you can edit to implement the methods in native code.

If you re-run the `Generate Native Access` tool you will get this dialog, if you answer yes all the files will be overwritten, if you answer no files you deleted/renamed will be recreated

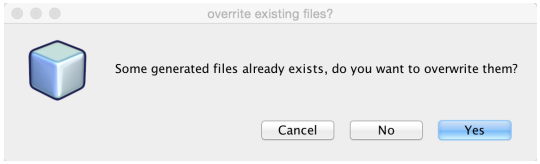

Figure 446. Running "Generate Native Access" when some/all the native files exist already

For now lets leave the stubs and come back to them soon. From the Codename One Java code you can call the implementation of this native interface using:

```
MyNative my = NativeLookup.create(MyNative.class);
if (my != null && my.isSupported()) {
    Log.p(my.helloWorld("Hi"));
}
```

Notice that for this to work you must implement the native code on all supported platforms.

You will start with Android which should be familiar and intuitive to many developers. The helper `MyNativeImplStub` class below mirrors the stub that the tooling generates under `android/src/main/java`:

```
class MyNativeImplStub {
    public String helloWorld(String param) {
        return null;
    }

    public boolean isSupported() {
        return false;
    }
}
```

The stub implementation always returns `false`, `null` or `0` by default. The `isSupported` also defaults to `false` thus allowing you to implement a `NativeInterface` on some platforms and leave the rest out without knowing anything about these platforms.

You can implement the Android version in Java or Kotlin. Here is the Java version:

```
public class MyNativeImpl { ② ③
    public String helloWorld(String param) {
        Log.d("MyApp", param); ①
        return "Tada";
    }

    public boolean isSupported() {
        return true; ④
    }
}
```

① Notice that you're using the Android native `android.util.Log` class which isn't accessible from standard Codename One code

② The impl class doesn't physically implement the `MyNative` interface!
This is intentional and due to the `PeerComponent` functionality mentioned below. You don't need to add an implements clause.

③ Notice that there is no constructor and the class is public. It's crucial that the system will be able to assign the class without obstruction. You can use a constructor but it can't have any arguments and you shouldn't rely on semantics of construction.

④ The native method is implemented, and `isSupported` answers true.

The IDE won't provide completion suggestions and will claim that there are errors in the code!
Codename One doesn't include the native platforms in its bundle for example: the full Android SDK or the full Xcode Objective-C runtime. For example, since the native code is compiled on the servers (where these runtimes are present) this

shouldn't be a problem

When implementing a non-trivial native interface, send a server build with the "Include Source" option checked. Implement the native interface in the native IDE then copy and paste the native code back into Codename One

The implementation of this interface is identical for Android (Java/Kotlin) & Java SE.

Swift (iOS) and Kotlin (Android) options

For iOS native interfaces you can implement the generated ⋯`Impl` class in Objective-C *or* Swift.
For Android native interfaces you can implement the generated ⋯`Impl` class in Java *or* Kotlin.

In a Maven project the directories below hold the native code whether the project has a module for that platform or not. `mvn cn1:generate-native-interfaces` creates them as needed, and a project without the platform's module builds them from the `common` module (see Section A.1.1, "Projects without platform modules").

Platform	Maven project	Gradle project
Android (Java/Kotlin)	`android/src/main/java/com/mycompany/myapp/MyNativeImpl.java` `android/src/main/java/com/mycompany/myapp/MyNativeImpl.kt`	`src/android/java/com/mycompany/myapp/MyNativeImpl.java` `src/android/java/com/mycompany/myapp/MyNativeImpl.kt`

iOS (Objective-C/Swift)	`ios/src/main/objectivec/com_mycompany_myapp_MyNativeImpl.h`
	`ios/src/main/objectivec/com_mycompany_myapp_MyNativeImpl.m`
	`ios/src/main/objectivec/com_mycompany_myapp_MyNativeImpl.swift`
		`src/ios/objectivec/com_mycompany_myapp_MyNativeImpl.h`
		`src/ios/objectivec/com_mycompany_myapp_MyNativeImpl.m`
		`src/ios/objectivec/com_mycompany_myapp_MyNativeImpl.swift`

Java SE (simulator and desktop)	`javase/src/main/java/com/mycompany/myapp/MyNativeImpl.java`	`src/javase/java/com/mycompany/myapp/MyNativeImpl.java`
Native Windows (win32, C)	`win/src/main/c/com/mycompany/myapp/MyNativeImplCodenameOne.c`	`src/win/c/com/mycompany/myapp/MyNativeImplCodenameOne.c`
Native Linux ©	`linux/src/main/c/com/mycompany/myapp/MyNativeImplCodenameOne.c`	`src/linux/c/com/mycompany/myapp/MyNativeImplCodenameOne.c`
JavaScript	`javascript/src/main/javascript/com_mycompany_myapp_MyNative.js`	`src/javascript/javascript/com_mycompany_myapp_MyNative.js`

A Gradle project creates each of these directories only when `./gradlew generateNativeInterfaces` first writes a stub into it; see Section 3.5, "Native interfaces".

The native Windows and native Linux ports compile your app to C (no JVM), so their native interface implementations are plain C, generated alongside the others by the "Generate Native Sources" tool. The native Mac target reuses the iOS

> Objective-C/Swift implementation, since it rides the same build.

Use the Android main thread (native EDT)

iOS, Android & pretty much any modern OS has an EDT like thread that handles events etc. The problem is that they differ in their nuanced behavior. For example: Android will respect calls off of the EDT and iOS will often crash. Some OSes enforce EDT access and will throw an exception when you violate that...

You don't need to know about these things, hidden functionality within your implementation bridges between your EDT and the native EDT to provide consistent cross-platform behavior. However, when you write native code you need awareness.

Why not Implicitly call Native Interfaces on the Native EDT?

Calling into the native EDT includes overhead and it might not be necessary for some features (for example, IO, polling etc.). Furthermore, some calls might work well with asynchronous calls while others might need synchronous results and you can't know in advance which ones you would need.

How do you access the native EDT

Within your native code in Android do something like:

```
com.codename1.impl.android.AndroidNativeUtil.getActivity().runOnUiThread(new Runnable() {
    public void run() {
       // your native code here...
    }
});
```

This will execute the block within `run()` asynchronously on the native Android UI thread. If you need synchronous execution you have a special method for Codename One:

```
com.codename1.impl.android.AndroidImplementation.runOnUiThreadAndBlock(new Runnable() {
    public void run() {
       // your native code here...
    }
});
```

This blocks in a way that's OK with the Codename One EDT which is unique to your Android port.

Gradle dependencies

Integrating a native OS library isn't hard but it sometimes requires some juggling. Most instructions target developers working with Xcode or Android Studio & you need to twist your head around them. In Android the steps for integration in most modern libraries include a Gradle dependency.

For example: you published a library that added support for Intercom [https://www.codenameone.com/blog/intercom-support.html]. The native Android integration instructions for the library looked like this:

Add the following dependency to your app's `build.Gradle` file:

```
dependencies {
    compile 'io.intercom.android:intercom-sdk:3.+'
}
```

Which instantly raises the question: "How do you do that in Codename One"?

Well, it's actually pretty simple. You can add the build hint:

```
android.gradleDep=compile 'io.intercom.android:intercom-sdk:3.+'
```

This would "work" but there is a catch...

You might need to define the specific version of the Android SDK used and specific version of Google Play Services version used. Intercom is pretty sensitive about those and demanded that you also add:

```
android.playServices=9.8.0
android.sdkVersion=25
```

Once those were defined the native code for the Android implementation became trivial to write and the library was easy as there were no jars to include.

132.4.2. Objective-C and Swift (iOS)

When generating the Objective-C code the "Generate Native Sources" tool produces two files by default: `com_mycompany_myapp_MyNativeImpl.h` & `com_mycompany_myapp_MyNativeImpl.m`. If you enable Swift stub generation in the Maven goal, it can also produce `com_mycompany_myapp_MyNativeImpl.swift`.

The `.m` files are the Objective-C equivalent of `.c` files and `.h` files contain the header/include information. In this case the `com_mycompany_myapp_MyNativeImpl.h` contains:

```
#import <Foundation/Foundation.h>

@interface com_mycompany_myapp_MyNativeImpl : NSObject {
}

-(NSString*)helloWorld:(NSString*)param;
-(BOOL)isSupported;
@end
```

And `com_mycompany_myapp_MyNativeImpl.m` contains:

```
#import "com_mycompany_myapp_MyNativeImpl.h"

@implementation com_mycompany_myapp_MyNativeImpl

-(NSString*)helloWorld:(NSString*)param{
    return nil;
}

-(BOOL)isSupported{
    return NO;
}

@end
```

Objective-C relies on argument names as part of the message (method) signature. `-(NSString*)helloWorld:(NSString*)param` isn't the same as `-(NSString*)helloWorld:(NSString*)iChangedThisName`!
don't change argument names in the Objective-C native interface!

Here is a simple implementation like above:

```
#import "com_mycompany_myapp_MyNativeImpl.h"

@implementation com_mycompany_myapp_MyNativeImpl

-(NSString*)helloWorld:(NSString*)param{
    NSLog(@"MyApp: %@", param);
    return @"Tada";
}

-(BOOL)isSupported{
    return YES;
}

@end
```

If you prefer Swift for iOS native interfaces, keep the same class naming convention (`com_mycompany_myapp_MyNativeImpl`) and annotate the class with `@objc(…)` so the runtime can discover it.

Using the iOS main thread (native EDT)

iOS has a native thread you should use for all calls like Android. Check out the Native EDT on Android section above for reference.

On iOS this is pretty like Android (if you consider objective-c to be similar). This is used for

asynchronous invocation:

```
dispatch_async(dispatch_get_main_queue(), ^{
    // your native code here...
});
```

You can use this for synchronous invocation, notice the lack of the a in the dispatch call:

```
dispatch_sync(dispatch_get_main_queue(), ^{
    // your native code here...
});
```

The problem with the synchronous call is that it will block the caller thread, if the caller thread is the EDT this can cause performance issues and even a deadlock. It's important to be cautious with this call!

Use Cocoapods for dependencies

Cocoapods are the iOS equivalent of Gradle dependencies.

CocoaPods allow you to add a native library dependency to iOS far more than Gradle. A pod that needs a newer iOS than the rest of your app says so through the `ios.pods.platform` build hint. The deployment target the build uses is the highest of everything that asks for one — the builder's own floor, `ios.deployment_target`, and `ios.pods.platform` — so that hint can raise the target and never lower it.

Including intercom itself required a single build hint: `ios.pods=Intercom` which you can obviously extend by using commas to include many libraries. You can search the CocoaPods website [https://cocoapods.org/] for supported 3rd party libraries which includes everything you would expect. One important advantage when working with CocoaPods is the faster build time as the upload to the Codename One website is smaller and the bandwidth you've to CocoaPods is faster. Another advantage is the ability to keep up with the latest developments from the library providers.

132.4.3. C (native Windows and native Linux)

The native Windows (win32) and native Linux ports have no JVM: the "clean" ParparVM target compiles your whole app to C and then to a native binary. A native interface on these ports is therefore implemented in plain **C** rather than C#/Objective-C/Java. The "Generate Native Sources" tool emits one C file per interface:

- `win/src/main/c/com/mycompany/myapp/MyNativeImplCodenameOne.c` (native Windows)
- `linux/src/main/c/com/mycompany/myapp/MyNativeImplCodenameOne.c` (native Linux)

The two files are identical, so a native interface written once works on both ports; only the directory differs. (The native Mac target reuses the iOS Objective-C/Swift implementation, because it rides the iOS build.)

The translator emits one C function per interface method. Unlike the Objective-C stub, the function name is the fully qualified, mangled C symbol the translated app links against, so **don't rename the functions or change their signatures**; just fill in the bodies. Each function takes the thread state as its first argument and JAVA_* typed parameters. For example, the interface:

```
public interface MyNative extends NativeInterface {
    String helloWorld(String hi);
}
```

This generates the C stub below (returning JAVA_NULL until you implement it):

```
#include "cn1_globals.h"

JAVA_OBJECT com_mycompany_myapp_MyNativeImplCodenameOne_helloWorld___java_lang_String_R_java_lang_String
(CODENAME_ONE_THREAD_STATE, JAVA_OBJECT param1) {
    return JAVA_NULL;
}
```

Type mapping: the primitives (int, long, boolean, byte, short, char, float, double) become their JAVA_INT/JAVA_LONG/JAVA_BOOLEAN equivalents; String, arrays and other objects become JAVA_OBJECT; a void method returns JAVA_VOID and omits the R suffix in its name; and a com.codename1.ui.PeerComponent is passed and returned as a JAVA_LONG native peer handle. Use the core helpers declared in cn1_globals.h (for example newStringFromCString / stringToUTF8) to convert between C and Java values. As with the other ports, you can drop additional .c/.h sources and prebuilt libraries into the same src/main/c directory and they're compiled into the binary.

132.4.4. JavaScript

Native interfaces in JavaScript look a little different than the other platforms since JavaScript doesn't natively support threads or classes. The native implementation should be placed in a file with name matching the name of the package and the class name combined where the "." elements are replaced by underscores.

The default generated stubs for the JavaScript build look like this com_mycompany_myapp_MyNative:

```
(function(exports){

var o = {};

    o.helloWorld__java_lang_String = function(param1, callback) {
        callback.error(new Error("Not implemented yet"));
    };

    o.isSupported_ = function(callback) {
        callback.complete(false);
    };

exports.com_mycompany_myapp_MyNative= o;
```

```
})(cn1_get_native_interfaces());
```

A simple implementation looks like this:

```
(function(exports){

var o = {};

    o.helloWorld__java_lang_String = function(param1, callback) {
        callback.complete("Hello World!!!");
    }

    o.isSupported_ = function(callback) {
        callback.complete(true);
    };

exports.com_my_code_MyNative = o;

})(cn1_get_native_interfaces());
```

Notice that you use the `complete()` method of the provided callback to pass the return value rather than using the `return` statement. This is to work around the fact that JavaScript doesn't natively support threads. The **Java** thread that's calling your native interface will block until your method calls `callback.complete()`. This allows you to use asynchronous APIs inside your native method while still allowing Codename One to work use your native interface through a synchronous API.

Make sure you call either `callback.complete()` or `callback.error()` in your method at some point, or you will cause a deadlock in your app (code calling your native method will sit and "wait" forever for your method to return a value).

The naming conventions for the methods themselves are modeled after the naming conventions shown in the previous examples:

`<method-name>__<param-1-type>_<param-2-type>_⋯<param-n-type>`

Where `<method-name>` is the name of the method in Java, and the `<param-X-type>`s are a string representing the parameter type. The general rule for these strings are:

1. Primitive types are mapped to their type name. (For example: `int` to "int," `double` to "double," etc.).
2. Reference types are mapped to their fully qualified class name with '.' replaced with underscores. For example: `java.lang.String` would be `java_lang_String`.
3. Array parameters are marked by their scalar type name followed by an underscore and `1ARRAY`. For example: `int[]` would be "int_1ARRAY" and `String[]` would be `java_lang_String_1ARRAY`.

JavaScript examples

Java API:

```
public interface JavaScriptNativeApi {
    void print(String str);
}
```

becomes

```
o.print__java_lang_String = function(param1, callback) {
    console.log(param1);
    callback.complete();
}
```

Java API:

```
interface JavaScriptNativeApiAddTwoArgs {
    int add(int a, int b);
}
```

becomes

```
o.add__int_int = function(param1, param2, callback) {
    callback.complete(param1 + param2);
}
```

```
interface JavaScriptNativeApiAddArray {
    int add(int[] a);
}
```

becomes

```
o.add__int_1ARRAY = function(param1, callback) {
    var c = 0, len = param1.length;
    for (var i =0; i<len; i++) {
        c += param1[i];
    }
    callback.complete(c);
}
```

132.4.5. Native GUI components

PeerComponent [https://www.codenameone.com/javadoc/com/codename1/ui/PeerComponent.html] return values are automatically translated to the platform native peer as an expected return value. For example: for a `NativeInterface` method such as this:

```
interface NativePeerProvider {
    PeerComponent createPeer();
}
```

Android native implementation would use:

```
class AndroidPeerImplementation {
    public View createPeer() {
        return null;
    }
}
```

The iphone would need to return a pointer to a view for example:

```
- (UIView*)createPeer;
```

Not all platforms support native peers. Specifically Java SE doesn't support them due to the way the Java SE native interfaces are mapped to their implementation. Note that this won't limit the code from running on an unsupported platform. Only that specific method won't work.

JavaScript would expect a DOM Element (for example: a `<div>` tag to be returned.). For example:

```
o.createHelloComponent_ = function(callback) {
    var c = jQuery('<div>Hello World</div>')
            .css({'background-color' : 'yellow', 'border' : '1px solid blue'});
    callback.complete(c.get(0));
};
```

Notice that if you want to use a native library (jar,.a file etc.) place it in the resources of the matching platform module — `android/src/main/resources`, `ios/src/main/resources` — and it will be packaged into the final executable. You would be able to reference it from the native code and not from the Codename One code, which means you will need to build native interfaces to access it.

This is discussed further below.

132.4.6. Type mapping & rules

Several rules govern the creation of NativeInterfaces and you covered some of them.

- The implementation class must have a default public constructor or no constructor at all
- Native methods can't throw exceptions, checked or otherwise
- A native method can't have the name `init` as this is a reserved method in Objective-C
- Only the supported types listed below can be used
- Native implementations can't rely on pass by reference/value semantics as those might change between platforms
- `hashCode`, `equals` & `toString` are reserved and won't be mapped to native code

Table 37. NativeInterface Supported Types

Java	Android	Java SE	Obj-C	C#
byte	byte	byte	char	sbyte
boolean	boolean	boolean	BOOL	bool
char	char	char	int	char
short	short	short	short	short
int	int	int	int	int
long	long	long	long	long
float	float	float	float	float
double	double	double	double	double
String	String	String	NSString*	String
byte[]	byte[]	byte[]	NSSData*	sbyte[]
boolean[]	boolean[]	boolean[]	NSData*	bool[]
char[]	char[]	char[]	NSData	char[]
short[]	short[]	short[]	NSData*	short[]
int[]	int[]	int[]	NSData*	int[]
long[]	long[]	long[]	NSData*	long[]
float[]	float[]	float[]	NSData*	float[]
double[]	double[]	double[]	NSData*	double[]
PeerComponent	android.view.View	PeerComponent	void*	FrameworkElement

JavaScript is excluded from the table above as it isn't a type safe language and thus has no such type mapping

`PeerComponent` on iOS is `void*` but `UIView` is expected as a result

The examples below show the signatures for this method on all platforms:

Listing 27. NativeInterface definition

```
interface AllTypesNativeApi {
    void test(byte b, boolean boo, char c, short s,
              int i, long l, float f, double d, String ss,
              byte[] ba, boolean[] booa, char[] ca, short[] sa, int[] ia,
              long[] la, float[] fa, double[] da,
              PeerComponent cmp);
}
```

Listing 28. Android Version

```
class AndroidAllTypesImplementation {
    public void test(byte param, boolean param1, char param2,
                     short param3, int param4, long param5, float param6,
                     double param7, String param8, byte[] param9,
                     boolean[] param10, char[] param11, short[] param12,
                     int[] param13, long[] param14, float[] param15,
                     double[] param16, android.view.View param17) {
    }
}
```

Listing 29. iOS Version

```
-(void)test:(char)param param1:(BOOL)param1
    param2:(int)param2 param3:(short)param3 param4:(int)param4
    param5:(long long)param5 param6:(float)param6
    param7:(double)param7 param8:(NSString*)param8
    param9:(NSData*)param9 param10:(NSData*)param10
    param11:(NSData*)param11 param12:(NSData*)param12
    param13:(NSData*)param13 param14:(NSData*)param14
    param15:(NSData*)param15 param16:(NSData*)param16
    param17:(void*)param17;
```

The lines are broken for the print version — the JavaScript name is one long method name that ran off the page.

Listing 30. JavaScript Version

```
o["test__byte_boolean_char_short_int_long_float_double_java_lang_String_byte_1ARRAY_boolean_1ARRAY_char_1ARRAY_short_1ARRAY_int_1ARRAY_long_1ARRAY_float_1ARRAY_double_1ARRAY_com_codename1_ui_PeerComponent"] = function(param1, param2, param3, param4, param5, param6, param7, param8, param9, param10, param11, param12, param13, param14, param15, param16, param17, param18, callback) {
    callback.error(new Error("Not implemented yet"));
};
```

Listing 31. Java SE Version

```
class JavaScriptAllTypesImplementation {
    public void test(byte param, boolean param1, char param2, short param3, int param4,
```

```
                    long param5, float param6, double param7, String param8, byte[] param9,
                    boolean[] param10, char[] param11, short[] param12, int[] param13,
                    long[] param14, float[] param15, double[] param16,
                    PeerComponent param17) {
    }
}
```

132.4.7. Android native permissions

Permissions in Codename One are seamless. Codename One traverses the bytecode and automatically assigns permissions to Android applications based on the API's used by the developer.

For example, when accessing native functionality this won't work since native code might require specialized permissions and you don't/can't run any serious analysis on it (it can be about anything).

If you require more permissions in your Android native code you need to define them in the build arguments using `android.permission.<PERMISSION_NAME>=true` for each permission you want to include. A full list of permissions are listed in Android's `Manifest.permission` documentation [https://developer.android.com/reference/android/Manifest.permission.html].

For example:

```
android.permission.ADD_VOICEMAIL=true
android.permission.BATTERY_STATS=true
...
```

You can specify the maximum SDK version in which the permission is needed using the `android.permission.<PERMISSION_NAME>.maxSdkVersion` build hint. You can also specify whether the permission is **required** for the app to run using the `android.permission.<PERMISSION_NAME>.required` build hint.

For example:

```
android.permission.ADD_VOICEMAIL=true
android.permission.BATTERY_STATS=true
android.permission.ADD_VOICEMAIL.required=false
android.permission.ADD_VOICEMAIL.maxSdkVersion=18
...
```

You can or use the `android.xpermissions` build hint to inject `<uses-permission>` tags into the manifest file. For example:

```
android.xpermissions=<uses-permission android:name="android.permission.READ_CALENDAR" />
```

You need to include the full XML snippet. You can unify many lines into a single line in the GUI as XML allows that.

132.4.8. Native AndroidNativeUtil

If you do any native interfaces programming in Android you should be familiar with the `AndroidNativeUtil` class which allows you to access native device functionality more from the native code. For example: many Android APIs need access to the `Activity` which you can get by calling `AndroidNativeUtil.getActivity()`.

The native util class includes a few other features such as:

- `runOnUiThreadAndBlock(Runnable)` - this is such a common pattern that it was generalized into a public static method. Its identical to `Activity.runOnUiThread` but blocks until the runnable finishes execution.
- `addLifecycleListener/removeLifecycleListener` - These essentially provide you with a callback to lifecycle events: `onCreate` etc. which can be pretty useful for some cases.
- `registerViewRenderer` - PeerComponent [https://www.codenameone.com/javadoc/com/codename1/ui/PeerComponent.html]'s are shown on top of the UI since they're rendered within their own thread outside of the EDT cycle. When you need to show a Dialog [https://www.codenameone.com/javadoc/com/codename1/ui/Dialog.html] on top of the peer you grab a screenshot of the peer, hide it and then show the dialog with the image as the background (the same applies for transitions). Some components (specifically the MapView) might not render and require custom code to implement the transferal to a native Bitmap, this API allows you to do that.

You can work with `AndroidNativeUtil` using native code such as this:

```
class NativeCallsImpl {
     public void nativeMethod() {
        AndroidNativeUtil.getActivity().runOnUiThread(new Runnable() {
            public void run() {
               // ...
            }
        });
     }
    // ...
}
```

132.4.9. Broadcast receiver

A common way to implement features in Android is the `BroadcastReceiver` API. This allows intercepting operating system events for common use cases.

A good example is intercepting incoming SMS which is specific to Android so you'd need a broadcast receiver to implement that. This is often confusing to developers who sometimes derive the impl class from broadcast receiver. That's a mistake...

The solution is to place any native Android class into `android/src/main/java`. It will get compiled with the rest of the native code and "works." You can therefore place this class under `android/src/main/java/com/codename1/sms/intercept`:

```
public class SMSListener extends BroadcastReceiver {

    @Override
    public void onReceive(Context cntxt, Intent intent) {
        if (intent.getAction().equals("android.provider.Telephony.SMS_RECEIVED")) {
            Bundle bundle = intent.getExtras();
            SmsMessage[] msgs = null;
            if (bundle != null) {
                try {
                    Object[] pdus = (Object[]) bundle.get("pdus");
                    msgs = new SmsMessage[pdus.length];
                    for (int i = 0; i < msgs.length; i++) {
                        msgs[i] = SmsMessage.createFromPdu((byte[]) pdus[i]);
                        String msgBody = msgs[i].getMessageBody();
                        SMSCallback.smsReceived(msgBody);
                    }
                } catch (Exception e) {
                    Log.e(e);
                    SMSCallback.smsReceiveError(e);
                }
            }
        }
    }
}
```

The code above is pretty standard native Android code, it's a callback in which most of the logic is like the native Android code mentioned in this stackoverflow question [https://stackoverflow.com/questions/39526138/broadcast-receiver-for-receive-sms-is-not-working-when-declared-in-manifeststat].

However, there is still more you need to do. To implement this natively you need to register the permission and the receiver in the `manifest.xml` file as explained in that question. This is how their native manifest looked:

```
<?xml version="1.0" encoding="utf-8"?>
<manifest xmlns:android="http://schemas.android.com/apk/res/android"
    package="com.bulsy.smstalk1">
    <uses-permission android:name="android.permission.RECEIVE_SMS" />
    <uses-permission android:name="android.permission.READ_SMS" />
    <uses-permission android:name="android.permission.SEND_SMS"/>
    <uses-permission android:name="android.permission.READ_CONTACTS" />

    <application
        android:allowBackup="true"
        android:icon="@mipmap/ic_launcher"
        android:label="@string/app_name"
```

```
        android:supportsRtl="true"
        android:theme="@style/AppTheme">
        <activity android:name=".MainActivity">
            <intent-filter>
                <action android:name="android.intent.action.MAIN" />
                <category android:name="android.intent.category.LAUNCHER" />
            </intent-filter>
        </activity>
        <receiver android:name="com.bulsy.smstalk1.SmsListener"
               android:enabled="true"
               android:permission="android.permission.BROADCAST_SMS"
               android:exported="true">
            <intent-filter android:priority="2147483647">//this doesnt work
                <category android:name="android.intent.category.DEFAULT" />
                <action android:name="android.provider.Telephony.SMS_RECEIVED" />
            </intent-filter>
        </receiver>
    </application>
</manifest>
```

You need the broadcast permission XML and the permission XML. Both are doable through the build hints. The former is pretty easy:

```
android.xpermissions=<uses-permission android:name="android.permission.RECEIVE_SMS" />
```

The latter isn't much harder; notice that many lines have been merged into a single line for convenience:

```
android.xapplication=<receiver android:name="com.codename1.sms.intercept.SMSListener"  android:enabled="true"
android:permission="android.permission.BROADCAST_SMS"  android:exported="true">                    <intent-filter
android:priority="2147483647"><category android:name="android.intent.category.DEFAULT" />       <action
android:name="android.provider.Telephony.SMS_RECEIVED" />               </intent-filter>            </receiver>
```

Here it's formatted for readability:

```
<receiver android:name="com.codename1.sms.intercept.SMSListener"
              android:enabled="true"
              android:permission="android.permission.BROADCAST_SMS"
              android:exported="true">
                   <intent-filter android:priority="2147483647">
                          <category android:name="android.intent.category.DEFAULT" />
                          <action android:name="android.provider.Telephony.SMS_RECEIVED" />
                   </intent-filter>
</receiver>
```

Listening & permissions

You will notice that these don't include the actual binding or permission prompts you would expect

for something like this. To do this you need a native interface.

The native sample in stack overflow bound the listener in the activity but here you want the app code to decide when you should bind the listening:

```
public interface NativeSMSInterceptor extends NativeInterface {
    void bindSMSListener();
    void unbindSMSListener();
}
```

That's easy!

Notice that `isSupported()` returns false for all other OSes so you won't need to ask whether this is "Android" you can use `isSupported()`.

The implementation is pretty easy too:

```
public class NativeSMSInterceptorImpl {
    private SMSListener smsListener;
    public void bindSMSListener() {
        if (AndroidNativeUtil.checkForPermission(Manifest.permission.RECEIVE_SMS, "We can automatically enter the SMS
code for you")) { ①
            smsListener = new SMSListener();
            IntentFilter filter = new IntentFilter();
            filter.addAction("android.provider.Telephony.SMS_RECEIVED");
            AndroidNativeUtil.getActivity().registerReceiver(smsListener, filter); ②
        }
    }

    public void unbindSMSListener() {
        AndroidNativeUtil.getActivity().unregisterReceiver(smsListener);
    }

    public boolean isSupported() {
        return true;
    }
}
```

① This will trigger the permission prompt on Android 6 and newer. Even though the permission is declared in XML this isn't enough for 6+. Notice that even when you run on Android 6 you still need to declare permissions in XML!

② Here you actually bind the listener, this allows you to grab one SMS and not listen in on every SMS coming through

132.4.10. Native code callbacks

Native interfaces standardize the invocation of native code from Codename One, but it doesn't standardize the reverse of callbacks into Codename One Java code. The reverse is more complicated since its platform specific and more error prone.

A common "trick" for calling back is to define a static method and then trigger it from native code. This works for Android & Java SE since those platforms use Java for their "native code." Mapping this to iOS requires some basic understanding of how the iOS VM works.

For this explanation lets pretend you have a class called NativeCallback in the src hierarchy under the package `com.mycompany` that has the method: `public static void callback()`:

```
public class NativeCallback {
    public static void callback() {
        // do stuff
    }

    public static void callback(int arg) {
        // do stuff
    }

    public static void callback(String arg) {
        // do stuff
    }

    public static int callbackR(int arg) {
        // do stuff
        return arg;
    }
}
```

If you want to call it from Android or all the Java based platforms you can write this in the "native" code:

```
public class NativeCallbackUsage {
    public void invokeCallbacks() {
        NativeCallback.callback();
        NativeCallback.callback("My Arg");
    }
}
```

You can also pass an argument as you do later on:

```
public class NativeCallbackUsage {
    public void invokeCallbacks() {
        NativeCallback.callback();
        NativeCallback.callback("My Arg");
    }
}
```

Accessing callbacks from Objective-C

If you want to invoke that method from Objective-C you need to do the following.

Add an include statement as such:

```
#include "com_mycompany_NativeCallback.h"
#include "CodenameOne_GLViewController.h"
```

Notice that the `CodenameOne_GLViewController.h` include defines various macros such as `CN1_THREAD_STATE_PASS_SINGLE_ARG`.

Then when you want to trigger the method do:

```
com_mycompany_NativeCallback_callback__(CN1_THREAD_STATE_PASS_SINGLE_ARG);
```

For most callbacks you should use the macro `CN1_THREAD_GET_STATE_PASS_SINGLE_ARG` instead of `CN1_THREAD_STATE_PASS_SINGLE_ARG` also make sure to add `#include "cn1_globals.h" in the file

The VM passes the thread context along method calls to save on API calls (thread context is used in Java for synchronization, gc and more).

You can pass arguments like:

```
public static void callback(int arg) {
    // do stuff
}
```

Which maps to native as (notice the extra _ before the int):

```
com_mycompany_NativeCallback_callback___int(CN1_THREAD_GET_STATE_PASS_ARG intValue);
```

Notice that there is no comma between the CN1_THREAD_GET_STATE_PASS_ARG and the value!

Why No Comma?

The comma is included as part of the macro which makes for code that isn't as readable.

The reason for this dates to the migration from XMLVM [1] to the current ParparVM implementation. CN1_THREAD_GET_STATE_PASS_ARG is defined as nothing in XMLVM since it didn't use that concept. Yet under ParparVM it will include the necessary comma.

A common use case is passing string values to the Java side, or NSString* which is iOS equivalent. Assuming a method like this:

```
public static void callback(String arg) {
    // do stuff
}
```

You would need to convert the `NSString*` value you already have to a `java.lang.String` which the callback expects.

The `fromNSString` function also needs this special argument so you will need to change the method as such:

```
com_mycompany_NativeCallback_callback___java_lang_String(CN1_THREAD_GET_STATE_PASS_ARG fromNSString
(CN1_THREAD_GET_STATE_PASS_ARG nsStringValue));
```

And you might want to return a value from callback as such:

```
public static int callbackR(int arg) {
    // do stuff
    return arg;
}
```

This is tricky since the method name changes to support covariant return types and so the signature would be:

```
com_mycompany_NativeCallback_callback___int_R_int(intValue);
```

The upper case R allows you to differentiate between void `callback(int,int)` and `int callback(int)`.

Covariant return types are a little known Java 5 feature. For example: the method `Object getX()` can be overridden by `MyObject getX()`. For example, in the VM level they can both exist side by side.

Accessing callbacks from JavaScript

The mechanism for invoking static callback methods from JavaScript (for the JavaScript port) is like Objective-C's. The `this` object in your native interface method contains a property named `$GLOBAL$` that provides access to static Java methods. This object will contain JavaScript mirror objects for each Java class (though the property name is mangled by replacing "." with underscores). Each mirror object contains a wrapper method for its underlying class's static methods where the method name follows the same naming convention as is used for the JavaScript native methods themselves (and like the naming conventions used in Objective-C).

For example, the Google Maps project includes the static callback method:

```
class MapContainerCallbacks {
    static void fireMapChangeEvent(int mapId, final int zoom, final double lat, final double lon) {
        // ...
    }
}
```

It's defined in the `com.codename1.googlemaps.MapContainer` class.

This method is called from JavaScript inside a native interface using the following code:

```
var fireMapChangeEvent = this.$GLOBAL$.com_codename1_googlemaps_MapContainer.fireMapChangeEvent__int_int_double_double;
google.maps.event.addListener(this.map, 'bounds_changed', function() {
    fireMapChangeEvent(self.mapId, self.map.getZoom(), self.map.getCenter().lat(), self.map.getCenter().lng());
});
```

In this example you first get a reference to the `fireMapChangeEvent` method, and then call it later. For example, you could have called it directly also.

Your code **MUST** contain the full string path `this.$GLOBAL$.your_class_name.your_method_name` or the build server won't be able to recognize that your code requires this method. The `$GLOBAL$` object is populated by the build server with those classes and methods that are used inside your native methods. If the build server doesn't recognize that the methods are being used (through this pattern) it won't generate the necessary wrappers for your JavaScript code to access the Java methods.

Callbacks of the SMS receiver

The SMS Broadcast Receiver code from before also used callbacks such as this:

```
package com.codename1.sms.intercept; ①

import com.codename1.util.FailureCallback;
import com.codename1.util.SuccessCallback;
import static com.codename1.ui.CN.*;

class SMSCallback {
    static SuccessCallback<String> onSuccess;
    static FailureCallback onFail;

    public static void smsReceived(String sms) {
        if (onSuccess != null) {
            SuccessCallback<String> s = onSuccess;
            onSuccess = null;
            onFail = null;
            SMSInterceptor.unbindListener();
            callSerially(() -> s.onSucess(sms)); ②
        }
    }

    public static void smsReceiveError(Exception err) {
        if (onFail != null) {
            FailureCallback f = onFail;
            onFail = null;
            SMSInterceptor.unbindListener();
            onSuccess = null;
            callSerially(() -> f.onError(null, err, 1, err.toString()));
```

```
        } else {
            if (onSuccess != null) {
                SMSInterceptor.unbindListener();
                onSuccess = null;
            }
        }
    }
}
```

① Notice that the package is the same as the native code and the other classes. This allows the callback class to be package protected so it isn't exposed through the API (the class doesn't have the public modifier)

② You wrap the callback in call serially to match the Codename One convention of using the EDT by default. The call will probably arrive on the Android native thread so it makes sense to normalize it and not expose the Android native thread to the user code

Asynchronous callbacks & threading

One of the problematic aspects of calling back into Java from JavaScript is that JavaScript has no notion of multi-threading. If the method you're calling uses Java's threads at all (for example: It includes a `wait()`, `notify()`, `sleep()`, `callSerially()`, etc.) you need to call it asynchronously from JavaScript. You can call a method asynchronously by appending `$async` to the method name. For example: With the Google Maps example above, you would change :

```
```

to

```
var asyncFireMapChangeEvent =
this.$GLOBAL$.com_codename1_googlemaps_MapContainer.fireMapChangeEvent__int_int_double_double$async;
```

This will cause the call to be wrapped in the appropriate bootstrap code to work with threads - and it's necessary in cases where the method **may** use threads of any kind. The side-effect of calling a method with the `$async` suffix is that you can't use return values from the method.

Usually you should use the **async** version of a method when calling it from your native method. Only use the synchronous (default) version if you're sure that the method doesn't use any threading primitives.

132.5. Libraries - cn1lib

Support for JAR files in Codename One has been a source of confusion so its probably a good idea to revisit this subject again and clarify all the details.

The first source of confusion is changing the classpath. You should NEVER change the classpath or add an external JAR through the IDE classpath UI. The reasoning here is simple, these IDEs don't package the JARs into the final executable and even if they did these JARs would probably use

features unavailable or inappropriate for the device (for example: `java.io.File` etc.).

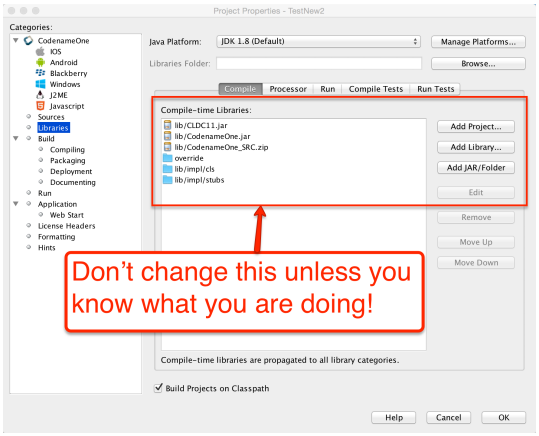

Figure 447. Don't change the classpath, this is how it should look for a typical Java 8 Codename One application

Cn1libs are Codename One's file format for 3rd party extensions. It's physically a zip file containing other zip files and some meta-data.

132.5.1. Why not use JAR

A jar can be compiled with usage of any Java API that might not be supported, it can be compiled with a Java target version that isn't tested.

Jars don't include support for writing native code; you could use JNI in jars but that doesn't match Codename One's needs for native support (see section above).

Jars don't support "proper" code completion, a common developer trick is to stick source code into the jar but that prevents usage with proprietary code. Cn1libs provide full IDE code completion (with JavaDoc hints) without exposing the sources.

There are two use cases for wanting JARs and they both have different solutions:

1. Modularity
2. Working with an existing JARs

Cn1lib's address the modularity aspect allowing you to break that down. Existing jars can sometimes be used native code settings but you would want to adapt the code to abide by Codename One restrictions.

132.5.2. How to use cn1libs

Codename One has a large repository of 3rd party cn1libs [https://www.codenameone.com/cn1libs.html]. With the Maven build tool, you consume a cn1lib the same way you consume any other Maven dependency: by adding it to the `<dependencies>` section of your application's `common/pom.xml` file. A typical entry looks like:

```
<dependency>
    <groupId>com.example</groupId>
    <artifactId>mylib-lib</artifactId>
```

```
    <version>1.0.0</version>
    <type>pom</type>
</dependency>
```

Add the dependency **before** the `<!-- INJECT DEPENDENCIES -->` comment in `common/pom.xml`. The `-lib` suffix on the `artifactId` and the `<type>pom</type>` declaration are both important - they tell Maven to pull in the library's "lib" aggregator module rather than a plain jar. See Section 2.5, "Codename One libraries" for the full library-consumption guide.

Some cn1libs require additional configuration such as build hints. Always read the library author's instructions when integrating a 3rd party library.

Legacy Ant projects

If you're still maintaining an Ant-based project, you can install a cn1lib by dropping its `.cn1lib` file into the project's `lib` directory and then right-clicking the project and selecting Codename One → Refresh cn1lib files (which invokes the `refresh-libs` Ant task). This unpacks classes and stub sources into `lib/impl/cls` and `lib/impl/stubs`, and native sources into `lib/impl/native`. New projects should use Maven instead - see Chapter 2, *Maven Project Workflow*.

132.5.3. Creating a simple cn1lib

Codename One libraries are generated from the `cn1lib-archetype` Maven archetype, which creates a multi-module project containing a `common` module for your cross-platform Java sources and one module per native platform (iOS, Android, Java SE, JavaScript) for any native interfaces. The detailed walkthrough - command-line, IntelliJ IDEA, NetBeans, and Eclipse - lives in Section 2.5, "Codename One libraries".

The quickest path from a shell:

```
mvn archetype:generate \
  -DarchetypeArtifactId=cn1lib-archetype \
  -DarchetypeGroupId=com.codenameone \
  -DarchetypeVersion=LATEST \
  -DgroupId=com.example.mylib \
  -DartifactId=mylib \
  -Dversion=1.0-SNAPSHOT \
  -DinteractiveMode=false
```

Once the project is generated, add your cross-platform Java sources under `common/src/main/java`, CSS under `common/src/main/css`, and run `mvn install` from the project root to build. The build produces both a Maven artifact for pom-style consumption and a legacy `.cn1lib` file in `common/target` for users still on Ant.

A library can also have a server half. The archetype's `backend` module holds classes for an

application's server: its controllers, beans, entities, repositories and migrations are wired into any server that depends on the library, as if that server had compiled them. When the module has sources or resources, the `.cn1lib` carries them as `backend.zip`. See Section 38.8, "Controllers and beans from a library".

132.5.4. Build hints in cn1libs

Some cn1libs are pretty simple to install - just add them as a Maven dependency in `common/pom.xml`. For example, many of the more elaborate cn1libs need some pretty complex configurations. This is the case when native code is involved where you need to add permissions or plist entries for the various native platforms to get everything to work. This makes the cn1lib's helpful but less than seamless which is where you want to go.

Codename One cn1libs include two files that can be placed into the root: `codenameone_library_required.properties` & `codenameone_library_appended.properties`.

In these files you can write a build hint as `codename1.arg.ios.plistInject=⋯` for the various hints.

Notice the usage of the properties syntax for the build hint with the `codename1.arg` prefix you would also need to escape reserved characters for properties files.
The best way to discover the right syntax for such build hints is to set them through the build hints GUI in a regular project and copy/paste them from `codenameone_settings.properties` into the cn1lib file.

The obvious question is why do you need two files?

There are two types of build hints: required and appended.

Required build hints can be something like `ios.objC=true` which you want to always work. For example: if a cn1lib defines `ios.objC=true` and another cn1lib defines `ios.objC=false` things won't work since one cn1lib won't get what it needs…
In this case you'd want the build to fail so you can remove the faulty cn1lib.

If two cn1libs define `ios.objC=true` there will be no collision as the value would be identical

An appended property would be something like `ios.plistInject=<key>UIBackgroundModes</key><array><string>audio</string> </array>`

Notice that this can still collide for example: if a different cn1lib defines its own background mode. For example, there are many valid cases where `ios.plistInject` can be used for other things. In this case you will append the content of the `ios.plistInject` into the build hint if it isn't already there.

Keep these things in mind:

- Properties are merged with every "refresh libs" call not dynamically on the server. This means it should be pretty simple for the developer to investigate issues in this process.
- Changing flags is problematic - there is no "uninstall" process. Since the data is copied into the `codenameone_settings.properties` file. If you need to change a flag later on you might need to

alert users to make changes to their properties essentially negating the value of this feature… be careful when adding properties here.

It's your responsibility as a library developer to decide which build hint goes into which file! Codename One can't automate this process as the whole process of build hints is by definition an ad hoc process.

The rule of thumb is that a build hint with a numeric or boolean value is always a required property. If an entry has a string that you can append with another string then its probably an appended entry.

These build hints are probably of the "required" type:

```
android.debug
android.release
android.installLocation
android.licenseKey
android.stack_size
android.statusbar_hidden
android.googleAdUnitId
android.includeGPlayServices
android.headphoneCallback
android.gpsPermission
android.asyncPaint
android.supportV4
android.theme
android.cusom_layout1
android.versionCode
android.captureRecord
android.removeBasePermissions
android.blockExternalStoragePermission
android.min_sdk_version
android.smallScreens
android.streamMode
android.enableProguard
android.targetSDKVersion
android.web_loading_hidden
facebook.appId
facebook.clientToken
ios.keyboardOpen
ios.project_type
ios.newStorageLocation
ios.prerendered_icon
ios.application_exits
ios.themeMode
ios.xcode_version
javascript.inject_proxy
javascript.minifying
javascript.proxy.url
javascript.sourceFilesCopied
```

```
javascript.teavm.version
google.adUnitId
ios.includePush
ios.headphoneCallback
ios.enableAutoplayVideo
ios.googleAdUnitId
ios.googleAdUnitIdPadding
ios.enableBadgeClear
ios.locationUsageDescription
ios.bundleVersion
ios.objC
ios.testFlight
ios.metal
desktop.width
desktop.height
desktop.adaptToRetina
desktop.resizable
desktop.fontSizes
desktop.theme
desktop.themeMac
desktop.themeWin
desktop.windowsOutput
noExtraResources
android.permission.<PERMISSION_NAME>
```

These build hints should probably be appended:

```
android.xapplication
android.xpermissions
android.xintent_filter
android.facebook_permissions
android.stringsXml
android.style
android.nonconsumable
android.xapplication_attr
android.xactivity
android.pushVibratePattern
android.proguardKeep
android.sharedUserId
android.sharedUserLabel
ios.urlScheme
ios.interface_orientation
ios.plistInject
ios.facebook_permissions
ios.applicationDidEnterBackground
ios.viewDidLoad
ios.glAppDelegateHeader
ios.glAppDelegateBody
ios.beforeFinishLaunching
ios.afterFinishLaunching
```

```
ios.add_libs
```

cn1lib Structure/File Format

The cb1lib file format is quite simple, it's a zip file containing zip files within it with fixed names to support the various features.

The table below covers the files that can/should be a part of a cn1lib file:

Table 38. cn1lib structure

File Name	Required	Purpose
main.zip	✔	Contains the bytecode and the library binary data. This is effectively the portable portion of the jar
stubs.zip	✔	Stub source files (autogenerated) containing javadocs to provide code completion
manifest.properties	×	General properties of the library, this isn't used for much at the moment
codenameone_ library_ appended.properties	×	Discussed above
codenameone_ library_ required.properties	×	Discussed above
nativeios.zip	×	Native iOS sources if applicable
nativeand.zip	×	Native Android sources if applicable
nativejavascript.zip	×	Native JavaScript sources if applicable
nativese.zip	×	Native Java SE sources if applicable
nativewin.zip	×	Native Windows sources if applicable
nativeme.zip	×	Native Java ME sources if applicable
backend.zip	×	The library's server half, compiled, if it has one. See Section 38.8, "Controllers and beans from a library"

132.6. Integrating Android 3rd party libraries & JNI

While its pretty easy to use native interfaces to write Android native code some things aren't necessarily as obvious. For example: if you want to integrate a 3rd party library, specifically one that includes native C JNI code this process isn't as straightforward.

If you need to integrate such a library into your native calls you have the following options:

1. The first option (and the easiest one) is to place a Jar file in `android/src/main/resources`. This will

link your binary with the jar file, and the build server picks it up and adds it to the classpath.
Notice that Android release apps are obfuscated by default which might cause issues with such libraries if they reference APIs that are unavailable on Android. You can work around this by adding a build hint to the proguard obfuscation code that blocs the obfuscation of the problematic classes using the build hint:
`android.proguardKeep=-keep class com.mypackage.ProblemClass { *; }`

2. Another option is the `aar` file is a binary format Google introduced to represent an Android Library project (similarly to the cn1lib format). One of the problem with the Android Library projects was the fact that it required the project sources which made it difficult for 3rd party vendors to publish libraries.
As a result so android introduced the `aar` file which is a binary format that represents a Library project. To learn more about arr you can read this [https://developer.android.com/studio/projects/android-library.html#aar-contents].

   You can link an `aar` file by placing it in `android/src/main/resources` and the build server will link it to the project.

Older material describes a third option, a zipped Eclipse library project renamed to `.andlib`. That format is gone. The Android builder stops with `andlib format is not supported anymore, use aar instead` the moment it finds one, so a project carrying an `.andlib` doesn't build at all. Convert it to an `aar`.

132.7. Integrating iOS 3rd party libraries

Reach for `ios.pods` first. CocoaPods resolves the dependency and its own dependencies for you, keeps the upload small, and is described in Section 113.8, "Using Cocoapods".

Not every SDK is published as a pod, though, and a vendor shipping a static library and headers can't be installed that way. Those files go into the `ios` module, which packages two directories into the native archive: put anything you would compile or `#import` beside your own native sources in `ios/src/main/objectivec`, and the vendor's binaries in `ios/src/main/resources`.

- `.h` headers go with the sources, in `ios/src/main/objectivec`.
- `.a` static libraries and `.bundle` resource directories go in `ios/src/main/resources`.
- A `.framework` has to be zipped first, keeping its name, so `MyFramework.framework` is placed as `ios/src/main/resources/MyFramework.framework.zip`.

Those are the Maven paths. A legacy Ant project put every one of those in `native/ios` instead, which is the layout older material refers to.

An SDK usually also expects a handful of the platform's own frameworks to be linked. Name those in the `ios.add_libs` build hint, separated by semicolons. A good many are linked by default already, so start with the vendor's list, build, and add only what the linker actually asks for.

132.8. Drag & drop

Unlike other platforms that tried to create overly generic catch all APIs Codename One tried to make things as simple as possible.

In Codename One components can be dragged and drop targets are always components. The logic of actually performing the operation indicated by the drop is the responsibility of the person implementing the drop.

This lightweight dragging never leaves the application. To drag content into another application, onto the desktop or into a file manager — and to accept a drag coming the other way — see Section 132.8.1, “Native operating system drag & drop” below.

The code below allows you to rearrange the items based on a sensible order. Notice it relies on the default `Container` drop behavior:

```
public class RearrangeableItemsDemo {
    public void show() {
        Form hi = new Form("Rearrangeable Items", new BorderLayout());
        String[] buttons = {"A Game of Thrones", "A Clash Of Kings",  "A Storm Of Swords",
            "A Feast For Crows", "A Dance With Dragons", "The Winds of Winter", "A Dream of Spring" };

        Container box = new Container(BoxLayout.y());
        box.setScrollableY(true);
        box.setDropTarget(true);
        java.util.List<String> got = Arrays.asList(buttons);
        Collections.shuffle(got);
        for (String current : got) {
            MultiButton mb = new MultiButton(current);
            box.add(mb);
            mb.setDraggable(true);
        }

        hi.add(BorderLayout.NORTH, "Arrange The Titles").add(BorderLayout.CENTER, box);
        hi.show();
    }
}
```

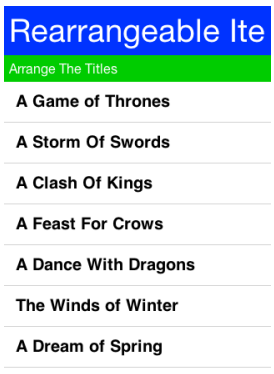

Figure 448. Drag demo

To enable dragging a component it must be flagged as draggable using `setDraggable(true)`, to allow

dropping the component onto another component you must first enable the drop target with `setDropTarget(true)` and override some methods (more on that later).

When dragging on top of a child component of a drop target the code recursively searches for a drop target parent. Dropping a component on the child will automatically find the right drop target, hence there is no need to make "everything" into a drop target.

You can override these methods in the draggable components:

- `getDragImage` - this generates an image preview of the component that will be dragged. This automatically generates a sensible default so you don't need to override it.
- `drawDraggedImage` - this method will be invoked to draw the dragged image at a given location, it might be useful to override it if you want to display some drag related information such as an icon based on location etc. (for example: a move/copy icon).

In the drop target you can override the following methods:

- `draggingOver` - returns true if a drop operation at this point is permitted. Otherwise releasing the component will have no effect.
- `dragEnter/Exit` - useful to track and cleanup state related to dragging over a specific component.
- `drop` - the logic for dropping/moving the component must be implemented here!

132.8.1. Native operating system drag & drop

The section above moves a component around inside one form. Native dragging hands the gesture to the operating system instead, so a drag can end in another application, on the desktop or in a file manager, and a drag started anywhere on the machine can end on one of your components.

The payload is a `ClipboardContent`, the same object a copy publishes. That's the whole idea: a drag is a copy that the user aims with the pointer, so whatever the application can already put on the clipboard it can already drag out, and whatever it can paste it can already accept as a drop. Offering several representations lets one drag land correctly in unrelated applications — a text editor takes the `text/html` representation, a plain text field takes `text/plain`, and the desktop takes the file list.

To drag something out, give the component an operation:

```
public void showDragSource() {
    Form hi = new Form("Drag Out", BoxLayout.y());
    Label card = new Label("Drag me into another application");

    ClipboardContent content = new ClipboardContent()
            .setData(ClipboardContent.MIME_TEXT, "Dragged out of Codename One")
            .setData(ClipboardContent.MIME_HTML, "<b>Dragged</b> out of Codename One");

    card.setNativeDragOperation(new NativeDragOperation(content)
            .setAllowedActions(NativeDragOperation.ACTION_COPY));

    hi.add(card);
```

```
    hi.show();
}
```

Dragging a file works the same way, except that the file often doesn't exist yet and the user may drop it nowhere at all. Register it as a provider and it's written at the moment a receiver asks for it rather than when the drag starts:

```
public void showFileDragSource() {
    Form hi = new Form("Drag A File Out", BoxLayout.y());
    Label card = new Label("Drag me onto the desktop");

    // The file is promised rather than written. The provider runs when a receiver actually
    // asks for the file list, so a drag the user abandons costs nothing.
    ClipboardContent content = new ClipboardContent()
            .setData(ClipboardContent.MIME_TEXT, "note.txt")
            .setDataProvider(ClipboardContent.MIME_FILE, new ClipboardDataProvider() {
                @Override
                public Object getClipboardData(String mimeType) {
                    return writeNote();
                }
            });

    NativeDragOperation op = new NativeDragOperation(content);
    op.addCompletionListener(e ->
            System.out.println("performed action: "
                    + ((NativeDragOperation) e.getSource()).getPerformedAction()));
    card.setNativeDragOperation(op);

    hi.add(card);
    hi.show();
}

private String writeNote() {
    FileSystemStorage fs = FileSystemStorage.getInstance();
    String path = fs.getAppHomePath() + "note.txt";
    try {
        OutputStream out = fs.openOutputStream(path);
        try {
            out.write("Written on drop\n".getBytes("UTF-8"));
        } finally {
            out.close();
        }
        return path;
    } catch (Exception err) {
        return null;
    }
}
```

Two platforms can't defer quite that far. An Android clip has to be complete before the drag begins, so a provider runs there as the drag starts; an iOS drag resolves its file list at the same moment,

because the system needs to know how many items the drag carries. Keep a provider cheap enough to run once per drag.

`NativeDragOperation.ACTION_MOVE` means the receiver takes ownership and the source deletes its copy. The source only learns whether that happened once the operating system has finished, which is why the outcome arrives through the completion listener rather than from the call that started the drag.

Receiving a drop is the mirror image. The deepest component under the pointer that's a native drop target and accepts the content wins, so a target nested inside another takes precedence and a target that refuses a particular payload lets an ancestor have it:

```
public void showDropTarget() {
    Form hi = new Form("Drop Here", new BorderLayout());
    Container zone = new Container(BoxLayout.y());
    zone.add(new Label("Drop files here"));

    zone.setNativeDropTarget(true);
    zone.setAcceptedDropMimeTypes(ClipboardContent.MIME_FILE);
    zone.setAcceptedDropActions(NativeDragOperation.ACTION_COPY);
    zone.addNativeDropListener(e -> {
        NativeDropEvent drop = (NativeDropEvent) e;
        for (String path : drop.getFiles()) {
            zone.add(new Label(path));
        }
        zone.getComponentForm().revalidateWithAnimationSafety();
    });

    hi.add(BorderLayout.CENTER, zone);
    hi.show();
}
```

`NativeDropEvent` also reports whether the drag started inside this application, which is how a container that reorders its own items tells that case from an import.

A complete runnable example lives in `Samples/samples/NativeDragAndDropSample`: one card drags plain text and HTML together so every receiver takes the best form it knows, another promises a file that's written only when a receiver asks for it, and a drop zone describes whatever arrives.

Where it works

Native dragging needs the platform to have it, and platforms differ on whether a drag may leave the application at all — a desktop can drop onto any other window, a tablet can drop into an application beside it, and a phone in full screen has nowhere for a drag to go even though drags within the application still work. Check both before offering the affordance:

```
public boolean canDragOut() {
    return NativeDragAndDrop.isSupported()
            && NativeDragAndDrop.isDragOutsideApplicationSupported();
```

```
}
```

Where the platform has none of this, the calls are harmless no-ops: the component simply can't be dragged through the operating system, and the lightweight dragging above is unaffected.

Platform	Drags	Leaves the app	Notes
Desktop (the simulator and "run as desktop app")	yes	yes	Drops onto other windows, the desktop and file managers. Text, HTML, images, arbitrary binary payloads and multiple files.
Android	yes	Nougat and later	A drag crosses applications through `DRAG_FLAG_GLOBAL`, which arrived in Nougat. Files travel as content URIs, the same way the clipboard carries them.
iPadOS and Mac Catalyst	yes	yes	Drops into another application beside this one, and into Files or the Finder.
iPhone	yes	iOS 15 and later	iOS 15 brought dragging between applications to the phone: hold the item with one finger, switch applications with another, drop. Before that the session worked but could only end on one of the application's own components.
Everything else	no	no	`isSupported()` answers false and the lightweight dragging above is unaffected.

Threading

Drops arrive on the operating system's own drag thread rather than the event dispatch thread. The framework resolves which component a drag is over on that thread, from the accepted MIME types and actions alone, and dispatches the callbacks — `nativeDragEnter`, `nativeDragOver`, `nativeDragExit` and `nativeDrop` — on the event dispatch thread. A filter set through `setAcceptedDropMimeTypes` therefore takes effect from the first drag event, while a decision made inside a callback reaches the cursor one event later.

The one method that runs off the event dispatch thread is `canAcceptNativeDrop`, which exists for a target whose answer depends on more than the MIME type. Read the content and the component's own configuration there; leave the user interface alone.

132.9. Coloring the native Android chrome

Codename One switches the native action bar off — the generated theme sets `android:windowActionBar` to `false` — so the title you see belongs to the Toolbar [https://www.codenameone.com/javadoc/com/codename1/ui/Toolbar.html] or the SideMenuBar [https://www.codenameone.com/javadoc/com/codename1/ui/SideMenuBar.html] and Codename One draws it. What's left for the platform to color is the chrome around your app: the status bar, and the card the task switcher shows for it.

Define a `colors.xml` file under `android/src/main/resources` for that. Every `<color>` whose name is an Android theme attribute becomes an `android:` item in the generated theme:

```
<resources>
   <color name="colorPrimary">#ff00ff00</color>
   <color name="colorPrimaryDark">#80ff0000</color>
   <color name="colorAccent">#800000ff</color>
</resources>
```

The colors reach the Material variant of the generated theme, so a device old enough to fall back to the Holo variant ignores them.

A color whose name isn't an Android theme attribute stays an ordinary `@color/` resource and never reaches the theme, and the build log names it. Android Studio puts ordinary app colors such as `ic_launcher_background` in this same file, so an imported `colors.xml` keeps working — but a misspelled attribute produces no theming, and that log line is where it says so. The names the build accepts are read from the installed platform, so any `android:` theme attribute works, not a fixed list.

132.10. Intercepting URLs on iOS & Android

A common trick in mobile application development, is communication between two unrelated applications.

In Android you can use intents which are pretty elaborate and can be used through `Display.execute`, but what if you would like to expose the functionality of your application to a different application running on the device. This would allow that application to launch your application.

This isn't something built into Codename One, but it does expose enough of the platform capabilities to enable that functionality rather on Android.

On Android you need to define an intent filter which you can do using the `android.xintent_filter` build hint, this accepts the XML to filter whether a request is relevant to your application:

```
android.xintent_filter=<intent-filter>   <action android:name="android.intent.action.VIEW" />    <category
android:name="android.intent.category.DEFAULT" />    <category android:name="android.intent.category.BROWSABLE" />
<data android:scheme="myapp" />  </intent-filter>
```

You can read more about it in this stack overflow question [https://stackoverflow.com/questions/11421048/android-ios-custom-uri-protocol-handling].

To bind the `myapp://` URL to your application. As a result typing `myapp://x` into the Android browser will launch the application.

132.10.1. Passing launch arguments to the app

You can access the value of the URL that launched the app using:

```
public class RearrangeableItemsDemo {
    public void show() {
        Form hi = new Form("Rearrangeable Items", new BorderLayout());
        String[] buttons = {"A Game of Thrones", "A Clash Of Kings",  "A Storm Of Swords",
            "A Feast For Crows", "A Dance With Dragons", "The Winds of Winter", "A Dream of Spring" };

        Container box = new Container(BoxLayout.y());
        box.setScrollableY(true);
        box.setDropTarget(true);
        java.util.List<String> got = Arrays.asList(buttons);
        Collections.shuffle(got);
        for (String current : got) {
            MultiButton mb = new MultiButton(current);
            box.add(mb);
            mb.setDraggable(true);
        }

        hi.add(BorderLayout.NORTH, "Arrange The Titles").add(BorderLayout.CENTER, box);
        hi.show();
    }
}
```

This value would be null if the app was launched through the icon.

132.10.2. Android App-to-App contracts (Wallet/Issuer style flows)

Some integrations (wallet provisioning, issuer verification, secure step-up) need more than a URL launch. They require:

- a custom Android intent action,
- caller validation,
- asynchronous app logic (login/back end verification),
- a native `setResult(…)` response back to the caller.

In Codename One, keep this flow in two layers:

1. **Android bridge activity** for contract lifecycle and `setResult(…)`.
2. **Codename One app code** for business logic in `start()`.

Why this isn't implicitly generated by AndroidGradleBuilder

A generic bridge can't infer:

- expected caller package(s),
- required result extra names,
- approval/decline mapping rules,

- timeout/failure policy.

Those are contract-specific, so the bridge activity is intentionally app-defined.

Registering the bridge activity

Use `android.xapplication` to inject a dedicated bridge activity and bind the action it should receive:

```
codename1.arg.android.xapplication=<activity android:name="com.example.wallet.WalletBridgeActivity"
android:exported="true" android:launchMode="singleTop" android:noHistory="true" android:excludeFromRecents="true"
android:theme="@android:style/Theme.Translucent.NoTitleBar"><intent-filter><action
android:name="com.example.wallet.ACTION_VERIFY"/><category android:name="android.intent.category.DEFAULT"/></intent-
filter></activity>
```

Keep `codename1.arg.android.activity.launchMode=singleTask` on your main CN1 activity so app resume behavior is predictable.

Bridge activity responsibilities

A minimal bridge activity should:

1. Receive and parse the incoming intent.
2. Capture caller identity using `getCallingPackage()`.
3. Launch or resume the CN1 app activity.
4. Hold contract state until CN1 completes verification.
5. Return `setResult(…)` and `finish()`.

For payment/wallet trust decisions, treat only `getCallingPackage()` as verified identity. Don't rely on referrer extras for caller authentication because callers can spoof those values. This implies the contract should be launched with `startActivityForResult(…)` so caller identity is available.

Wallet Contract Security Guidelines

Use this checklist when the integration can activate payment credentials or accounts:

1. **Fail closed on missing verified caller**. If `android.intent.caller` is empty (or `android.intent.caller.verified` isn't `true`), reject the request and return a failure/cancel result.
   Where: CN1 `start()` guard before any business logic.
2. **Use an allow-list** of trusted caller package names and reject everything else.
   Where: CN1 `start()` (or native bridge) before network calls.
3. **Verify signing certificate fingerprints natively** for each allowed package. Package name checks alone aren't enough in high-trust wallet scenarios.
   Where: native Android code (bridge activity/native interface), because this requires Android `PackageManager` APIs.

4. **Check payload freshness** (nonce/timestamp/challenge) before approving.
   Where: back end/API service as the source of truth.
5. **Bind response to request** (request ID / correlation ID) and reject mismatched or replayed responses.
   Where: back end first, then enforce in CN1/native completion flow.
6. **Time-box bridge activity state** and fail closed on timeout, process death, or missing bridge instance.
   Where: native Android bridge + CN1 timeout handling.
7. **Audit log** caller package, request ID, decision, and failure reason (without storing full PAN/token data).
   Where: back end and security telemetry pipeline.

Optional native Android example for certificate fingerprint verification (called from bridge/native layer before trusting caller):

```
public static boolean isTrustedCallerSignature(Context ctx, String packageName, Set<String> allowedSha256) {
    if (ctx == null || packageName == null || packageName.isEmpty() || allowedSha256 == null || allowedSha256.isEmpty())
{
        return false;
    }
    try {
        PackageManager pm = ctx.getPackageManager();
        PackageInfo info;
        if (Build.VERSION.SDK_INT >= 28) {
            info = pm.getPackageInfo(packageName, PackageManager.GET_SIGNING_CERTIFICATES);
            Signature[] sigs = info.signingInfo != null
                    ? info.signingInfo.getApkContentsSigners()
                    : null;
            return hasAllowedFingerprint(sigs, allowedSha256);
        } else {
            info = pm.getPackageInfo(packageName, PackageManager.GET_SIGNATURES);
            return hasAllowedFingerprint(info.signatures, allowedSha256);
        }
    } catch (PackageManager.NameNotFoundException | NoSuchAlgorithmException ex) {
        return false;
    }
}

private static boolean hasAllowedFingerprint(Signature[] sigs, Set<String> allowedSha256)
        throws NoSuchAlgorithmException {
    if (sigs == null) {
        return false;
    }
    MessageDigest md = MessageDigest.getInstance("SHA-256");
    for (Signature s : sigs) {
        String fp = toHex(md.digest(s.toByteArray()));
        if (allowedSha256.contains(fp)) {
            return true;
        }
    }
    return false;
}

private static String toHex(byte[] data) {
    char[] digits = "0123456789ABCDEF".toCharArray();
    StringBuilder out = new StringBuilder(data.length * 2);
    for (byte b : data) {
        int value = b & 0xff;
```

```
            out.append(digits[value >>> 4]);
            out.append(digits[value & 0x0f]);
        }
        return out.toString();
    }
```

```
public class WalletBridgeActivity extends Activity {
    private static WeakReference<WalletBridgeActivity> active;

    @Override
    protected void onCreate(Bundle savedInstanceState) {
        super.onCreate(savedInstanceState);
        active = new WeakReference<>(this);

        Intent in = getIntent();
        String caller = getCallingPackage();
        String payload = in == null ? null : in.getStringExtra("payload");

        Intent launch = getPackageManager().getLaunchIntentForPackage(getPackageName());
        if (launch == null) {
            finish();
            return;
        }
        launch.addFlags(Intent.FLAG_ACTIVITY_NEW_TASK | Intent.FLAG_ACTIVITY_CLEAR_TOP | Intent.
FLAG_ACTIVITY_SINGLE_TOP);
        launch.putExtra("wallet_payload", payload);
        launch.putExtra("wallet_caller", caller == null ? "" : caller);
        startActivity(launch);
        // Do not finish yet. CN1 will finish this activity via native callback once verification completes.
    }

    @Override
    protected void onDestroy() {
        WalletBridgeActivity current = getActive();
        if (current == this) {
            active = null;
        }
        super.onDestroy();
    }

    public static WalletBridgeActivity getActive() {
        return active == null ? null : active.get();
    }
}
```

Reading contract data in `start()`

Codename One exposes launch metadata through `AppArg` and `Display` properties. Read these in `start()`:

- `AppArg` (primary launch payload)
- `android.intent.action`
- `android.intent.data`
- `android.intent.type`
- `android.intent.caller`
- `android.intent.caller.verified`

- `android.intent.extra.<KEY>`

```
public void start() {
    Display d = Display.getInstance();
    String action = d.getProperty("android.intent.action", null);
    if ("com.example.wallet.ACTION_VERIFY".equals(action)) {
        boolean callerVerified = "true".equals(d.getProperty("android.intent.caller.verified", "false"));
        String payload = d.getProperty("android.intent.extra.wallet_payload", d.getProperty("AppArg", null));
        String caller = d.getProperty("android.intent.caller", "");

        if (!callerVerified || !isAllowedCaller(caller)) {
            failClosed(); // return declined/canceled via bridge completion API
            return;
        }

        verifyWalletPayload(payload, caller);
        return;
    }
    showMainForm();
}
```

Returning results to the wallet API

Implement a small native interface method (Android implementation) that:

1. gets `WalletBridgeActivity.getActive()`,
2. verifies `getActive()` is non-null and fails closed if the bridge timed out/canceled,
3. builds caller-specific result extras,
4. calls `setResult(Activity.RESULT_OK, resultIntent)`,
5. calls `finish()` on the bridge activity.

This is where you bind to the wallet contract's exact response schema. Keep these extra names in one place so upgrades are manageable.

Foreground behavior on Android 14/15

Foreground transitions are best-effort because Android may block background launches in some states. Build for:

- immediate resume when allowed,
- notification fallback when blocked.

iOS is practically identical to Android with some small caveats, iOS's equivalent of the manifest is the plist.

You can inject more data into the plist by using the `ios.plistInject` build hint.

The equivalent on the iOS side would be:

```
ios.plistInject=<key>CFBundleURLTypes</key>     <array>         <dict>             <key>CFBundleURLName</key>
<string>com.yourcompany.myapp</string>         </dict>         <dict>             <key>CFBundleURLSchemes</key>
```

```
<array>              <string>myapp</string>          </array>       </dict>    </array>
```

For example, that can conflict with the Facebook integration if you use `FacebookConnect` which needs access to the schemes. To work around this you can use the build hint `ios.urlScheme` for example:

```
ios.urlScheme=<string>myapp</string>
```

132.11. Native peer components

Many Codename One developers don't truly grasp the reason for the separation between peer (native) components and Codename One components. This is a crucial thing you need to understand if you plan on working with native widgets for example: Web Browser, native maps, text input, media and native interfaces (which can return a `PeerComponent`).

Codename One draws all its widgets on its own, this is a concept which was modeled in part after Swing. This allows functionality that can't be achieved in native widget platforms:

1. The Codename One GUI builder & simulator are almost identical to the device - notice that this also enables the build cloud, otherwise device specific bugs would overwhelm development and make the build cloud redundant.
2. Ability to override everything - paint, pointer, key events are all overridable and replaceable. Developers can also paint over everything for example: glasspane and layered pane.
3. Consistency - provides identical functionality on all platforms.

This all contributes to your ease of working with Codename One and maintaining Codename One. More than 95% of Codename One's code is in Java hence its portable and pretty easy to maintain!

132.11.1. Why does Codename One need native widgets at all

You need the native device to do input, html rendering etc. These are too big and too complex tasks for Codename One to do from scratch.

They're sometimes impossible to perform without the native platform. For example: the virtual keyboard input on the devices is tied directly to the native text input. It's impractical to implement everything from scratch for all languages, dictionaries etc. The result would be sub-par.

A web browser can't be implemented in this age without a JavaScript JIT and including a JIT within an iOS app is prohibited by Apple.

132.11.2. Problems with native widgets

Codename One does pretty much everything on the EDT (Event Dispatch Thread), this provides a lot of cool features for example: modal dialogs, invokeAndBlock etc.

For example native widgets have to be drawn on the devices native UI thread.
The oldest answer to that was to paint in two passes: loop over the Codename One components and paint them, then loop over the native peers and let the platform paint those over the result. That's

where the rule that a peer always covers whatever sits under it comes from, and it isn't how the current ports work.

`Display` asks the implementation one question, `paintNativePeersBehind()`, and a `false` answer doesn't mean the peer can't be covered. It leaves the compositing to the port, and the ports differ:

- iOS and the JavaScript port answer `true`. The native layer sits underneath and Codename One paints above it, punching a hole through its own surface with `clearRect` wherever a peer belongs.
- Android hands the peer's native `View` to the same ordered stream of drawing operations as every other component, so a component painted after the peer covers it. The simulator does the same for a peer that renders into a buffer.
- Where the peer owns a surface of its own, the system composites that surface and paint order never reaches it. The screenshot technique below can't reach it either, for the same reason.

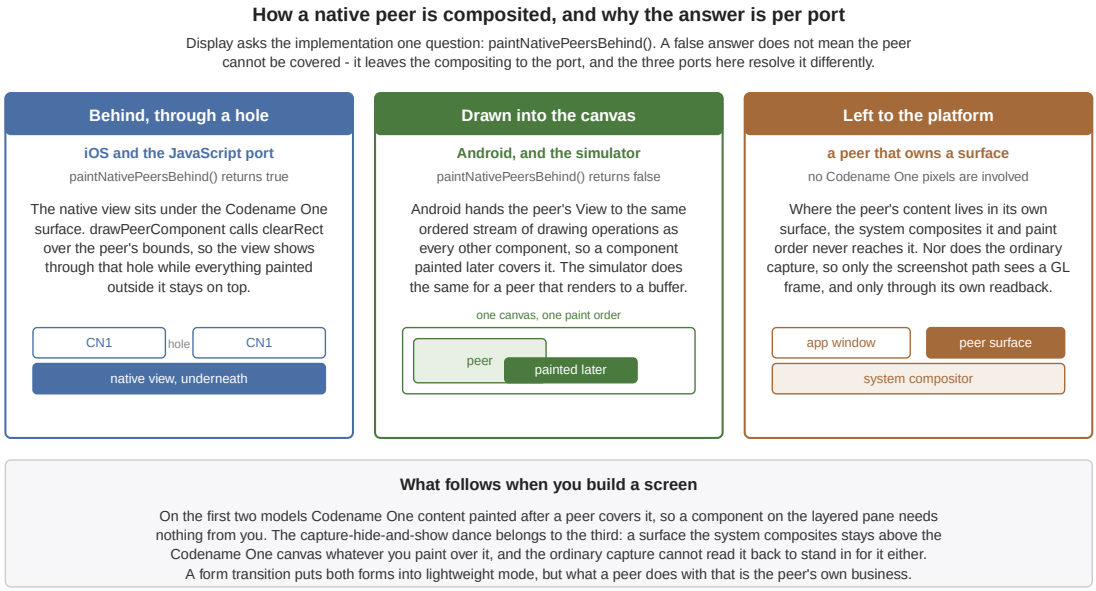

Figure 449. Where a peer sits, and what follows from it

This was also the case in AWT/Swing to one degree or another…

132.11.3. Showing dialogs on top of peer components

Under the first two models this needs nothing from you: a `Dialog` paints after the peer and covers it. What follows is for the third, where the system composites the peer's own surface and no amount of painting reaches it.

A form transition tells the peers about itself without any help from you: `initTransition` puts both forms into lightweight mode, which is how the framework says that a peer isn't truly visible for a while. How a peer responds is left to the peer, and it varies by port. Codename One grabs a screenshot of the peer, hide it and then you can show the screenshot. Since the screenshot is static it can be rendered through the standard UI. You can't do that always since grabbing a screenshot is an expensive process on all platforms and must be performed on the native device thread.

`PeerComponent` declares that callback empty, so a port opts into the still by overriding it. The iOS and Android peers do, and on Android what the still contains varies again: the browser peer overrides the capture and draws its `WebView` into the bitmap, the default renders the `View` the ordinary way, and a peer that owns a surface has nothing there to render, so its still is blank. That doesn't hide the peer, though. In super peer mode `setLightweightMode` only generates the image, it never changes the view's visibility, and `AndroidGLSurface` asks for `setZOrderMediaOverlay(true)`, so the live surface goes on drawing above the Codename One canvas while a blank still is painted into the canvas underneath it. The transition animates around a peer that never moved. The OpenGL peer keeps a copy of each frame read back with `glReadPixels`, but that copy feeds the screenshot path rather than the peer's still image, so it doesn't cover this. The JavaScript peer overrides nothing, so it stays live throughout.

132.11.4. Why can't you combine peer component scrolling and Codename One scrolling

Since the form title/footer etc. Are drawn by Codename One the peer component might paint itself on top of them. Clipping a peer component is often pretty difficult. Furthermore, if the user drags his finger within the peer component he might trigger the native scroll within the might collide with your scrolling?

132.11.5. Native components in the first Form

Another problem might be counterintuitive. iOS has screenshot images representing the first form. If your first page is an HTML or a native map (or other peer widget) the screenshot process on the build server will show fallback code instead of the real thing thus providing sub-par behavior.

Its impractical to support something like HTML for the screenshot process since it would also look different from the web component running on the device.

The launch storyboard replaced the build server's screenshot generator. See launch screen storyboard best practices.

132.12. Building your own Layout manager

A Layout [https://www.codenameone.com/javadoc/com/codename1/ui/layouts/Layout.html] contains all the logic for positioning Codename One components. It essentially traverses a Codename One Container [https://www.codenameone.com/javadoc/com/codename1/ui/Container.html] and positions components based on internal logic.

When you build the layout you need to take margin into consideration and make sure to add it into the position/size calculations. Building a layout manager involves two simple methods: `layoutContainer` & `getPreferredSize`.

`layoutContainer` is invoked whenever Codename One decides the container needs rearranging, Codename One tries to avoid calling this method and invokes it at the last possible moment. Since this method is expensive (imagine the recursion with nested layouts). Codename One marks a flag indicating layout is "dirty" when something important changes and tries to avoid "reflows."

`getPreferredSize` allows the layout to determine the size desired for the container. This might be a difficult call to make for some layout managers that try to provide both flexibility and simplicity.

Most of `FlowLayout` bugs stem from the fact that this method is impossible to implement efficiently for all the use cases of a nested `FlowLayout`. The size of the final layout won't necessarily match the requested size (it probably won't) but the requested size is taken into consideration, when scrolling and also when sizing parent containers.

This is a layout manager that arranges components in a center column aligned to the middle. You then show the proper usage of margin to create a stair like effect with this layout manager:

```
class CenterLayout extends Layout {
    public void layoutContainer(Container parent) {
        int components = parent.getComponentCount();
        Style parentStyle = parent.getStyle();
        int centerPos = parent.getLayoutWidth() / 2 + parentStyle.getMargin(Component.LEFT);
        int y = parentStyle.getMargin(Component.TOP);
        boolean rtl = parent.isRTL();
        for (int iter = 0; iter < components; iter++) {
            Component current = parent.getComponentAt(iter);
            Dimension d = current.getPreferredSize();
            Style currentStyle = current.getStyle();
            int marginRight = currentStyle.getMarginRight(rtl);
            int marginLeft = currentStyle.getMarginLeft(rtl);
            int marginTop = currentStyle.getMarginTop();
            int marginBottom = currentStyle.getMarginBottom();
            current.setSize(d);
            int actualWidth = d.getWidth() + marginLeft + marginRight;
            current.setX(centerPos - actualWidth / 2 + marginLeft);
            y += marginTop;
            current.setY(y);
            y += d.getHeight() + marginBottom;
        }
    }

    public Dimension getPreferredSize(Container parent) {
        int components = parent.getComponentCount();
        Style parentStyle = parent.getStyle();
        int height = parentStyle.getMargin(Component.TOP) + parentStyle.getMargin(Component.BOTTOM);
        int marginX = parentStyle.getMargin(Component.RIGHT) + parentStyle.getMargin(Component.LEFT);
        int width = marginX;
        for (int iter = 0; iter < components; iter++) {
            Component current = parent.getComponentAt(iter);
            Dimension d = current.getPreferredSize();
            Style currentStyle = current.getStyle();
            width = Math.max(d.getWidth() + marginX + currentStyle.getMargin(Component.RIGHT)
                    + currentStyle.getMargin(Component.LEFT), width);
            height += currentStyle.getMargin(Component.TOP) + d.getHeight()
                    + currentStyle.getMargin(Component.BOTTOM);
        }
        Dimension size = new Dimension(width, height);
        return size;
    }
}
```

```
public class CenterLayoutDemo {
    public static Form createForm() {
        Form hi = new Form("Center Layout", new CenterLayout());
        for (int iter = 1; iter < 10; iter++) {
            Label l = new Label("Label: " + iter);
            l.getUnselectedStyle().setMarginUnit(Style.UNIT_TYPE_DIPS);
            l.getUnselectedStyle().setMarginLeft(iter * 4);
            l.getUnselectedStyle().setMarginRight(0);
            hi.add(l);
        }
        hi.add(new Label("Really Wide Label Text!!!"));
        return hi;
    }

    public void show() {
        createForm().show();
    }
}
```

Figure 450. Center layout staircase effect with margin

132.12.1. Porting a Swing/AWT Layout manager

The GridBagLayout [https://www.codenameone.com/javadoc/com/codename1/ui/layouts/GridBagLayout.html] was ported to Codename One considering the complexity of that specific layout manager. Here are some tips you should consider when porting a Swing/AWT layout manager:

1. Codename One doesn't have `Insets`, but adds some support for them to port GridBag but components in Codename One have a margin they need to consider instead of the `Insets` (the padding is in the preferred size and is thus hidden from the layout manager).
2. AWT layout managers also synchronize a lot on the AWT thread. This is no longer necessary since Codename One is single threaded, like Swing.
3. AWT considers the top left position of the `Container` to be 0,0 whereas Codename One considers the position based on its parent `Container`. The top left position in Codename One is `getX()`, `getY()`.

Other than those things it's fixing method and import statements, which are slightly different. Pretty trivial stuff.

132.13. Update framework

When Codename One launched in 2012 there was a need to ship updates and fixes faster than the plugin update system, leading to the client lib update system. There was also a need to update the designer tool (resource editor), the GUI builder, and the skins, as well as the built-in builder code (`CodeNameOneBuildClient.jar`).

The Update Framework [https://github.com/codenameone/UpdateCodenameOne] solves many problems in the old systems:

- Download once - if you have many projects the library will download once to the `.codenameone` directory. All the projects will update from local storage
- Skins update automatically - this is hugely important. When you change a theme you need to update it in the skins and if you don't update the skin you might see a difference between the simulator and the device
- Update of designer tools without an IDE plugin update - The IDE plugin update process is slow and tedious. This way a GUI builder fix can ship without a new IDE plugin release. The standalone Settings artifact is versioned with the Maven plugin instead.

This framework should be seamless. You should no longer see the "downloading" message whenever you push an update after your build client is updated. Your system would poll for a new version daily and update when new updates are available.

To force an update check, run `mvn cn1:update` from the project root.

132.13.1. How does it work

`mvn cn1:update` does two separate things.

First it makes sure `~/.codenameone/UpdateCodenameOne.jar` is there — installed from a resource bundled in the plugin, or downloaded if that resource is missing — and runs it. That's what keeps the shared tooling and the device skins under `~/.codenameone` current, and it's why the download happens once per machine rather than once per project. It no longer runs against your project directory, which is why a Maven project has no jars of its own to update: the plugin hands it a synthetic directory under `common/target/codenameone/update-dummy`, seeded with the project's `codenameone_settings.properties`. It's under `common` because that module holds `codenameone_settings.properties` and is therefore the one the plugin treats as the Codename One project; run from the root, the aggregator skips itself and `common` does the work.

Then it reads the plugin's Maven metadata, resolves the newest published release and rewrites the `cn1.version` and `cn1.plugin.version` properties in the pom.

Which metadata it reads depends on the project. Releases are published to the Codename One repository [https://repo.codenameone.com/maven2], and the mojo uses it only when the project declares that host in BOTH `<repositories>` and `<pluginRepositories>`. A project that declares it in one section only, or in neither, is offered what Maven Central holds instead — and Central keeps every version published before the cutover but receives no new ones, so such a project is told it's up-to-date at the last pre-cutover release however long it waits. The build log says so when it happens. Adding the repository to both sections is the fix. The framework and plugin artifacts for that version then resolve on the next build like any other dependency. The Resource Editor doesn't: it's a separate artifact of around 43MB that's fetched when you run `mvn cn1:designer`.

A project pinned to a `-SNAPSHOT` keeps its version, because a snapshot already tracks the newest build. To move to a particular release rather than the newest one, name it: `mvn cn1:update -DnewVersion=X.Y.Z`.

132.13.2. What isn’t covered

You will notice 3 big things that aren’t covered in this unified framework:

- You don’t update cn1libs - whether you would like to update them automatically is unclear
- Versioned builds - a lot of complexity exists in the versioned build system. This might be something you address in the future but for now the framework stays simple.

[1] The old Codename One VM

Chapter 133. Java in the browser: The Playground compiler and the self-hosted translator

The Codename One Playground runs the Java you type. In its browser build nothing leaves the page: a Java compiler running in the page compiles the source to class files, the ParparVM translator running in the same page turns those class files into JavaScript, and the running virtual machine loads the result and calls it. The compiler and the translator are ordinary Java programs, translated by ParparVM into the Playground's own JavaScript bundle.

This chapter describes how those pieces fit together, what each one is responsible for, and how the build keeps them correct. It's aimed at contributors working on the compiler, the translator or the Playground, and at anyone who wants to know what Java the Playground accepts.

133.1. The pipeline at a glance

```
CodeEditor text
     |  PlaygroundRunner.compile()
     v
Java compiler (com.codename1.tools.javac)  <--  stub library: the API the page contains
     |  class files
     v
ParparVM translator, incremental mode (JavascriptIncremental)
     |  JavaScript class definitions
     v
__cn1LoadClasses()  -->  classes defined in the running VM  -->  entry point runs  -->  preview
```

Each run goes through every step. An edit triggers a run 300 milliseconds after typing stops; the console prints how long the compile, load and run phases took.

Piece	Where	What it does
Compiler	`vm/JavaCompiler` (artifact `codenameone-javac`)	Compiles Java source to class files, with javac's diagnostics
Stub library	`playground-api.cn1stubs`, built by `BuildStubLibrary`	Tells the compiler which classes and members the page contains
Class-file reader	`vm/ByteCodeTranslator/…/translator/classfile`	Reads class files for the translator, in place of ASM
Incremental translator	`JavascriptIncremental`	Translates the user's classes against an already-running bundle
Open-world host bundle	`JavascriptOpenWorld`, `translator-opts.txt`	Keeps the API user code can call, under names user code can find
Loader	`__cn1LoadClasses` in `parparvm_runtime.js`	Defines the new classes in the running virtual machine

Piece	Where	What it does
Runner	`PlaygroundRunner`	Wraps a script, finds its entry point and shows its result

133.2. The compiler

`com.codename1.tools.javac` compiles Java source to class files. Its input is the Java language of current Java releases: records, sealed types, `switch` expressions and pattern matching (including record patterns), text blocks, `var`, lambdas and method references, generics with inference, and the rest of the language a Codename One application uses. Its output is class files that the HotSpot verifier accepts, and its error messages use javac's wording and positions.

Because it has to run inside ParparVM, it's built against ParparVM's class library (`vm/JavaAPI`) rather than the JDK. That rules out reflection, `java.util.regex`, `java.nio.file` and the JDK's own class-file tools, so the compiler writes class files itself and computes their `StackMapTable` from its own type information.

The compiler is a classic pipeline:

1. `Lexer` and `JavaSourceParser` build a syntax tree. Malformed input always produces a diagnostic, never an exception, because the Playground compiles while the user is still typing.
2. `Enter` declares the classes and their members.
3. `Attr` resolves names, picks overloads, infers generic types and type-checks every expression.
4. `Flow` checks definite assignment, unreachable code and which local variables are effectively final.
5. `Gen` lowers the tree and writes bytecode; `FrameComputer` derives the stack-map frames from the finished code.

Some constructs are lowered by the compiler itself rather than left to a run-time bootstrap method, because the translator doesn't implement those bootstraps: string concatenation becomes `StringBuilder` calls, records get explicit `toString`, `equals` and `hashCode` methods, and a pattern `switch` becomes a chain of `instanceof` tests. Lambdas and method references are emitted as `LambdaMetafactory` call sites, which the translator lowers.

133.2.1. What the compiler doesn't do

- No annotation processing and no modules. Annotation types are resolved and `@Override` is checked, but no annotation is written to the class files: ParparVM can't read annotations at run time, so the simulator doesn't see them either.
- No `native` methods. A `native` declaration is a compile error. Codename One reaches platform code through native interfaces (see Section 132.4, "Native interfaces"), and neither the browser nor the simulator has a library to bind a Java `native` method to.
- No API beyond what the page contains. User code compiles against the stub library described below, so a call to a JDK class or method that ParparVM's class library lacks is a compile error rather than a failure at run time. One case compiles and still fails: ParparVM's

`java.util.regex.Pattern` exists so code that names it compiles, but its methods throw when called in the browser.

133.3. Script mode

The Playground accepts more than complete classes. A script can mix import statements, statements, methods and classes at the top level, the way a notebook cell does. The compiler's script mode (`JavaCompiler.addScript` with a `ScriptSpec`) wraps such a script into one class:

- top-level classes, interfaces, enums and records stay top-level types;
- top-level methods become methods of a generated `PlaygroundScript` class;
- top-level statements become the body of its `run(PlaygroundContext ctx)` method, which returns the value of a trailing expression and the script's top-level local variables.

`PlaygroundRunner` then looks for the entry point, in this order: a `build` method, the lifecycle methods `init` and `start`, and finally a top-level class that declares `start` or `build`. A `build` or `start` method qualifies only when it returns `void`, `Object` or a `Component`. When the entry point isn't the script class itself, the runner compiles a small `PlaygroundLauncher` class that calls it.

Two more adjustments make ordinary application code work unchanged:

- Every unit sees a set of default imports, among them `com.codename1.ui.`, `com.codename1.ui.layouts.`, `com.codename1.components.` and `java.util.`. The user's own imports take precedence.
- Calls to `Form.show()` and `Form.showBack()` are compiled as calls to `PlaygroundContext`, which places the form in the preview instead of replacing the Playground's own user interface. This also applies to a form shown later, for example from a button's action listener.

The run's result is the first of these that exists: the component the script returned, a form it showed, the first form it created, or the first component it created.

133.4. The stub library

The compiler needs the class files of every class user code can reference, but the page can't afford to download the full class files of the framework. A stub library is the compact form: the same classes with their method bodies, private members, synthetic members, annotations and debug information removed. What remains is what compilation needs: access flags, superclasses and interfaces, generic signatures, constants, member signatures, thrown exceptions and inner-class information.

`BuildStubLibrary`, a build-time tool in `vm/JavaCompiler/tools-src`, packs the stubs into one file. The Playground's build generates `playground-api.cn1stubs` from ParparVM's class library, the Codename One core and the Playground's own helper classes, in that order, so user code compiles against exactly the API the browser's virtual machine contains. The same file feeds the editor's code completion.

133.5. The translator, inside the page

The translator that builds every Codename One iOS, desktop and JavaScript application also runs inside the Playground page. That requires the translator itself to be translatable by ParparVM, which places the same constraint on it as on the compiler: it compiles against ParparVM's class library alone. Three parts of the translator exist because of that constraint:

- **Its own class-file reader.** The `classfile` package is a rewrite of the parts of the ASM bytecode framework the translator uses, keeping ASM's API and design. ASM's copyright and BSD license notice is retained in each of its files and reproduced in the repository's `NOTICE` file.
- **Its own regular-expression engine**, used by the JavaScript backend's peephole passes, because `java.util.regex` isn't available.
- **Its own SHA-256**, used to hash inline scripts for the content security policy.

Running in the page, the translator works in **incremental** mode (`JavascriptIncremental.translate`). It reads the user's class files, reads from the stub library every class they reference (and their superclasses and interfaces), links the hierarchy, and emits JavaScript definitions for the user's classes only. Every user method is emitted as a generator, so user code can block cooperatively wherever it calls into the framework. Calls into the host bundle go through `_GW`, which looks up the host function by name when it's called.

133.5.1. Loading the result

`__cn1LoadClasses(source, classNames)` in `parparvm_runtime.js` defines the translated classes in the running virtual machine:

1. It refuses a class whose JavaScript name belongs to a class of the running application. The translator maps both `/` and `$` to `_`, so a user class can collide with a framework class whose name only differs in those characters; the check runs before the code is evaluated, because evaluation would replace the host's functions.
2. In the page's worker it evaluates the code with `importScripts` on a `blob:` URL, which is why the Playground's content security policy allows `blob:` scripts.
3. A later run redefines classes it loaded before, so editing a class and running again replaces its old definition without restarting the worker.

The runner then creates the entry class and calls it.

133.6. The open-world host bundle

An ordinary Codename One JavaScript bundle is a **closed world**: the translator removes every class and method the application doesn't reach, renames identifiers to shorter ones, and calls a method directly when only one implementation exists. The Playground's bundle can't be built that way, because code that arrives after the bundle was built has to find the framework still there, under names it can predict, with dispatch that a new subclass can join.

The system property `parparvm.js.openWorld` names the packages to keep open, as a comma-separated list of prefixes where a leading `!` excludes one. The Playground sets it in

scripts/cn1playground/javascript/translator-opts.txt:

```
-Dparparvm.js.openWorld=java/,com/codename1/,com/codenameone/playground/,org/teavm/,!com/codename1/tools/,!com/codename1/impl/
```

For the classes it keeps, the translator:

- keeps every class and method, instead of removing what the bundle itself doesn't call;
- keeps their function names, so a user class can call them by name;
- emits every field and dispatch identifier;
- treats an abstract method that nothing in the bundle implements as one that may block, because the implementation that arrives later is always a generator.

Across the whole bundle, it also stops replacing a virtual call with a direct call when only one implementation exists, since a user class can add another.

The compiler and translator classes (`com/codename1/tools/`) and the platform implementation (`com/codename1/impl/`) stay closed: the bundle needs them, but user code never calls them, so they're reduced and renamed like ordinary application code.

133.7. The simulator path

In the simulator and the desktop build there's no translator step. The same compiler produces the same class files against the same stub library, and `PlaygroundClassDefiner` defines them in a fresh class loader for each run. On other platforms the Playground can't run compiled code and says so.

133.8. How the build keeps it correct

Every piece has a gate that compares it against an independent implementation, so a defect shows up as a difference rather than depending on a test anticipating it.

Gate	What it requires
`JavaCompilerConformanceTest`	Each program in `vm/JavaCompiler/tests/corpus` compiled by javac 21 and by this compiler prints the same output under `-Xverify:all`; each case in `tests/negative` reports javac's diagnostic on javac's line; no prefix of a program makes the compiler throw or hang
`TranslatorBuiltByJavaCompilerTest`	The translator compiled by this compiler emits byte-identical JavaScript to the translator compiled by javac
`ClassReaderConformanceTest`	The `classfile` reader produces the same visitor events as ASM, and its subroutine inliner places code as ASM's does
`TranslatorRegexTest`	The translator's regular-expression engine agrees with `java.util.regex` on every operation the backend uses

Gate	What it requires
`verify-selfhost.sh`, gates D, A and J	The translator built by ParparVM is deterministic and emits byte-identical C and JavaScript to the translator running on the JVM
`verify-selfhost-js.sh`, gates C and S	The translator translated to JavaScript and run under Node emits byte-identical C and JavaScript to the translator running on the JVM
Playground harnesses	Every bundled sample compiles and runs on the JVM, and in a real headless browser the samples, compile errors, re-runs, listener exceptions and form navigation all behave

To run the compiler's conformance suite, which needs a JDK 21 for the reference compiler:

```
$ source tools/env.sh
$ cd vm
$ JDK_21_HOME=/path/to/jdk-21 mvn -pl tests test -Dtest=JavaCompilerConformanceTest
```

To build the self-hosted translator and run the self-hosting gates:

```
$ source tools/env.sh
$ vm/selfhost/build-selfhost.sh
$ CORPUS="$PWD/vm/selfhost/target/asm-classes;$PWD/vm/selfhost/target/classes"
$ vm/selfhost/verify-selfhost.sh "$CORPUS" \
    com_codename1_tools_translator_ByteCodeTranslator com.codename1.tools.translator
$ vm/selfhost/verify-selfhost-js.sh "$CORPUS" \
    com_codename1_tools_translator_ByteCodeTranslator com.codename1.tools.translator
```

To run the Playground's suites on the JVM and in a headless browser, which builds the open-world bundle and serves it locally:

```
$ cd scripts/cn1playground
$ tools/run-playground-smoke-tests.sh
$ tools/run-playground-browser-tests.sh
```

133.9. Where to read more

- `vm/JavaCompiler/README.md` covers the compiler's layout and use as a library.
- `vm/selfhost/README.md` covers self-hosting the translator, on the native targets and on JavaScript.
- `scripts/cn1playground/README.md` covers building and running the Playground.
- `vm/ByteCodeTranslator/src/com/codename1/tools/translator/classfile/README.md` covers the class-file reader and its relation to ASM.

Chapter 134. Working with Codename One sources

The Codename One SDK is published as a Maven multi-module project. Building the aggregator in the `/maven` directory compiles every module, installs the artifacts into your local Maven repository, and lets you depend on the exact snapshot you cloned from GitHub.

134.1. Prerequisites

Codename One uses multiple JDKs and Maven profiles during the build. Make sure your development machine includes the following tooling (see `BUILDING.md` for platform-specific installation tips):

- JDK 8 (required for the core build of the framework itself)
- JDK 11 through 25 (required at **runtime** to launch the simulator or "Run as desktop app" target)
- JDK 17 (required when compiling the Android port)
- Apache Maven 3.6 or newer
- macOS with Xcode (if you plan to build or test the iOS port)

134.2. Preparing the Maven workspace

Clone the repository and run the Maven aggregator from inside the `maven` subdirectory. This installs the complete SDK (core runtime, simulator, and ports) into your local Maven cache:

```
$ git clone https://github.com/codenameone/CodenameOne
$ cd CodenameOne/maven
$ mvn install
```

The default build runs every module and its unit tests. Append `-DskipTests` if you want to skip the test phases to speed up local builds.

The version printed by Maven will end with `-SNAPSHOT` when you build from the `master` branch. Published releases omit the suffix.

134.3. Installing the Maven archetypes

Codename One ships its project archetypes in a companion repository. Install them once so that `mvn archetype:generate` (and the Codename One Initializr) can reference your locally built SDK artifacts:

```
$ git clone https://github.com/shannah/cn1-maven-archetypes
$ cd cn1-maven-archetypes
$ mvn install
```

134.4. Running tests selectively

The Maven aggregator exposes modules for the different automated test suites. Run any of these from the `CodenameOne/maven` directory:

- Core unit tests:

```
$ mvn -pl core-unittests test
```

- Integration tests (simulator and build client):

```
$ mvn -pl tests -am verify
```

Refer to the READMEs in `maven/core-unittests` and `maven/tests` for more configuration flags, platform requirements, and environment variables.

134.5. Using your local build in application projects

After running the `mvn install` commands above, the Codename One artifacts are available in your local Maven repository. To consume that build in an application generated from the Codename One Initializr (or any other Maven project), adjust the `pom.xml` properties to reference your snapshot version:

```
<properties>
    <!-- Replace with the snapshot printed during mvn install -->
    <cn1.version>{cn1-snapshot-version}</cn1.version>
    <cn1.plugin.version>{cn1-snapshot-version}</cn1.plugin.version>
</properties>
```

Open the project in your IDE and build or run it. Maven will resolve the local snapshot instead of downloading the latest published release.

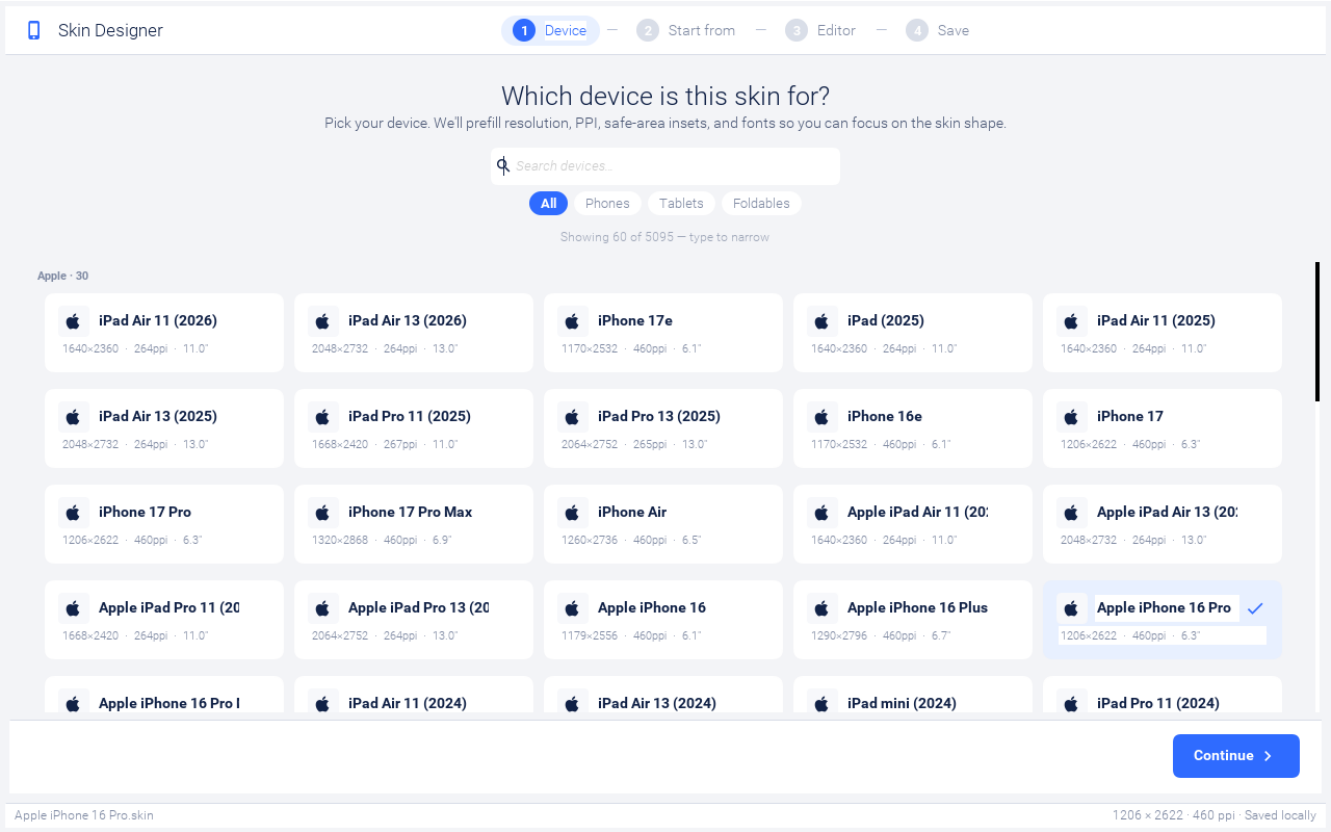
134.6. Why build from source

Building the SDK yourself gives you:

- Immediate access to fixes and features before they reach a release.
- The ability to inspect, debug, and change the framework when you need custom behavior.

Once you're comfortable with the baseline build, continue with the scripts in `scripts/` or the `BUILDING.md` guide to compile specific ports (Android or iOS) or to automate CI workflows.

Chapter 135. Skin Designer

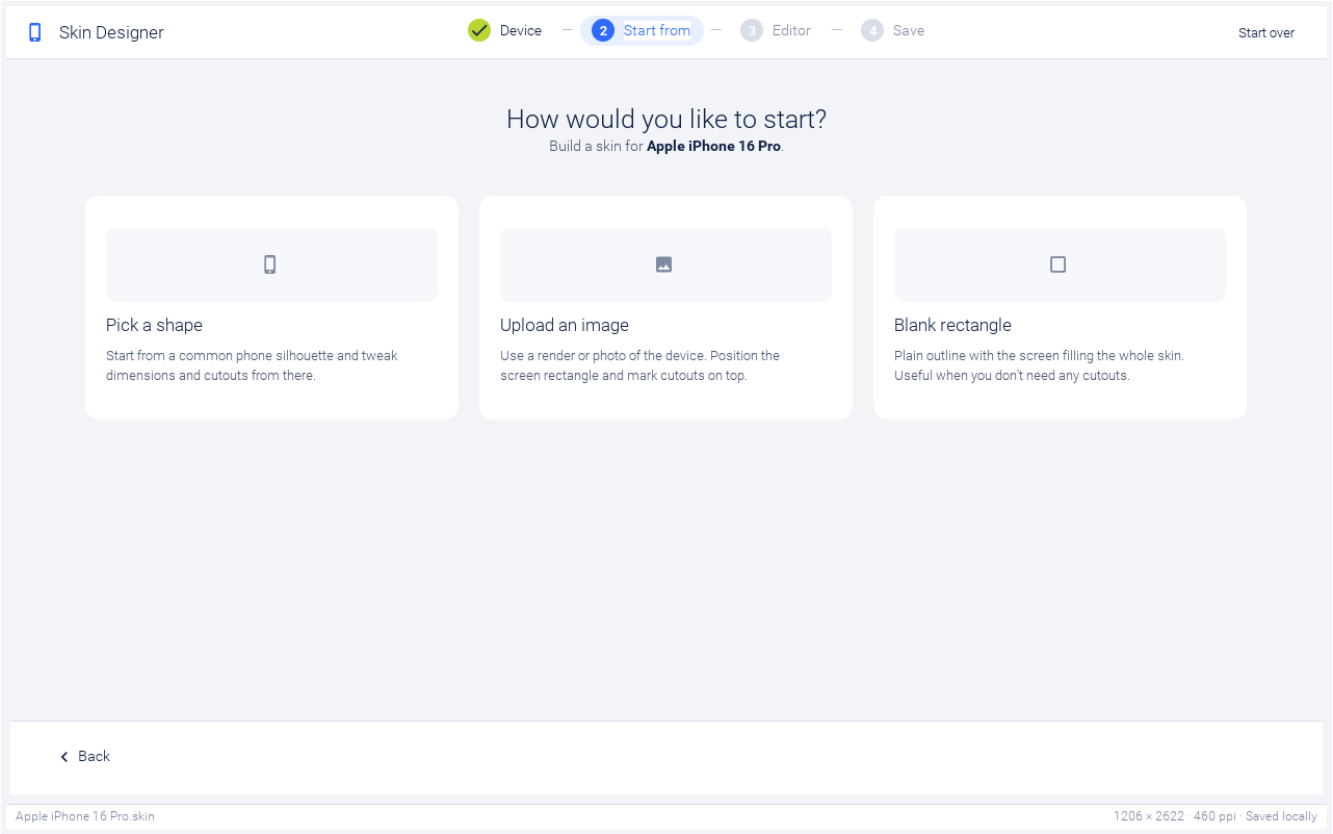


The Skin Designer turns a device specification (resolution, PPI, fonts, safe-area insets, cutouts) into a `.skin` file that the JavaSE simulator can load. It runs in your browser at https://www.codenameone.com/skindesigner — there is nothing to install.

This chapter walks through the wizard and explains what each step contributes to the generated `.skin`. If you only want a skin and don't care how it's built: pick a device, accept the defaults, click **Finish**, then **Download skin**. The file is ready to load via **Add** in the simulator's **Skins** menu.

The wizard is intentionally opinionated. It ships with a curated device catalog, generates the device frame procedurally, and writes a skin layout that matches the `Themes/iPhoneTheme.res`, `Themes/iOS7Theme.res`, and `Themes/android_holo_light.res` themes shipped with Codename One. For a custom skin from a hand-painted device render, jump straight to the "Upload an image" source.

135.1. Stage 1 — pick a device



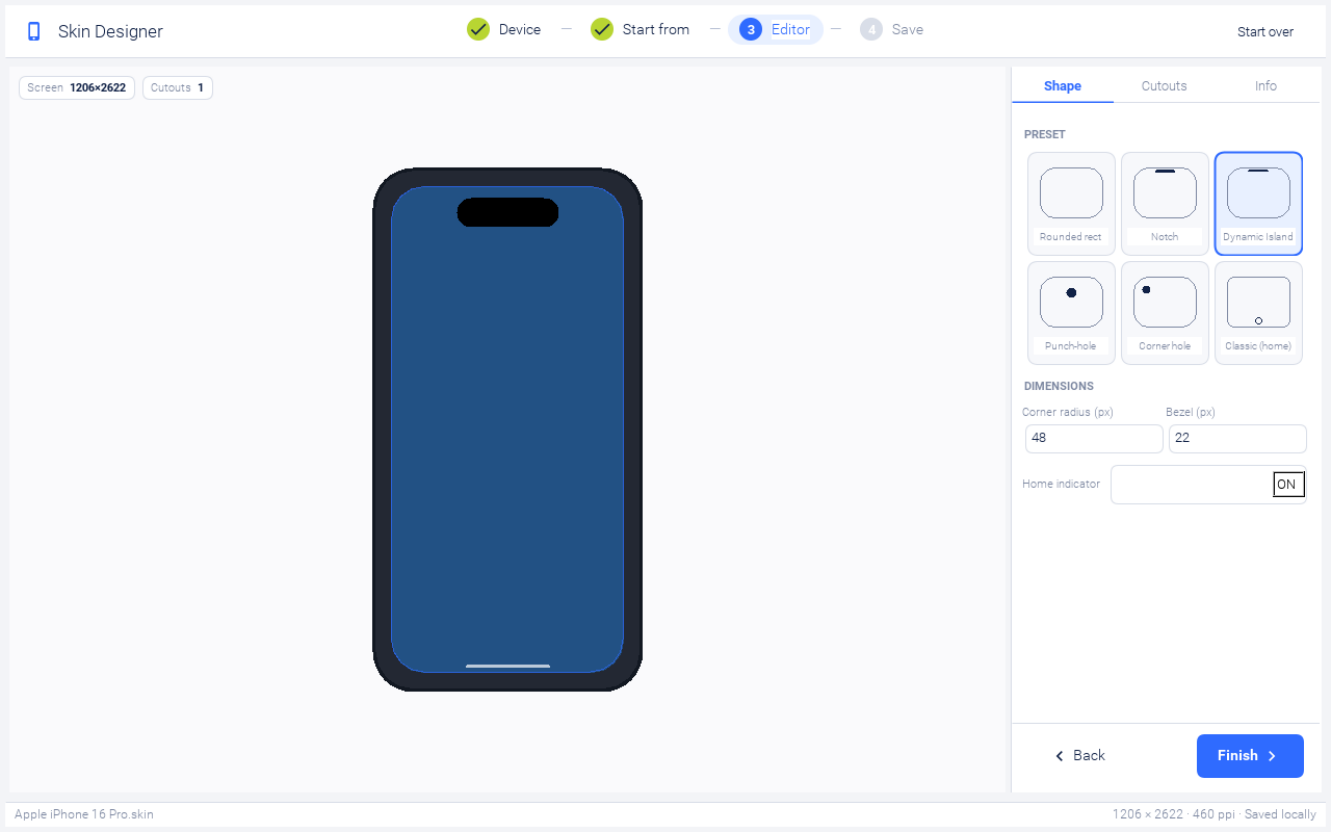
The first step shows a card per device from the bundled catalog. Use the search box to filter by name (it matches both the model and the brand) and the chips below to narrow by form factor: **All** / **Phones** / **Tablets** / **Foldables**. Tapping a card selects the device and enables the **Continue** button in the footer.

Picking a device pulls in its resolution, PPI, screen size, default safe-area insets, and the iOS / Android system font names from the device catalog, then seeds a sensible starting frame: notch, island, or hole presets are applied automatically based on the device's hardware.

The catalog is large. The grid is capped to the most recent matches by default; type into the search field to find older or less-common devices. The `Showing X of Y` hint between the chips and the grid tells you when you're looking at a clamped subset.

135.2. Stage 2 — pick a starting source

Three ways exist to seed the skin's body image:



Pick a shape — generates the device frame procedurally from a small preset library (rounded rect, notch, dynamic island, punch-hole, corner hole, classic home-button). The frame is rendered as a dark gradient with the screen rect (and any cutouts) carved into it. Best when you want a generic-looking iPhone or Android frame and don't care about exact hardware fidelity.

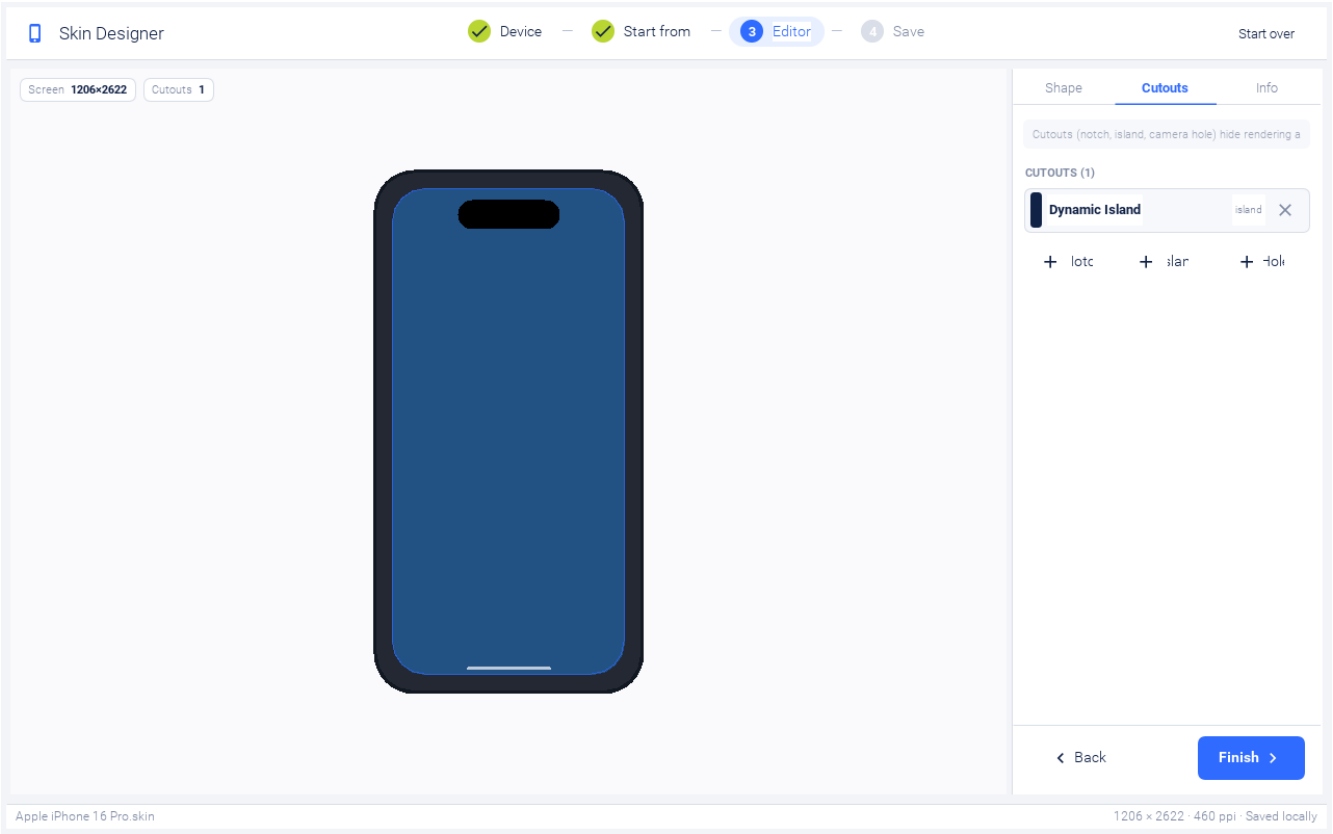
Upload an image — opens an image picker. The wizard scales the image into the device's resolution, then carves the screen rect (and cutouts) on top. Use this when you have a marketing render of the specific device you're targeting.

Blank rectangle — collapses the bezel and corner radius to almost nothing, drops every cutout, and turns the home indicator off. The screen fills the entire skin. Useful for desktop / web simulators where the device frame would just be visual noise.

Hover over a card on desktop to see the blue selection ring; click to advance to the editor.

135.3. Stage 3 — the editor

The editor is split into two panes: a live preview on the left that paints the device frame, screen tint, cutouts, and home indicator, and a sidebar on the right with three tabs.



135.3.1. Shape tab

When you started from **Pick a shape**, the Shape tab shows a preset grid (**Rounded rect** / **Notch** / **Dynamic Island** / **Punch-hole** / **Corner hole** / **Classic home**) and dimension fields:

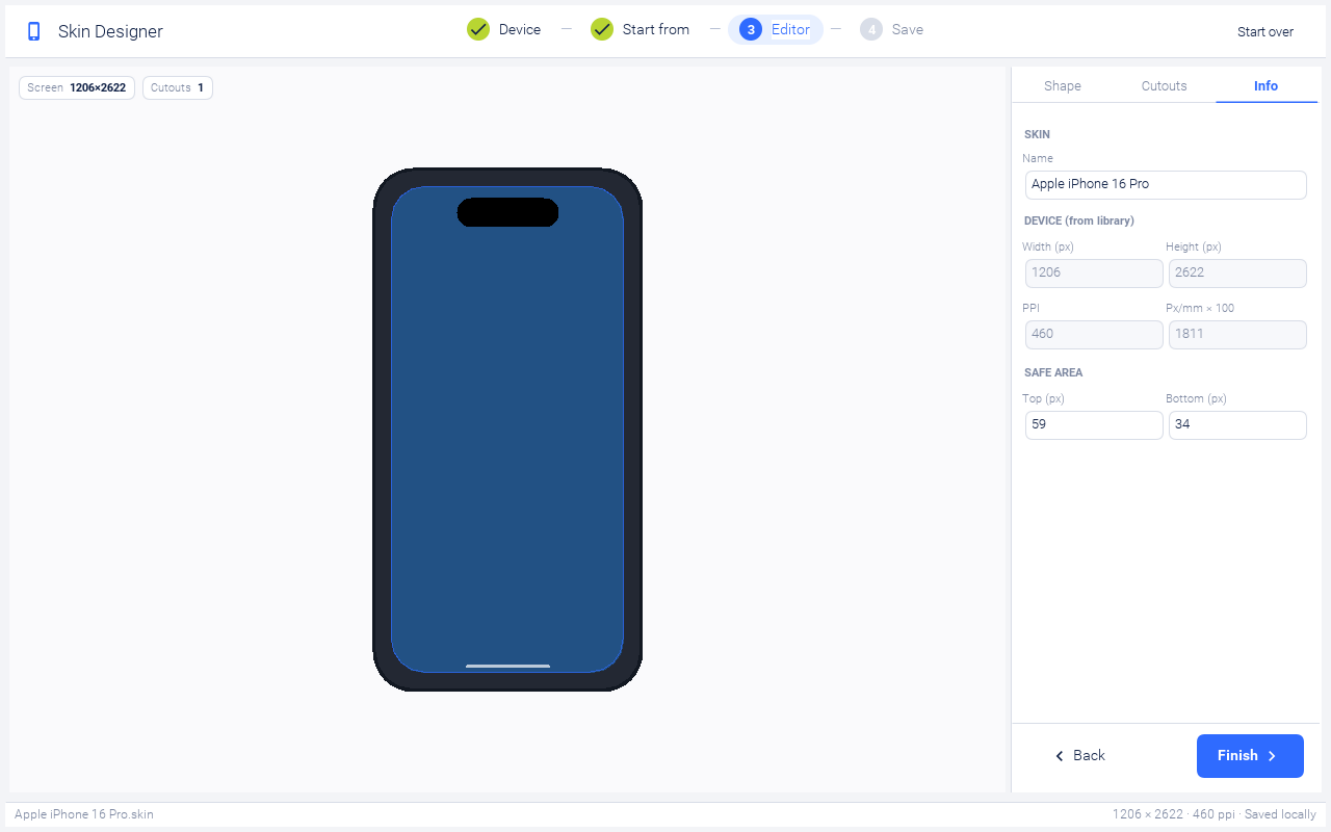
- **Corner radius** — the device's outer corner radius in viewbox pixels (the design uses a 320 × 620 viewbox; the actual skin image is scaled to the device's resolution).
- **Bezel** — frame thickness in viewbox pixels. The screen rect is positioned at `(bezel, bezel)` inside the skin image.
- **Home indicator** — toggles the lime pill drawn at the bottom edge. iPhones from X onward and most modern Androids should leave this on; classic devices with a hardware home button should turn it off.

When you started from **Upload an image**, the Shape tab swaps the preset grid for a **Replace image** button so you can swap the body image without restarting the wizard.

135.3.2. Cutouts tab

The Cutouts tab lists every cutout currently on the skin. Tap a row to expand its width / height / offset fields; the X button on the right removes it. The three add buttons at the bottom seed a sensible default of each type:

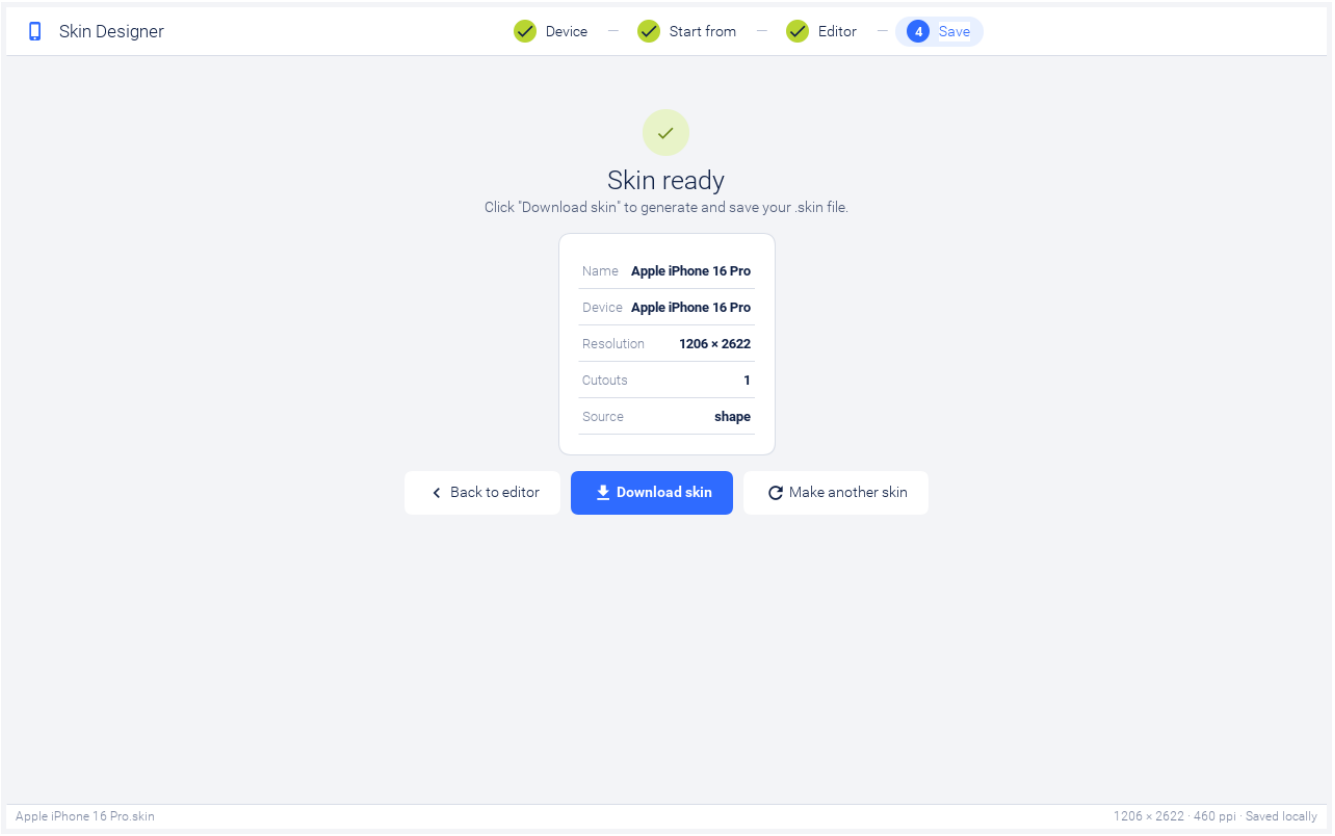
- **Notch** (180 × 30 viewbox px) — the iPhone X / 11 / 12 / 13 hardware cutout. Drawn as an opaque shape hanging from the top edge **inside** the screen rect, square at the top and rounded at the bottom, because that's where it sits on the hardware: an iPhone 13 Pro Max reports 1284 × 2778 pixels and the notch eats into the top of that rectangle.
- **Island** (120 × 35) — Dynamic Island. Software-reserved space rendered as an opaque pill inside the screen rect, floating on top of the iOS status bar.
- **Hole** (28 × 28) — Android punch-hole camera. Rendered like the island: opaque circle inside the screen rect.



Offsets are relative to the top-center of the screen, in viewbox pixels. For islands and holes, `Offset Y` is the gap between the cutout's top edge and the screen top. For notches, `Offset Y` is ignored, because a notch is anchored to the screen's top edge.

The wizard also writes each cutout's rectangle into the `cutouts` property. The simulator drops pointer events that land inside one, so a click on an opaque notch or island can't reach app content hidden underneath it, the way the hardware cutout can't be touched at all.

When the wizard generates the `.skin` file, it automatically pushes `safePortraitY` down to the lowest cutout edge whenever that sits below the platform's own status-bar inset, so app content lands below the shape instead of underneath it. You don't need to adjust the safe area for a cutout yourself; only adjust it if you want extra padding above your title bar.



135.3.3. Info tab

The Info tab is mostly read-only and shows what's about to be written into `skin.properties`:

- **Name** — the only editable field. Determines the saved file name (sanitised: spaces become hyphens, special characters dropped, appended with `.skin`).
- **Width** / **Height** — display resolution from the device catalog.
- **PPI** / **Pixels per millimeter** — the simulator uses `pixelMilliRatio = ppi / 25.4` to derive font sizes when none are specified in the skin.
- **Safe area Top** / **Bottom** — the user-editable safe-area insets, in the density-independent units the platform vendors publish: points on iOS, dp on Android. A notched iPhone reserves 47pt at the top and 34pt at the bottom, a Dynamic Island iPhone 59pt and 34pt, and an iPad 24pt on both edges. The wizard multiplies them by the device's density scale to get the display-relative pixel insets it writes into `skin.properties`, so the same 47 is correct on every notched iPhone regardless of resolution.

135.4. Stage 4 — finish and download

Clicking **Finish** in the editor's footer:

1. Renders the portrait skin image (`skin.png`) at the device's actual resolution plus the bezel on all four sides, with rounded corners, a transparent screen, opaque cutouts painted on that screen, and a home indicator if enabled.
2. Synthesises the landscape skin (`skin_l.png`) by 90° rotation.
3. Writes `skin_map.png` / `skin_map_l.png` overlays that mark the screen rectangle for the simulator's screen-position detection.
4. Bundles the appropriate native theme (`iOS7Theme.res`, `android_holo_light.res`, or `winTheme.res`) inside the skin zip.
5. Writes `skin.properties` with `roundScreen=true`, `displayX/Y/Width/Height`, `safePortrait*` / `safeLandscape*`, `cutouts`, the platform name, override names, fonts, and PPI.

Clicking **Download skin** on the done page hands the file to the browser's download dialog. The button is the only reliable trigger because the browser's user-gesture window expires during the heavy image-generation step that **Finish** runs.

After the file is on disk, drop it into your simulator's skins folder (or use the **Add** command in the simulator's **Skins** menu) and your new device should appear in the picker.

135.5. File layout of a generated skin

A generated `.skin` is just a renamed zip. Unzip it to see the layout:

```
Apple-iPhone-16-Pro.skin/
  skin.png            # portrait body (device frame + transparent screen + cutouts)
```

```
  skin_l.png          # 90° rotated portrait
  skin_map.png        # black rect = screen, white = frame, used for hit-testing
  skin_map_l.png      # rotated map
  iOS7Theme.res       # bundled native theme (or android_holo_light.res / winTheme.res)
  skin.properties     # platform metadata, safe-area, PPI, display rect
```

The `skin.properties` file is a normal Java `.properties`. The most important keys the wizard writes:

```
touch=true
platformName=ios
tablet=false
ppi=460
pixelRatio=18.110236220472443

# roundScreen=true makes the simulator paint skin.png *over* the rendered
# UI rather than clipping the UI to non-frame pixels. That overlay step is
# what makes the Dynamic Island / punch-hole shapes appear "floating" on
# top of the iOS status bar instead of being carved out of the display.
roundScreen=true
displayX=151
displayY=151
displayWidth=1206
displayHeight=2622

# The cutouts the skin paints on the screen, as display-relative
# x,y,w,h rectangles separated by ";". The simulator drops pointer events
# inside them, so a click on the opaque island cannot reach app content
# hidden underneath. A skin that omits this key keeps every cutout
# clickable.
cutouts=377,53,452,132

# Safe area in display-relative coordinates (origin = screen top-left),
# in PIXELS. The Info tab's Top/Bottom fields are points (iOS) or dp
# (Android); the wizard multiplies them by the device's density scale.
# Here the Dynamic Island's bottom edge sits below the 59pt status-bar
# inset, so it is the island that sets safePortraitY.
safePortraitX=0
safePortraitY=185
safePortraitWidth=1206
safePortraitHeight=2335
# skin_l.png is skin.png rotated clockwise, so the portrait TOP inset lands
# on the landscape RIGHT edge. X therefore carries the BOTTOM inset (34pt x
# 3), and the 185px island inset is what is left on the right.
safeLandscapeX=102
safeLandscapeY=0
safeLandscapeWidth=2335
safeLandscapeHeight=1206

# These get composed by overrideNames(device) — they let users layer
# device-specific styling on top of the platform theme via
```

```
# UIManager.addThemeProps()-style theme inheritance.
overrideNames=phone,ios,iphone

systemFontFamily=SF Pro
proportionalFontFamily=SF Pro
monospaceFontFamily=SF Mono
```

The wizard intentionally does **not** write `smallFontSize`, `mediumFontSize`, or `largeFontSize`. When those are absent the simulator automatically derives them from `pixelMilliRatio` (`med = round(2.6 * ppmm)`, `sm = 2 * ppmm`, `la = 3.3 * ppmm`), which is what you want on high-PPI screens. Writing iOS-style point values (12 / 15 / 22) into the file used to make text render at sub-millimeter sizes on a 460 PPI device.

Appendices

Chapter 136. Promises

`com.codename1.util.promise.Promise` is an implementation of the JavaScript promise for Codename One. It exists to compose asynchronous work without nesting a callback inside a callback inside a callback: each step is a value you can hand around, chain onto and combine with others.

Two method names differ from the JavaScript originals, because `catch` and `finally` are Java keywords. `except` takes the place of `catch`. `always` runs for either outcome, but it isn't a `finally`: it's implemented as `then(f, f)`, so whatever the functor returns becomes the value of the promise `always` hands back. Returning `null` after a rejection resolves the rest of the chain instead of keeping it rejected, and returning `null` after a success replaces the value. Returning the incoming value keeps a successful chain unchanged, but it doesn't preserve a rejection: any non-promise return is treated as a result, so returning the `Throwable` fulfils the chain with it. To stay rejected you have to throw, because `processThens` catches what a functor throws and rejects with it — but `Functor.call` declares no checked exceptions, so a checked reason can't simply be rethrown. Wrap it, as `throw new RuntimeException(err)`, or return a promise you rejected with the original reason, whose state the chain adopts.

136.1. Creating and consuming one

The constructor takes an `ExecutorFunction`, which receives the two functions that settle the promise. It runs immediately, on the calling thread:

```
Promise<String> greeting = new Promise<>((resolve, reject) -> {
    // called once, on whatever thread you start the work from
    Log.p("working");
    resolve.call("hello");
});

// ready() attaches both callbacks to this promise. Chaining
// onSuccess().onFail() instead would attach the failure handler to the
// promise onSuccess returns, which has already put the default casting
// rejection functor in the way
greeting.ready(
        value -> Log.p(value),
        err -> Log.e(err));
```

Resolution is marshalled for you. `resolve` and `reject` check whether they're on the EDT and hand themselves to `callSerially` when they aren't, so the callbacks you attach always run on the EDT and can touch the UI directly. That is worth contrasting with `EasyThread`, whose result callback stays on the worker thread.

136.2. Chaining

There are two families of callback and the difference is what they return. `then`, `except` and `always` take a `Functor`, whose return value becomes the input of the next step — that's what makes a chain a pipeline. `onSuccess`, `onFail` and `onComplete` take a `SuccessCallback` instead, which returns nothing,

so they suit the end of a chain where there is no value to pass on. Attach both outcomes with `ready(success, failure)` rather than chaining `onSuccess(…).onFail(…)`: the second form hangs the failure handler off the promise `onSuccess` returns, one link further down the chain than the promise whose failure you meant to catch:

```
// then() pipes the return value of one step into the next, so each
// Functor has to return something
Promise<String> name = Promise.resolve("ada");
name.then(
        n -> ((String)n).toUpperCase(),
        // a rejection functor is optional -- omit it and the reason
        // passes through untouched to the next handler. Supply one, as
        // here, and it has to rethrow: anything RETURNED from it
        // RESOLVES the rest of the chain, so returning null would run
        // the steps below on a failure. Functor.call declares no
        // checked exception, hence the wrap
        err -> { throw new RuntimeException((Throwable)err); })
    .then(upper -> "Hello " + upper)
    .ready(
        msg -> Log.p((String)msg),
        err -> Log.e((Throwable)err));
```

`getState()` reports `Pending`, `Fulfilled` or `Rejected`, and `getValue()` returns the resolved value once there is one.

A `then` given only a success functor passes a rejection straight through to the promise it returns, carrying the original reason, so an `IOException` from a network call arrives at your `except` as that `IOException`. The success functor is skipped for a rejected promise, which is why a chain can end in a single `except` rather than handling failure at every link.

136.3. Combining several

`all` and `allSettled` both take a varargs list of promises and return one promise, and they differ in how they treat a failure:

```
Promise<String> a = Promise.resolve("one");
Promise<String> b = Promise.resolve("two");

// all() rejects the moment any input rejects
Promise.all(a, b).onSuccess(values -> Log.p("both arrived"));

// allSettled() waits for every input whatever the outcome
Promise.allSettled(a, b).onSuccess(results -> Log.p("all finished"));
```

`all` rejects as soon as any input rejects, so it fits work where one failure makes the rest pointless. Don’t depend on which error you get when several inputs fail. A handler attached before the rejections arrive is drained by the first one, while a handler attached afterward reads the stored

error, which each later rejection overwrites. `allSettled` waits for every input whatever happens to each, which fits independent tasks. It resolves with the original array of promises rather than a list of outcome descriptors, so inspect each one with `getState()` and `getValue()`. There's no getter for a rejected promise's error, so attach a failure handler to an input if you need to see why it failed.

136.4. Working with AsyncResource

Much of the framework returns `AsyncResource` rather than a promise, and the conversion goes both ways:

```
// an AsyncResource-returning API becomes a Promise
Promise<String> p = Promise.promisify(asyncCall());

// and back again, for an API that expects AsyncResource
com.codename1.util.AsyncResource<String> back = p.asAsyncResource();

// await() blocks with invokeAndBlock, so it is safe on the EDT; it
// throws AsyncResource.AsyncExecutionException if the promise rejected
String value = p.await();
Log.p(value + back.getClass().getName());
```

`await()` is the blocking form. It waits through `invokeAndBlock`, so calling it on the EDT doesn't freeze the UI, and it throws `AsyncResource.AsyncExecutionException` when the promise rejected.

A promise from `promisify` never settles if the underlying `AsyncResource` is cancelled **after** `promisify` registered on it. `AsyncResource.cancel` records the cancellation and notifies its observers without running that callback, so the promise stays `Pending` and an `await()` waits forever. A resource already cancelled beforehand is fine: registering on a resource that has finished with an error fires the callback straight away. Don't await a promise wrapping a resource something else can cancel.

Chapter 137. Plugins

A plugin lets a library take over a framework call before the platform sees it. `com.codename1.plugin.Plugin` is the hook, `PluginSupport` is the registry, and the calls that can be intercepted announce themselves by firing a `PluginEvent`.

137.1. Writing one

`Plugin` extends `ActionListener<PluginEvent>` and adds nothing, so a plugin is one `actionPerformed` method that receives every event fired while it's registered. Check the event type, answer through `setPluginEventResponse`, and call `consume()` to say the framework should use your answer:

```
class GalleryPlugin implements Plugin {
    public void actionPerformed(PluginEvent evt) {
        if (evt instanceof IsGalleryTypeSupportedEvent) {
            IsGalleryTypeSupportedEvent e = (IsGalleryTypeSupportedEvent)evt;
            if (e.getType() == Display.GALLERY_VIDEO) {
                // answer instead of the platform, and stop the dispatch
                e.setPluginEventResponse(Boolean.TRUE);
                e.consume();
            }
        }
    }
}
```

Consuming is what makes the interception happen. `Display.isGalleryTypeSupported` fires the event, and when it comes back consumed it returns `getPluginEventResponse()` rather than asking the platform. Leave the event alone and the platform answers as usual, so a plugin that recognizes nothing costs only the call.

137.2. Registering

The registry is a single instance reachable from `CN`:

```
PluginSupport support = CN.getPluginSupport();
Plugin p = new GalleryPlugin();
support.registerPlugin(p);
// ... later, when the plugin should stop taking part
support.deregisterPlugin(p);
```

`firePluginEvent` copies the plugin list under a lock and walks the copy, checking `isConsumed()` before each plugin. The first consumer therefore ends the dispatch, and plugins registered after it never see that event. Registering and deregistering during dispatch is safe, because the copy is what's being walked.

137.3. What can be intercepted

Two events exist today, both fired by `Display` around the gallery:

- `IsGalleryTypeSupportedEvent` is a `PluginEvent<Boolean>` carrying the gallery type. Answer it to claim support for a type the platform doesn't offer.
- `OpenGalleryEvent` is a `PluginEvent<Void>` carrying the type and the `ActionListener` waiting for the result. Consume it to open your own picker and call that listener yourself.

The mechanism is general — `PluginEvent` is public and `firePluginEvent` takes any subclass — so the set of interception points grows as the framework fires more of them.

Appendix A: Project archetypes

A.1. Codename One application project archetype (cn1app-archetype)

The `cn1app-archetype` is the basis for all Maven Codename One application projects. Two properties choose the shape of the project it generates:

`platformModules`

The platform modules to generate. The default, `none`, is the minimal layout: the root `pom.xml` and the `common` module, and nothing else. `all` generates a module for each platform (`javase`, `android`, `ios`, `javascript`, `win` and `linux`), and a comma-separated list such as `javase,android` generates just those.

`projectType`

`app` (the default), `app-with-backend`, which adds the `backend` module (see the backend chapter), or `backend-only`, which generates a server on its own: a single module at the root with no application.

`-DplatformModules=all -DprojectType=app-with-backend` generates the full multi-module layout.

A.1.1. Projects without platform modules

The platform modules are optional. When a platform has no module, the `common` module builds it: `./build.sh android` and `mvn package -Dcodename1.platform=android` work the same with or without an `android` module, and so do the simulator, the desktop app and the unit tests. A platform has a module of its own exactly when `<platform>/pom.xml` exists, so you can add one later, for example to give that platform its own build plugins or dependencies, and from then on the module builds that platform instead of `common`.

Native interface implementations live in the same directories either way. `mvn cn1:generate-native-interfaces` creates `android/src/main/java`, `ios/src/main/objectivec`, `javase/src/main/java` and the others as needed, without a `pom.xml`, and the build picks them up from there. The Java SE implementations are compiled into `common/target/cn1-javase/classes`, apart from the application's own classes, so they never reach a device build.

A project without a `javase` module keeps the desktop app's native theme in `common/src/desktop/resources`. `mvn package -Pexecutable-jar -Dcodename1.platform=javase` writes the desktop jar to `common/target`.

The desktop jar is one archive for Windows, macOS and Linux, so it carries the media libraries of all three. This layout adds them without being asked. A project with a `javase` module packages the libraries of the machine that builds it unless the command passes `-Dcn1.ffmpeg.allPlatforms=true`, which the generated `build.sh`, `build.bat` and IDE launchers do. Add the property to a launcher written before it existed; the build prints a warning when it's missing.

A.1.2. Backend-only projects

A project generated with `-DprojectType=backend-only` is a server and nothing else: a `pom.xml`, `application.properties` and the sources under `src/main/java`, all at the root. The commands drop the module and the profile:

```
./mvnw cn1:backend           # run it on this JVM
./mvnw cn1:backend-package   # build the native binary
```

See Getting Started with the Bare-Bones Java App Template [https://shannah.github.io/cn1-maven-archetypes/cn1app-archetype-tutorial/getting-started.html] for details on using this archetype.

Also see Section 2.2.2.2.2, “Bare-bones Java project” for an example using this archetype from the command-line to create a bare-bones Java project.

A.2. Codename One library project archetype (cn1lib-archetype)

The `cn1lib-archetype` provides a project for building Codename One libraries. See Section 2.5, “Codename One libraries” for details on using this archetype.

Appendix B: Maven goals

B.1. Codename One build (`build`)

The `build` goal is used to send builds to the Codename One build server. It also supports a few local build targets, such as `ios-source`, which generates an Xcode project, and `android-source` which generates an Android Gradle project.

This goal is bound to the `package` phase of the Section A.1, “Codename One application project archetype (cn1app-archetype)”, so you don’t need to run this directly.

B.1.1. Example

Listing 32. Submitting a Mac Desktop build directly using this goal:

```
mvn cn1:build -Dcodename1.platform=javase -Dcodename1.buildTarget=mac-os-x-desktop
```

B.1.2. Properties

codename1.platform

Specifies the platform to build for. Values include Java SE, android, ios, JavaScript, and win.

codename1.buildTarget

The build target. Different platforms support different build sets of build targets.

Build Target	Platform	Description
mac-os-x-desktop	Java SE	Sends a Mac desktop build to the Codename One build server.
windows-desktop	Java SE	Sends a Windows desktop build to the Codename One build server.
android-device	android	Sends an Android build to the Codename One build server.
android-source	android	Generates an Android Gradle project locally that can be opened and built in Android Studio.
ios-device	ios	Sends an iOS build to the Codename One build server.
ios-source	ios	Generates an iOS Xcode project locally that can be opened and built in Xcode.

Build Target	Platform	Description
JavaScript	JavaScript	Sends a JavaScript build to the Codename One build server.

automated

Set to `true` to submit build as an automated build. When using this flag, the goal will wait for the build server to complete the build, then download it and save it in the target directory (of the associated module) using standard maven artifact file naming conventions. This allows you to set up automated CI workflows more.

Default value is `false`.

Requires a Codename One enterprise subscription.

open

If set to `true`, this will automatically open the generated Gradle or Xcode project in Android studio or Xcode. Only applicable to the `ios-source` and `android-source` buildTargets.

Default is `false`

B.2. Generate legacy cn1lib (`cn1lib`)

This goal generates a legacy.cn1lib file. It's bound to the `package` phase of `cn1lib-archetype` projects so you will never need to run this goal directly.

B.2.1. Output location

This will output the cn1lib file inside the common/target directory of the root multimodule maven project.

B.3. Compliance check (`compliance-check`)

Checks API usage in the project's "common" module to ensure that it doesn't use any classes or methods that aren't supported by Codename One.

This goal is bound to the `process-classes` phase of both Section A.1, "Codename One application project archetype (cn1app-archetype)" projects and Section A.2, "Codename One library project archetype (cn1lib-archetype)" projects, so you shouldn't ever need to run this goal directly.

B.4. Compile CSS (`css`)

Compiles the project's CSS files, generating a `theme.res` file which is placed in the build/classes directory.

The compiler runs without a window or a display, so the goal works unchanged over SSH, in a container, and on a continuous integration server. When a style has no native equivalent in Codename One, the compiler paints the image for it during this goal and stores it in `theme.res`. Local

stylesheets named by `@import` are inlined into the result. See Border and Splitting a stylesheet with `@import` in the CSS chapter.

This goal is bound to the `process-classes` phase of Section A.1, “Codename One application project archetype (cn1app-archetype)” projects, so you shouldn’t need to run this goal directly.

B.5. Generate app project (`generate-app-project`)

Generates a Maven project using the Section A.1, “Codename One application project archetype (cn1app-archetype)” as a basis, and applying an optional project template. This goal can also be used to migrate legacy Codename One Ant-based Application projects into maven.

B.5.1. Usage example

This goal shouldn’t be run inside an existing Maven project directory. It will output a project into a directory named after the `artifactId` parameter.

Because there is no existing project, you will need to provide the full maven path to the goal:

```
mvn com.codenameone:codenameone-maven-plugin:$CN1VERSION:generate-app-project \
  -DsourceProject=/path/to/my/ProjectTemplate \
  -DgroupId=com.example \
  -DartifactId=myapp \
  -Dcn1Version=$CN1VERSION
```

Substitute the latest Codename One plugin version, listed as `<release>` in the repository metadata [https://repo.codenameone.com/maven2/com/codenameone/codenameone-maven-plugin/maven-metadata.xml], for the `$CN1VERSION` in the above example. Because this goal runs outside any project, Maven can only find that version if you have configured the Codename One repository in your Maven settings; see the *Configuring the Codename One repository* section of Creating a new project.

This command is formatted for the bash prompt (for example, Linux or Mac). It will work on Windows also if you use bash. If you’re on Windows and are using PowerShell or the regular command prompt, then you’ll need to modify the command slightly. In particular, the entire command would need to be on a single line. (Remove the '\' at the end of each line, and merge lines together, with space between the command-line flags)

In the above example, assuming all went well, it would output your project into a directory named `myapp`.

B.5.2. Parameters

cn1Version

The Codename One version that you want to use for the project. This will be manifested as the

`cn1.version` and `cn1.plugin.version` properties in the common/pom.xml file of the generated project. If omitted it will default to the cn1Version that's hard-coded in the cn1app-archetype artifact.

sourceProject

The path to an optional project template to use. This may be either a legacy Ant project, or a Maven project that follows the structure of Section A.1, "Codename One application project archetype (cn1app-archetype)".

artifactId

The `artifactId` to use for the new project.

groupId

The `groupId` to use for the new project.

version

The `version` to use for the new project. Optional.

Default value is "1.0-SNAPSHOT"

packageName

The package name to use for the new project.

This is necessary if the `sourceProject` property is a Maven project. If the `sourceProject` is a legacy Ant project, then this property is ignored.

mainName

The main class name to use for the new project.

This is necessary if the `sourceProject` property is a Maven project. If the `sourceProject` is a legacy Ant project, then this property is ignored.

B.5.3. Migrating legacy Ant projects into Maven

When providing an Ant-based Codename One application project as the `sourceProject` parameter, this goal will generate an equivalent Maven project to the Ant project, with the same settings and sources.

See Section 2.2.3, "Migrating an existing project" for examples using this goal to migrate an existing project into Maven.

B.5.4. Project templates

When using a Section A.1, "Codename One application project archetype (cn1app-archetype)" maven project as the `sourceProject` parameter, the project will be treated project template, and perform some basic processing of the source files as necessary convert the template into a **real** project. This includes replacing all occurrences of `${mainName}` and `${packageName}` in project sources with the value of the `mainName` and `packageName` parameters provided on the command-line.

Any occurrences of `mainName` and `packagePath` in file or directory names will be swapped with the values of `mainName` and `packagePath` (which is automatically derived from `packageName` by substituting '.' with file separators).

The `generate-app-project.rpf` file

The (optional) secret sauce that differentiates a regular Maven project from a Maven project template is the existence of a `generate-app-project.rpf` file in the root project directory. This file is in rich property file format, and allows you to define a minimal amount of configuration details that the `generate-app-project` goal needs to convert the template into a real project.

This file may contain the following properties:

template.mainName

The name of the main class that's used in this project. This property isn't required if the project is already using the `mainName` placeholder in the file name that contains the main class, and the `${mainName}` placeholder in any source code referring to the main class.

Often times it's easier to specify this property here rather than injecting placeholders into the template source base, because that way the template itself can be used as a valid project.

template.packageName

The package name for the app. This property isn't required if the project is already using the `packagePath` placeholder in directories containing your main package files, and the `${packageName}` placeholder in any source code that refers to the main package.

Often times it's easier to specify this property here rather than injecting placeholders into the template source base, because that way the template itself can be used as a valid project.

template.type

Either `maven` or `ant`, depending on the project type.

dependencies

An XML snippet containing any more Maven dependencies that should be added to the project. This is handy of the project template relies on other cn1libs that are on Maven central.

Sample `generate-app-project.rpf` file

```
template.mainName=MyApp
template.packageName=com.example
template.type=maven

[dependencies]
====
<dependency>
  <groupId>com.codenameone</groupId>
  <artifactId>googlemaps-lib</artifactId>
  <version>1.0.1</version>
  <type>pom</type>
```

```
</dependency>
====
```

B.5.5. Sample: The bare-bones Kotlin app project

As a fuller example of a project template, see the generate-app-project.rpf [https://github.com/shannah/cn1app-archetype-kotlin-template/blob/master/generate-app-project.rpf] file in the bare-bones Kotlin app template [https://github.com/shannah/cn1app-archetype-kotlin-template].

This is the template that's used in Codename One initializr [https://www.codenameone.com/initializr] for the Bare-bones Kotlin project.

B.6. Clone project (`clone`)

Clones the current project as a new project with a different *groupId*, *artifactId*, *packageName*, and *mainName*. Resulting project will be made available in the *common/target/generated-sources/cn1-cloned-projects* directory.

B.6.1. Usage example

```
mvn cn1:clone \
  -DgroupId=com.example.newgroup \
  -DartifactId=newapp \
```

This command is formatted for the bash prompt (for example, Linux or Mac). It will work on Windows also if you use bash. If you're on Windows and are using PowerShell or the regular command prompt, then you'll need to modify the command slightly. In particular, the entire command would need to be on a single line. (Remove the '\' at the end of each line, and merge lines together, with space between the command-line flags)

In the above example, assuming all went well, it would output your project into a directory named `myapp`.

B.6.2. Parameters

artifactId

The `artifactId` to use for the cloned project.

groupId

The `groupId` to use for the cloned project.

B.7. Create GUI Form (`create-gui-form`)

The `create-gui-form` goal will generate a GUI form that can be edited in the GUI builder.

Basic Usage Example

```
mvn cn1:create-gui-form -DclassName=com.example.MyForm
```

The above example will generate a GUIBuilder form with the provided class name. It effectively generates two files:

1. `common/src/main/guibuilder/com/example/MyForm.gui`
2. `common/src/main/java/com/example/MyForm.java`

The paths above assume that this goal was run from the root multimodule maven project. If it were run inside the "common" submodule, then the files would be generated in the "src/main/..." directory of that module. (It would try to create yet another "common" submodule). See Project Structure [https://shannah.github.io/cn1-maven-archetypes/cn1app-archetype-tutorial/getting-started.html#_project_structure].

You can then open the GUI builder to edit this form using the `cn1:guibuilder` goal:

```
mvn cn1:guibuilder -DclassName=com.example.MyForm
```

B.7.1. Parameters

className

(Required) The class name of the form that you wish to generate. E.g `com.example.MyForm`.

guiType

The kind of GUI component to generate. Supports `Form`, `Dialog`, and `Container`. Default value is "Form"

autoLayout

Whether to use autolayout. This is boolean (true/false), and the default value is `true`.

B.8. Generate cn1lib project (`generate-cn1lib-project`)

Generates a Maven cn1lib project (using the cn1lib-archetype) given an ANT cn1lib project as a template.

This is to assist in migrating Ant projects to Maven projects. This won't make any changes to the source Ant project. It generates a new project using the Section A.2, "Codename One library project archetype (cn1lib-archetype)" and copies all files and configuration from the source project, into the new project.

B.8.1. Usage example

This goal isn't run in an existing maven project directory, so you need to include

> the absolute Maven coordinates for the goal.

Suppose you have an Ant Codename One library project at `/path/to/MyLegacyAntLibraryProject` and you want to convert it to a Maven project.

You can run the `generate-cn1lib-project` goal as follows:

Listing 33. Maven command to migrate an Ant project to Maven:

```
mvn com.codenameone:codenameone-maven-plugin:$CN1VERSION:generate-cn1lib-project \
  -DsourceProject=/path/to/MyLegacyAntLibraryProject \
  -DgroupId=com.example \
  -DartifactId=my-maven-lib \
  -Dversion=1.0-SNAPSHOT \
  -U
```

> Make sure you substitute the latest `codenameone-maven-plugin` version, listed as `<release>` in the repository metadata [https://repo.codenameone.com/maven2/com/codenameone/codenameone-maven-plugin/maven-metadata.xml], for the `$CN1VERSION` in this command. Because this goal runs outside any project, Maven can only find that version if you have configured the Codename One repository in your Maven settings; see the *Configuring the Codename One repository* section of Creating a new project.

Some notes about this command as shown above:

1. This command is formatted for Unix/Mac on multiple lines, using the `\` character to escape the new-lines. On Windows the command will need to be all one line, and you should omit those `\` escape characters.
2. The `-U` flag tells Maven to update its catalogs to ensure that it can find the `$CN1VERSION` that you specify.

If all goes well, you should find a new maven project generated in the "your-maven-lib" directory (named after the `artifactId` that you specified).

To test that the project was generated successfully, try opening the resulting project in your IDE or run its "install" goal on the command-line.

For example:

```
cd my-maven-lib
mvn install
```

After running the "install" command, you should be able to add your library as a dependency to a Section A.1, “Codename One application project archetype (cn1app-archetype)” project using the following dependency:

```
<dependency>
  <groupId>com.example</groupId>
  <artifactId>my-maven-lib-lib</artifactId>
  <version>1.0-SNAPSHOT</version>
  <type>pom</type>
</dependency>
```

Notice that the `artifactId` has an extra "-lib" appended. That is, it's `<artifactId>my-maven-lib-lib</artifactId>` and not `<artifactId>my-maven-lib</artifactId>`. This is because the `artifactId` that you specify in the `generate-cn1lib-project` goal is used for the "root" module of the multimodule maven project. The actual "lib" project that you can use as a Maven dependency is the "lib" submodule, which uses the specified artifactId with a "-lib" suffix.

See Section 2.5, “Codename One libraries” for more information about the resulting maven library project.

B.8.2. Properties

sourceProject

The path to the legacy Ant project that you want to convert to a Maven project.

groupId

The maven `groupId` to use for the resulting project.

artifactId

The maven `artifactId` to use for the resulting project.

version

The maven `version` to use for the resulting project. Default "1.0-SNAPSHOT"

B.9. Generate desktop app wrapper (`generate-desktop-app-wrapper`)

Generates the bootstrapping wrapper class for the Java SE desktop app. This is used by the `Java SE` module of Section A.1, “Codename One application project archetype (cn1app-archetype)” projects.

You shouldn't need to call this goal directly.

B.10. Generate GUI sources (`generate-gui-sources`)

Generates Java sources from the Codename One GUI builder files. This goal is bound to the `process-sources` phase of Section A.1, “Codename One application project archetype (cn1app-archetype)” projects, so you should never need to run this goal explicitly.

B.11. Generate native interfaces (`generate-native-interfaces`)

Generates stub implementations for all native interfaces defined in the project. This won't overwrite any existing implementations that may exist.

You should run this goal explicitly after you create a native interface in your class.

See the Codename One Developer guide section on native interfaces for more information on creating native interfaces.

B.11.1. Usage example

Suppose you've created a native interface as the Java interface `com.mycompany.myapp.MyNative`, as described in the example in native interfaces.

After creating this (and possibly other) native interfaces in your project, run the `generate-native-interfaces` Maven goal as follows:

```
mvn cn1:generate-native-interfaces
```

By default this generates Java/Objective-C stubs. You can optionally include Swift and Kotlin stubs (both off by default):

```
mvn cn1:generate-native-interfaces \
  -Dcn1.generateNativeInterfaces.swift=true \
  -Dcn1.generateNativeInterfaces.kotlin=true
```

This will generate the following files (if they don't exist yet).

Java SE

`javase/src/main/java/com/mycompany/myapp/MyNativeImpl.java`

iOS

1. `ios/src/main/objectivec/com_mycompany_myapp_MyNativeImpl.h`
2. `ios/src/main/objectivec/com_mycompany_myapp_MyNativeImpl.m`

Android

`android/src/main/java/com/mycompany/myapp/MyNativeImpl.java`

Android (optional Kotlin)

`android/src/main/java/com/mycompany/myapp/MyNativeImpl.kt`

JavaScript

`javascript/src/main/javascript/com_mycompany_myapp_MyNative.js`

iOS (optional Swift)

`ios/src/main/objectivec/com_mycompany_myapp_MyNativeImpl.swift`

Native Windows

`win/src/main/c/com/mycompany/myapp/MyNativeImplCodenameOne.c`

Native Linux

`linux/src/main/c/com/mycompany/myapp/MyNativeImplCodenameOne.c`

Open and edit these files to implement your native interface methods as desired.

A Gradle project runs the same generator as `./gradlew generateNativeInterfaces`, and writes the stubs under `src/<platform>/<lang>` instead; see Section 3.5, “Native interfaces”.

B.12. Generate OpenAPI client (`generate-openapi`)

Generates a typed Codename One client from an OpenAPI 3.x JSON specification. Writes one `@Mapped` record (Java 17+) or class (Java 8 target) per `components.schemas` entry and one `@RestClient`-annotated interface per OpenAPI tag. The generated files land in `common/src/main/java` so the project owns the contract; the matching networking implementation is emitted into `common/target/generated-sources` by the build-time annotation processor so the project source stays clean.

The mojo is paired with the existing `process-annotations` pipeline: identical schemas across operations collapse to one record/class, and operationIds become interface methods that resolve at runtime via a `com.codename1.io.rest.RestClients` registry populated by the generated bootstrap class (the same splice pattern as `@Mapped` mappers).

B.12.1. Usage example

```
mvn -pl common cn1:generate-openapi \
    -Dcn1.openapi.spec=petstore.json \
    -Dcn1.openapi.basePackage=com.example.petstore
```

Configuration:

Property	Description
`-Dcn1.openapi.spec=PATH`	Local file path or URL of the OpenAPI 3.x JSON document, for example `petstore.json` or `https://petstore3.swagger.io/api/v3/openapi.json`. YAML isn’t supported — convert with `yq` upstream.
`-Dcn1.openapi.basePackage=PKG`	Java package the generated sources are written under. Records / classes go under `<basePackage>.model`; the `@RestClient` interfaces go under `<basePackage>`.
`-Dcn1.openapi.outputDirectory=DIR` (optional)	Defaults to `${project.basedir}/src/main/java`.

Property	Description
`-Dcn1.openapi.overwrite=false` (optional)	Defaults to `true`. Set to `false` to preserve user edits to existing files (only missing files are written).

B.12.2. Generated output

The listings in this section are the goal's own output, generated from a Swagger Petstore specification cut down to the `pet`, `store` and `user` tags. That spec is in the repository at `docs/demos/common/src/main/snippets/developer-guide/appendix-goal-generate-openapi-petstore.json`, so you can run the goal against it and compare. The committed copies carry a license header and the `tag::` markers this guide includes them by; strip those two additions and the rest is exactly what the goal wrote.

One `@RestClient` interface per tag and one model per schema land under `common/src/main/java`:

```
com/example/petstore/
  PetApi.java          // @RestClient interface, methods addPet, updatePet,
                       // findPetsByStatus, getPetById, deletePet
  StoreApi.java        // @RestClient interface, methods placeOrder,
                       // getOrderById, deleteOrder
  UserApi.java         // @RestClient interface, methods createUser,
                       // getUserByName
com/example/petstore/model/
  Pet.java             // @Mapped record (Java 17+) or class (Java 8)
  Order.java
  User.java
  Category.java
```

`Tag.java` is missing from that list on purpose. The Petstore declares `Tag` and `Category` with the same two properties, and identical shapes collapse to one record, so `Pet.tags()` comes back typed as a list of `Category`. Give the two schemas different shapes if you want them to stay separate classes.

Each `@RestClient` interface method is annotated with the HTTP verb and path; parameters are annotated `@Path` / `@Query` / `@Header` / `@Body` so the processor knows how to assemble the `Rest` call. The emitted method shape:

```
@RestClient
public interface PetApi {

    @POST("/pet")
    void addPet(@Body com.example.petstore.model.Pet body, @Header("Authorization") String bearerToken, OnComplete
<Response<com.example.petstore.model.Pet>> callback);

    @PUT("/pet")
    void updatePet(@Body com.example.petstore.model.Pet body, @Header("Authorization") String bearerToken, OnComplete
<Response<com.example.petstore.model.Pet>> callback);

    @GET("/pet/findByStatus")
    void findPetsByStatus(@Query("status") String status, @Header("Authorization") String bearerToken, OnComplete
<Response<java.util.List<com.example.petstore.model.Pet>>> callback);

    @GET("/pet/{petId}")
```

```
    void getPetById(@Path("petId") Long petId, @Header("Authorization") String bearerToken, OnComplete<Response<com
.example.petstore.model.Pet>> callback);

    @DELETE("/pet/{petId}")
    void deletePet(@Path("petId") Long petId, @Header("Authorization") String bearerToken, OnComplete<Response<String>>
callback);

    static PetApi of(String baseUrl) {
        return RestClients.create(PetApi.class, baseUrl);
    }
}
```

The model type referenced by the generated API is emitted into the generated model package:

```
@Mapped
public record Pet(@JsonProperty("id") Long id, @JsonProperty("name") String name, @JsonProperty("category") com.example
.petstore.model.Category category, @JsonProperty("photoUrls") java.util.List<String> photoUrls, @JsonProperty("tags")
java.util.List<com.example.petstore.model.Category> tags, @JsonProperty("status") String status) {}
```

Model types are emitted as fully qualified names (the API interface lives in `<basePackage>` and models under `<basePackage>.model`) so the generator never needs to track imports or worry about collisions between an API class name and a same-named model.

Call sites use the static factory:

```
void loadPet(String bearerToken) {
    PetApi api = PetApi.of("https://petstore3.swagger.io/api/v3");

    api.getPetById(10L, bearerToken, response -> {
        // Two things have to be settled before the payload is a Pet.
        // The generated impl passes null when the request never
        // completed, and on an error status it forwards the raw
        // Response<String> under this type -- so on that path
        // getResponseData() is the error body, not a Pet, and
        // touching it as one is a cast that does not throw on iOS.
        if (response == null) {
            ToastBar.showErrorMessage("The request did not complete");
        } else if (response.getResponseCode() < 200 || response.getResponseCode() > 299) {
            ToastBar.showErrorMessage(response.getResponseErrorMessage());
        } else if (response.getResponseData() == null) {
            ToastBar.showErrorMessage("The server returned no pet");
        } else {
            ToastBar.showInfoMessage(response.getResponseData().name());
        }
    });
}
```

The call site here is written against the Java 17 output, where `Pet` is a record. On a Java 8 target the generator emits a class with public fields instead, so `pet.name()` becomes `pet.name`.

The <Tag>ApiImpl class that actually performs the HTTP call lives in target/generated-sources — the project source never references it directly. The build server probes the project zip for the generated cn1app.RestClientBootstrap and splices the registry wiring in, mirroring the existing cn1app.MapperBootstrap pattern.

B.12.3. Scope

- HTTP verbs: GET, POST, PUT, DELETE, PATCH.
- Parameter locations: path, query, header, cookie. Multiple cookie parameters on the same operation are joined into a single Cookie: a=1; b=2 request header.
- Request bodies: application/json — serialized via Mappers.toJson(body) before being attached.
- Response schemas: $ref resolution, primitives (string / number / integer / boolean), arrays, object schemas. oneOf / anyOf / allOf collapse to Object — callers cast.
- String enum schemas are emitted as Java enums and bound by the JSON mapper through each constant's name(), so a model property typed by an enum $ref gets the generated enum type. This requires every enum value to be a valid (non-reserved) Java identifier; an enum whose values are not — for example "two-day" — degrades to String rather than generating an enum that couldn't round-trip. Integer/number enums keep their numeric type.
- Schema unification: two components.schemas entries with identical property shapes collapse to a single record/class to avoid an explosion of duplicates.
- Authentication: bearer token is exposed as a @Header("Authorization") String bearerToken parameter on every operation. API-key auth declared in the spec is emitted as @Header or @Query like any other parameter; basic auth and OAuth bearer tokens travel through the same bearerToken slot.

B.13. Generate gRPC client (generate-grpc)

Generates a typed Codename One gRPC-Web client from a proto3 .proto specification. Writes one @ProtoMessage record (Java 17+) or class (Java 8 target) per message, one @ProtoEnum enum per enum, and one @GrpcClient-annotated interface per service. The generated files land in common/src/main/java so the project owns the contract; the matching protobuf codec and gRPC-Web call site are emitted into common/target/generated-sources by the build-time annotation processors so the project source stays clean.

The mojo is paired with the existing process-annotations pipeline: @ProtoMessage triggers per-class binary protobuf codec generation and a cn1app.ProtoBootstrap registration entry; @GrpcClient triggers per-interface <Service>GrpcImpl generation chained through com.codename1.io.grpc.GrpcWeb.invokeUnary(…) and a cn1app.GrpcClientBootstrap that wires everything to the com.codename1.io.grpc.GrpcClients registry (same splice pattern as @Mapped mappers).

B.13.1. Usage example

```
mvn -pl common cn1:generate-grpc \
    -Dcn1.grpc.proto=helloworld.proto \
```

```
    -Dcn1.grpc.basePackage=com.example.hello
```

Configuration:

Property	Description
`-Dcn1.grpc.proto=PATH`	Local path to the `.proto` file (proto3 syntax).
`-Dcn1.grpc.basePackage=PKG`	Java package the generated sources are written under. Messages, enums, and the `@GrpcClient` interface all land directly in `<basePackage>` (no nested model package — proto namespaces are flat by design).
`-Dcn1.grpc.outputDirectory=DIR` (optional)	Defaults to `${project.basedir}/src/main/java`.
`-Dcn1.grpc.overwrite=false` (optional)	Defaults to `true`. Set to `false` to preserve user edits to existing files (only missing files are written).

B.13.2. Generated output

For a `helloworld.proto` declaring `message HelloRequest`, `message HelloReply`, `enum Mood`, and `service Greeter { rpc SayHello(HelloRequest) returns (HelloReply); }`, the goal emits under `common/src/main/java`:

```
com/example/hello/
  HelloRequest.java     // @ProtoMessage record / class
  HelloReply.java
  Mood.java             // @ProtoEnum enum with `number` accessor
  GreeterGrpc.java      // @GrpcClient interface
```

Each `@ProtoMessage` carries one `@ProtoField(tag = N)` per field; scalar fields use the default varint wire kind, `sint32` / `sint64` use `wireType = ProtoField.WireKind.SINT`, and `fixed32` / `fixed64` / `sfixed32` / `sfixed64` use `wireType = ProtoField.WireKind.FIXED`. Renamed fields (e.g. `snake_case` → `camelCase`) carry the original proto name via the optional `name` attribute so introspection tooling can recover it.

The `@GrpcClient` interface looks like:

```
@GrpcClient("helloworld.Greeter")
public interface GreeterGrpc {

    @Rpc("SayHello")
    void sayHello(com.example.hello.HelloRequest request, @Header("Authorization") String bearerToken, OnComplete
<GrpcResponse<com.example.hello.HelloReply>> callback);

    static GreeterGrpc of(String baseUrl) {
        return GrpcClients.create(GreeterGrpc.class, baseUrl);
    }
}
```

Call sites use the static factory:

```
void sayHello(String bearerToken) {
    GreeterGrpc greeter = GreeterGrpc.of("https://grpc.example.com");
    HelloRequest request = new HelloRequest("Ada", Arrays.asList("ada", "countess"), Mood.HAPPY);

    greeter.sayHello(request, bearerToken, response -> {
        if (response.isOk() && response.getResponseData() != null) {
            ToastBar.showInfoMessage(response.getResponseData().message());
        } else if (response.isOk()) {
            ToastBar.showErrorMessage("The server returned an empty reply");
        } else {
            // getResponseCode() is the gRPC status, not the HTTP one --
            // a gRPC-Web call can carry a failure under HTTP 200.
            ToastBar.showErrorMessage("gRPC status " + response.getResponseCode()
                    + ": " + response.getResponseErrorMessage());
        }
    });
}
```

The call site above is written against the Java 17 output, where the messages are records. On a Java 8 target the generator emits classes with a public no-arg constructor and public fields instead, so construction becomes `new HelloRequest(); r.name = …` and a read is `reply.message` rather than `reply.message()`.

The `<Service>GrpcImpl` class that actually performs the gRPC-Web POST lives in `target/generated-sources` — the project source never references it directly. The build server probes the project zip for `cn1app.ProtoBootstrap` and `cn1app.GrpcClientBootstrap` and splices the registry wiring in, mirroring the existing `cn1app.MapperBootstrap` pattern.

B.13.3. Wire protocol

The runtime speaks **gRPC-Web binary** (`application/grpc-web+proto`) over HTTP/1.1, which is the standard mobile / browser variant of gRPC supported by Envoy, the official `grpcweb` Go proxy, and the gRPC-Web filter in modern gRPC server implementations. Plain HTTP/2 gRPC requires trailers that `ConnectionRequest` doesn't expose; gRPC-Web carries `grpc-status` in a synthetic trailer frame in the response body instead.

A successful call:

1. Encodes the request message via the build-time-generated `ProtoCodec` for the request type.
2. Wraps the encoded bytes in a 5-byte frame header (`flag + length`) and posts to `<baseUrl>/<service-fqn>/<method>` with `Content-Type: application/grpc-web+proto` and `X-Grpc-Web: 1`.
3. Reads the response body, iterates frames, accumulates data payload, and parses the trailer frame for `grpc-status` / `grpc-message`.
4. Decodes the accumulated payload via the response codec and invokes the supplied `OnComplete<GrpcResponse<T>>`.

B.13.4. Scope

- Unary RPCs (single request, single response). Streaming RPCs (`stream` keyword on request or response) are rejected at generation time — gRPC-Web client streaming requires HTTP/2.
- proto3 syntax. proto2 `required` is rejected; `optional` is accepted but treated as a nullable field.
- Scalar types: `int32`, `int64`, `uint32`, `uint64`, `sint32`, `sint64`, `fixed32`, `fixed64`, `sfixed32`, `sfixed64`, `float`, `double`, `bool`, `string`, `bytes`.
- `enum` declarations (nested or top-level) emit `@ProtoEnum` enums with a `public final int number` field and a `static T forNumber(int n)` lookup.
- Nested `message` declarations are emitted as top-level siblings in the same package so the generated codec layout stays flat.
- `repeated` fields land as `java.util.List<T>`. Scalar lists are encoded packed on the wire (proto3 default); the reader accepts both packed and unpacked forms.
- `oneof` collapses to a group of nullable fields on the parent message — the mutual-exclusion guarantee is lost but round-trips work. Use application code to enforce the invariant if needed.
- Not yet supported: `map<K, V>`, well-known types (Timestamp, Empty, etc.), file `import`, streaming RPCs. These produce a clear error from the parser pointing at the offending line.
- Authentication: a bearer token is exposed uniformly as a `@Header("Authorization") String bearerToken` parameter on every RPC method, mirroring the OpenAPI bearer-token slot.

B.14. Generate GraphQL client (`generate-graphql`)

Generates a typed Codename One GraphQL client from a GraphQL SDL schema, optionally driven by a set of operation documents. Writes one `@Mapped` record (Java 17+) or class (Java 8 target) per response shape and input type, a Java `enum` per GraphQL `enum`, and one `@GraphQLClient`-annotated interface carrying one method per operation. The generated files land in `common/src/main/java` so the project owns the contract; the matching client implementation and JSON mappers are emitted into `common/target/generated-sources` by the build-time annotation processors so the project source stays clean.

The mojo is paired with the existing `process-annotations` pipeline: the generated `@Mapped` types trigger per-class JSON mapper generation and a `cn1app.MapperBootstrap` entry, while `@GraphQLClient` triggers per-interface `<Name>Impl` generation chained through `com.codename1.io.graphql.GraphQL.execute(…)` (queries and mutations) or `com.codename1.io.graphql.GraphQL.subscribe(…)` (subscriptions), plus a `cn1app.GraphQLClientBootstrap` that wires everything to the `com.codename1.io.graphql.GraphQLClients` registry (same splice pattern as `@Mapped` mappers and `@GrpcClient` clients).

B.14.1. Usage example

```
mvn -pl common cn1:generate-graphql \
    -Dcn1.graphql.schema=schema.graphqls \
    -Dcn1.graphql.operations=operations.graphql \
```

```
    -Dcn1.graphql.basePackage=com.example.starwars
```

Configuration:

Property	Description
`-Dcn1.graphql.schema=PATH`	Local path to the GraphQL SDL schema (`.graphqls` / `.graphql`). Required: it supplies the type graph used to resolve field types.
`-Dcn1.graphql.basePackage=PKG`	Java package the generated sources are written under. Models, enums, input types, and the `@GraphQLClient` interface all land directly in `<basePackage>`.
`-Dcn1.graphql.operations=PATH` (optional)	Path to a `.graphql` operation-document file, or a directory of them. When supplied the generator runs in the precise operations mode (one method and one response-type tree per named operation). When omitted it falls back to the schema-only quick-start mode.
`-Dcn1.graphql.clientName=NAME` (optional)	Simple name of the generated `@GraphQLClient` interface. Defaults to `GraphQLApi`.
`-Dcn1.graphql.endpoint=URL` (optional)	Default endpoint URL recorded on the generated annotation. The effective endpoint is always the argument passed to `of(String endpoint)`.
`-Dcn1.graphql.maxDepth=N` (optional)	Maximum selection-set depth used by the schema-only quick-start mode. Defaults to `2`.
`-Dcn1.graphql.outputDirectory=DIR` (optional)	Defaults to `${project.basedir}/src/main/java`.
`-Dcn1.graphql.overwrite=false` (optional)	Defaults to `true`. Set to `false` to preserve user edits to existing files (only missing files are written).

B.14.2. Generation modes

Unlike OpenAPI paths or gRPC service methods, a GraphQL schema doesn't enumerate the operations a client wants — the client chooses which fields to select. The goal therefore supports two modes:

- **Operations mode** (recommended): supply `cn1.graphql.operations`. For each named `query` / `mutation` / `subscription` the generator emits one interface method plus a precise `@Mapped` response-type tree that mirrors exactly that operation's selection set (nested selections become nested generated types). Referenced fragment definitions are merged into the request document automatically.
- **Schema-only quick-start mode**: omit `cn1.graphql.operations`. For each field of the root `Query` / `Mutation` / `Subscription` type the generator emits one method whose selection set is automatically expanded to `cn1.graphql.maxDepth` levels, stopping at recursive types. This is a convenience for getting started; it may over- or under-fetch, so prefer operations mode for production code.

B.14.3. Generated output

For a Star Wars schema and an `operations.graphql` declaring `query HeroName`, `mutation AddReview`, and `subscription OnReview`, the goal emits under `common/src/main/java`:

```
com/example/starwars/
  Episode.java                // GraphQL enum -> Java enum
  ReviewInput.java            // @Mapped input type
  HeroNameData.java           // @Mapped query response root
  HeroNameData_Hero.java      // nested selection type
  AddReviewData.java          // @Mapped mutation response root
  OnReviewData.java           // @Mapped subscription response root
  StarWarsApi.java            // @GraphQLClient interface
```

GraphQL enums map to a generated Java `enum` in response types, input types, and method variables alike — the JSON mapper binds enums by their `name()`. Built-in scalars map to their boxed Java type (`Int` → `Integer`, `Float` → `Double`, `Boolean` → `Boolean`, `String` / `ID` → `String`); custom scalars fall back to `String`.

The `@GraphQLClient` interface looks like:

```
@GraphQLClient("https://example.com/graphql")
public interface StarWarsApi {

    @Query(value = "query HeroName($episode: Episode) { hero(episode: $episode) { ...HeroFields friends { name } } }
fragment HeroFields on Character { name }", operationName = "HeroName")
    void heroName(@Var("episode") Episode episode, @Header("Authorization") String bearerToken, OnComplete
<GraphQLResponse<HeroNameData>> callback);

    @Mutation(value = "mutation AddReview($ep: Episode!, $review: ReviewInput!) { createReview(episode: $ep, review:
$review) { stars commentary } }", operationName = "AddReview")
    void addReview(@Var("ep") Episode ep, @Var("review") ReviewInput review, @Header("Authorization") String bearerToken,
OnComplete<GraphQLResponse<AddReviewData>> callback);

    @Subscription(value = "subscription OnReview($ep: Episode!) { reviewAdded(episode: $ep) { stars } }", operationName =
"OnReview")
    GraphQLSubscription onReview(@Var("ep") Episode ep, @Header("Authorization") String bearerToken, GraphQLSubscription
.Handler<OnReviewData> handler);

    static StarWarsApi of(String endpoint) {
        return GraphQLClients.create(StarWarsApi.class, endpoint);
    }
}
```

Call sites use the static factory. Queries and mutations report through an `OnComplete<GraphQLResponse<T>>`:

```
void heroName(String bearerToken) {
    StarWarsApi api = StarWarsApi.of("https://swapi.example.com/graphql");

    api.heroName(Episode.EMPIRE, bearerToken, response -> {
        // isOk() classifies the GraphQL payload, not the trip: a call that
        // never reached the server, and a 2xx whose body would not parse,
```

```
        // both arrive with an empty errors array and null data, so isOk()
        // answers true for them. getResponseErrorMessage() is the one
        // thing that is null only on a clean success -- it carries the
        // first GraphQL error, the transport failure, or the parse
        // failure -- and the HTTP code catches an error status whose body
        // happened to decode.
        boolean reachedTheServer = response.getResponseCode() >= 200
                && response.getResponseCode() <= 299;
        if (!reachedTheServer || response.getResponseErrorMessage() != null) {
            ToastBar.showErrorMessage(response.getResponseErrorMessage());
        } else if (response.getData() == null || response.getData().hero() == null) {
            // And an error-free answer still need not have found anything:
            // the schema declares hero as Character, not Character!.
            ToastBar.showInfoMessage("No hero for that episode");
        } else {
            ToastBar.showInfoMessage(response.getData().hero().name());
        }
    });
}
```

The call sites here are written against the Java 17 output, where the response types are records. On a Java 8 target the generator emits classes with public fields instead, so `response.getData().hero().name()` becomes `response.getData().hero.name`.

A subscription returns a `GraphQLSubscription` handle whose `cancel()` ends the stream:

```
GraphQLSubscription watchReviews(String bearerToken) {
    StarWarsApi api = StarWarsApi.of("https://swapi.example.com/graphql");

    return api.onReview(Episode.JEDI, bearerToken,
            new GraphQLSubscription.Handler<OnReviewData>() {
        @Override
        public void onNext(GraphQLResponse<OnReviewData> response) {
            // onError is for the end of the stream. A per-field failure
            // arrives here instead, as a next payload whose errors array
            // is non-empty and whose data may be partial or absent.
            if (response.hasErrors()) {
                ToastBar.showErrorMessage(response.getResponseErrorMessage());
            }
            OnReviewData data = response.getData();
            if (data != null && data.reviewAdded() != null) {
                ToastBar.showInfoMessage(data.reviewAdded().stars() + " stars");
            }
        }

        @Override
        public void onError(GraphQLResponse<OnReviewData> response) {
            ToastBar.showErrorMessage(response.getResponseErrorMessage());
```

```
        }

        @Override
        public void onComplete() {
        }
    });
    // Hold on to the handle and call cancel() to end the stream --
    // leaving the form is the usual place to do it.
}
```

The `<Name>Impl` class that performs the request lives in `target/generated-sources` — the project source never references it directly. The build server probes the project zip for `cn1app.GraphQLClientBootstrap` and splices the registry wiring in, mirroring the existing `cn1app.MapperBootstrap` pattern.

B.14.4. Wire protocol

Queries and mutations are sent as an HTTP `POST` to the endpoint with a JSON body `{"query":…,"operationName":…,"variables":{…}}` and a `Content-Type: application/json` header. The response envelope (`{"data":…,"errors":[…]}`) is parsed into a typed `GraphQLResponse<T>`; because a GraphQL response can carry both data and errors, `GraphQLResponse` exposes `getData()` and `getErrors()` independently and `isOk()` reports whether the `errors` array was empty.

Subscriptions run over a WebSocket using the `graphql-transport-ws` protocol (offered via the `Sec-WebSocket-Protocol` handshake header): the client sends `connection_init`, waits for `connection_ack`, sends a `subscribe` message carrying the operation, and maps each `next` payload's `data` to `T` before delivering it to the handler. The WebSocket endpoint defaults to the query endpoint with its scheme rewritten to `ws` / `wss`; pass a `ws://` / `wss://` URL to `of(…)` to override it. All handler callbacks are dispatched on the EDT.

B.14.5. Scope

- Queries, mutations, and subscriptions.
- GraphQL enums map to generated Java enums in every position (response fields, input fields, and method variables); unknown enum names decode to `null` rather than throwing.
- Input object types map to generated `@Mapped` classes; variables of scalar, enum, input-object, and list types are supported.
- Named and inline fragments are resolved against the schema and merged into the generated response types and the request document.
- Built-in scalars (`Int`, `Float`, `Boolean`, `String`, `ID`) map to their boxed Java types. Custom scalars fall back to `String`.
- `union` / `interface` selections are emitted with their common fields in the quick-start mode; use explicit operation documents with inline fragments for full polymorphic typing.
- Authentication: a bearer token is exposed uniformly as a `@Header("Authorization") String bearerToken` parameter on every method, mirroring the OpenAPI and gRPC bearer-token slots.

B.15. GUIBuilder goal (`guibuilder`)

The `guibuilder` goal opens the Codename One GUI builder to edit a specified GUIBuilder form.

B.15.1. Usage

```
mvn cn1:guibuilder -DclassName=com.example.MyForm
```

This will open the GUI builder to edit the form whose class is `com.example.MyForm`.

B.15.2. Parameters

className

The fully qualified name to the form class that you wish to edit. This must have been earlier generated using Section B.7, “Create GUI Form (`create-gui-form`)”.

B.16. Generate archetype (`generate-archetype`)

This goal isn’t used. It was originally developed to simplifying the maintenance of multiple application archetypes, but this approach was later abandoned in favor of application project templates.

The `generate-archetype` mojo will generate a new archetype maven project based on an existing archetype project. It’s designed to ease the maintenance of several similar archetypes which differ in some dependencies or default project source code. It takes as input a template file which references the base archetype project and specifies what to customize.

Example Usage

```
mvn cn1:generate-archetype -Dtemplate=/path/to/mytemplate.java
```

B.16.1. Parameters

template

Required. The path to a template file that should be used to generate the archetype project.

outputDir

Optional. The output directory where the archetype project should be written to. The project will be created at `outputDir/artifactId`, where the `artifactId` is as specified in the `[archetype]` section of the template. By default this will be the current working directory.

This goal doesn’t require a project to run. You can run it directly using the full goal coordinates:

```
mvn com.codenameone:codenameone-maven-plugin:7.0-SNAPSHOT:generate-archetype \
```

```
-Dtemplate=/path/to/mytemplate.java
```

B.16.2. Template syntax

Here is a sample template file:

Listing 34. A sample template, which is a.Java file:

```
#set( $symbol_pound = '#' )
#set( $symbol_dollar = '$' )
#set( $symbol_escape = '\' )
package ${package};
/*
[archetype] ①
----
extends=../cn1app-archetype ②
groupId=com.codenameone.archetypes
artifactId=helloworld2-archetype
version=7.0-SNAPSHOT
----

[dependencies] ③
----
<dependency>
<groupId>com.codenameone.libs</groupId>
<artifactId>filechooser-lib</artifactId>
<version>1.0-SNAPSHOT</version>
<type>pom</type>
</dependency>
----
 */
import static com.codename1.ui.CN.*;
import com.codename1.ui.*;
import com.codename1.ui.layouts.*;
import com.codename1.io.*;
import com.codename1.ui.plaf.*;
import com.codename1.ui.util.Resources;

/**
 * This file was generated by <a href="https://www.codenameone.com/">Codename One</a> for the purpose
 * of building native mobile applications using Java.
 */
public class ${mainName} {

 private Form current;
 private Resources theme;

 public void init(Object context) {
 // use two network threads instead of one
 updateNetworkThreadCount(2);

 theme = UIManager.initFirstTheme("/theme");

 // Enable Toolbar on all Forms by default
 Toolbar.setGlobalToolbar(true);

 // Pro feature
 Log.bindCrashProtection(true);

 addNetworkErrorListener(err -> {
 // prevent the event from propagating
 err.consume();
 if(err.getError()!= null) {
```

```
 Log.e(err.getError());
 }
 Log.sendLogAsync();
 Dialog.show("Connection Error", "There was a networking error in the connection to " +
err.getConnectionRequest().getUrl(), "OK", null);
 });
 }

 public void start() {
 if(current!= null){
 current.show();
 return;
 }
 //WebSocket sock;
 Form hi = new Form("Hi World", BoxLayout.y());
 hi.add(new Label("Hello World"));

 hi.show();
 }

 public void stop() {
 current = getCurrentForm();
 if(current instanceof Dialog) {
 ((Dialog)current).dispose();
 current = getCurrentForm();
 }
 }

 public void destroy() {
 }

}
```

① The `[archetype]` section specifies details about the archetype project to be generated. For example, the `groupId`, `artifactId`, etc.

② The `extends` property in the `[archetype]` section is required, and points to the location of the archetype project that this template is based on. Path is relative to the location of the template file.

③ The `[dependencies]` section includes content that should be injected into the `<dependencies>` section of the pom.xml file. Note that this isn't the pom file for the archetype project itself. It's the pom.xml file for the project that the archetype project is to generate.

Notice that the above template is velocity template for a Java file. It will be used as the source code for the main class in the resulting project. It's a velocity template because maven's `archetype:generate` goal will process it to replace properties such as package and the main class name.

Template sections

archetype

This is a required section and specifies both the location of the base archetype project from which this project is to be derived, and the coordinates of the output archetype project, such as `groupId`, `archetypeId`, and `version`.

Example

```
[archetype]
----
extends=../cn1app-archetype
groupId=com.codenameone.archetypes
artifactId=helloworld2-archetype
version=7.0-SNAPSHOT
----
```

Properties

extends

Required. The path to the archetype project that this is based on. This should usually be the `cn1app-archetype` project as it includes the placeholders that this generator relies on for injecting content into the pom.xml file and its project structure was used as a basis for developing this mojo.

groupId

The groupID of the resulting archetype project. You can or use the `id` property to specify `groupId`, `artifactId` and `version` in a single string.

artifactId

The artifactId of the resulting archetype project. You can or use the `id` property to specify `groupId`, `artifactId` and `version` in a single string.

version

The version of the resulting archetype project. You can or use the `id` property to specify `groupId`, `artifactId` and `version` in a single string.

id

A colon-separated string in the format `groupId:artifactId:version` that can be used as an alternative to `groupId`, `artifactId`, and `version`.

parentGroupId

If the output archetype project should be part of a multi-module project, then this will specify the parent `groupId` for the `<parent>` tag in the pom.xml file.

parentArtifactId

If the output archetype project should be part of a multi-module project, then this will specify the parent `archetypeId` for the `<parent>` tag in the pom.xml file.

parentVersion

If the output archetype project should be part of a multi-module project, then this will specify the parent `archetypeId` for the `<parent>` tag in the pom.xml file.

parent

A colon-delimited string in the format `parentGroupId:parentArtifactId:parentVersion` that can be used as an alternative to the `parentGroupId`, `parentArtifactId`, and

`parentVersion` properties.

dependencies

Specify more dependencies that should be injected into the `<dependencies>` section of the pom.xml file for the common module of the maven project that the archetype will generate. The content of this section will be injected into the `src/main/resources/archetype-resources/common/pom.xml` of the archetype project.

Example

```
[dependencies]
---
<dependency>
    <groupId>com.codenameone.libs</groupId>
    <artifactId>filechooser-lib</artifactId>
    <version>1.0-SNAPSHOT</version>
    <type>pom</type>
</dependency>
---
```

css

CSS content that should be injected into the theme.css file of the project. This CSS will be injected into the `src/main/resources/archetype-resources/common/src/main/css/theme.css` file of the archetype project.

Example

```
[css]
---
#Constants {
    includeNativeBool: true;
}
Button {
    color:green;
    border:1px solid green;
    border-radius: 2mm;
    margin: 5mm;
}
---
```

properties

Properties that should be appended to the `codenameone_settings.properties` file. These will be added to the `src/main/resources/archetype_resources/common/codenameone_settings.properties`

file of the archetype project.

Example

```
[properties]
---
codename1.arg.win.desktop-vm=zuluFx8-32bit
codename1.arg.win.desktopExtractDll=true
codename1.arg.win.launchOnStart=true
codename1.arg.win.runAfterInstall=true
---
```

files

Files contains a list of files that should be created in the archetype project. All file paths are relative to the "common" project root directory. Each path should have a corresponding section with the heading `[file:path/to/file]`.

Example

```
[files]
----
src/main/guibuilder/__mainName__MainForm.gui
src/main/java/__mainName__MainForm.java
----

[file:src/main/guibuilder/__mainName__MainForm.gui]
----
<?xml version="1.0" encoding="UTF-8"?>

<component type="Form" layout="LayeredLayout" layeredLayoutPreferredWidthMM="0.0"
layeredLayoutPreferredHeightMM="0.0"  autolayout="true" title="${mainName}MainForm" scrollableY="true"
name="${mainName}MainForm">
<component type="Button" text="Click Me" name="Button">
<layoutConstraint insets="auto auto auto auto" referenceComponents="-1 -1 -1 -1" referencePositions="0.0 0.0
0.0 0.0" />
</component>
</component>
----

[file:src/main/java/__mainName__MainForm.java]
----
package ${package};
public class ${mainName}MainForm extends com.codename1.ui.Form {
public ${mainName}MainForm() {
this(com.codename1.ui.util.Resources.getGlobalResources());
}

    public ${mainName}MainForm(com.codename1.ui.util.Resources resourceObjectInstance) {
        initGuiBuilderComponents(resourceObjectInstance);
    }

//-- DON'T EDIT BELOW THIS LINE!!!
    protected com.codename1.ui.Button gui_Button = new com.codename1.ui.Button();
```

```
// <editor-fold defaultstate="collapsed" desc="Generated Code">
    private void initGuiBuilderComponents(com.codename1.ui.util.Resources resourceObjectInstance) {
        setLayout(new com.codename1.ui.layouts.LayeredLayout());
        setInlineStylesTheme(resourceObjectInstance);
        setScrollableY(true);
                setInlineStylesTheme(resourceObjectInstance);
        setTitle("MyForm");
        setName("MyForm");
        gui_Button.setText("Click Me");
                gui_Button.setInlineStylesTheme(resourceObjectInstance);
        gui_Button.setName("Button");
        addComponent(gui_Button);
        ((com.codename1.ui.layouts.LayeredLayout)gui_Button.getParent().getLayout()).setInsets(gui_Button,
"auto auto auto auto").setReferenceComponents(gui_Button, "-1 -1 -1 -1").setReferencePositions(gui_Button, "0.0
0.0 0.0 0.0");
    }// </editor-fold>

//-- DON'T EDIT ABOVE THIS LINE!!!
}
----
```

B.17. Install Codename One (`install-codenameone`)

Installs/Updates Codename One into the user's home directory. This goal is automatically run if a Maven build is attempted and it detects that Codename One isn't yet installed (in the `$HOME/.codenameone`) directory.

B.18. Install legacy Cn1lib (`install-cn1lib`)

Installs a legacy cn1lib file as a dependency in this application project.

See Section 2.2.4, "Adding project dependencies" for fuller coverage of project dependencies.

Using this goal explicitly is a last resort. The best solution for installing add-ons into your project is Section 2.2.4.5, "Managing add-ons in Codename One Settings".

B.18.1. Usage example

```
mvn cn1:install-cn1lib -Dfile=/path/to/MyLegacyLib.cn1lib
```

This will generate a Maven pom project for this lib inside the "cn1libs" directory, and it will add a dependency inside the common/pom.xml file.

The generated project isn't a cn1lib-archetype project, and it isn't meant to change. It's merely a Maven wrapper around the cn1lib file that provides compatibility with Maven's dependency mechanism.

B.18.2. Removing the Cn1lib later

If you need to remove the cn1lib later (that is, revert an installation), you can remove the

<dependency> tag that was added to the common/pom.xml file for the cn1lib.

You can also remove the directory that was created inside the cn1libs folder for this cn1lib - but this step isn't necessary.

B.18.3. Parameters

file

Path to the cn1lib file you want to install.

groupId

The groupId to use for the generated pom project. Optional. If not specified, it will use the same groupId as the root project.

artifactId

The artifactId to use for the generated pom project. Optional. If not provided, it will generate an artifactId derived from the project's artifactId.

version

The version to use for the generated pom project. Optional. If not provided, it will use the project version.

updatePom

A boolean flag indicating whether it should automatically update the pom.xml file with the dependency.

Default is `true`

overwrite

A boolean flag indicating whether it should overwrite an existing project of the same name. Default false.

Default is `false`

B.19. Open Designer (`designer`)

Opens the legacy Codename One designer app to edit the project "theme.res" file.

If your project is using CSS it may not have a theme.res file, thus this goal will fail in this case.

B.19.1. Usage example

```
mvn cn1:designer
```

This will open the Codename One designer.

B.20. Prepare simulator classpath (`prepare-simulator-classpath`)

Sets up some properties and environment variables required for the Codename One simulator to run properly.

This goal is bound to the `initialize` phase of the `Java SE` module of the Section A.1, “Codename One application project archetype (cn1app-archetype)” and shouldn’t be executed directly.

B.21. Open settings (`settings`)

Downloads and opens the standalone Codename One Settings editor bound to the current Maven project. The editor manages basic project properties, build hints, and extensions.

```
mvn cn1:settings
```

See Appendix D, *Codename One Settings*

B.22. Run tests (`test`)

Runs Codename One unit tests.

This goal is bound to the `test` phase of Section A.1, “Codename One application project archetype (cn1app-archetype)” projects, so that running it directly isn’t necessary. If you build a cn1app-archetype project using:

```
mvn install
```

or

```
mvn package
```

Then this goal will be executed automatically.

Prevent tests from running using the `skipTests` flag. For example, `mvn install -DskipTests`

B.23. Update Codename One (`update`)

Updates Codename One. This updates tools that live inside `$HOME/.codenameone`, such as the GUI builder, and tries to update the `cn1.version` and `cn1.plugin.version` properties in the project’s `pom.xml`. The standalone Settings editor is resolved from Maven using `cn1.plugin.version` when you run `mvn cn1:settings`.

B.23.1. Usage example

```
mvn cn1:update
```

Parameters

newVersion

(Optional) The version to update to. This should be a published Codename One version. Will accept a value of "LATEST" to cause it to resolve to the latest version in the Codename One Maven repository. `LATEST` never downgrades a project: if the newest version offered is older than the one the project already uses, the goal reports it and leaves `cn1.version` and `cn1.plugin.version` untouched.

If this parameter is omitted, then it will be implicitly set to `LATEST`, but it won't update the `cn1.version` or `cn1.plugin.version` properties if they're set to a SNAPSHOT version.

See Section 2.3, "Updating Codename One" for more information about updating Codename One.

Appendix C: API

This section isn't a comprehensive treatment of the Codename One API. For a more in-depth discussion of Codename One and it's supported APIs, refer to the Developer Guide [https://www.codenameone.com/developer-guide.html].

Codename One apps support a subset of the Java SE 8 API as well as its own light-weight runtime and UI component library that includes support for everything that would expect in a mobile application platform.

See the JavaDocs [https://www.codenameone.com/javadoc/] for a full list of supported classes, and check out the source in the git repository [https://github.com/codenameone/CodenameOne].

The Codename One source is open source. Released under GPLv2 with Classpath Exception.

Codename One is much more than an API library. It provides a full tool-chain and eco-system for developing beautiful, performant native mobile apps with a single codebase in Java and Kotlin. Please see the introduction in the Developer guide for a proper overview of Codename One.

C.1. Limitations

No reflection

Codename One apps don't support reflection because reflection makes it impossible to keep app-size down.

C.2. Kotlin API support

Codename One apps support the Kotlin Standard Library [https://kotlinlang.org/api/latest/jvm/stdlib/]. Kotlin support is still new, so are still discovering which libraries are compatible. APIs that rely on reflection won't be supported, but most other libraries should work.

C.3. Add-on libraries

Add-on libraries can be added to your library in the common/pom.xml file, but, if you use APIs that aren't supported by Codename One (for example, which use reflection), then your app will fail to build.

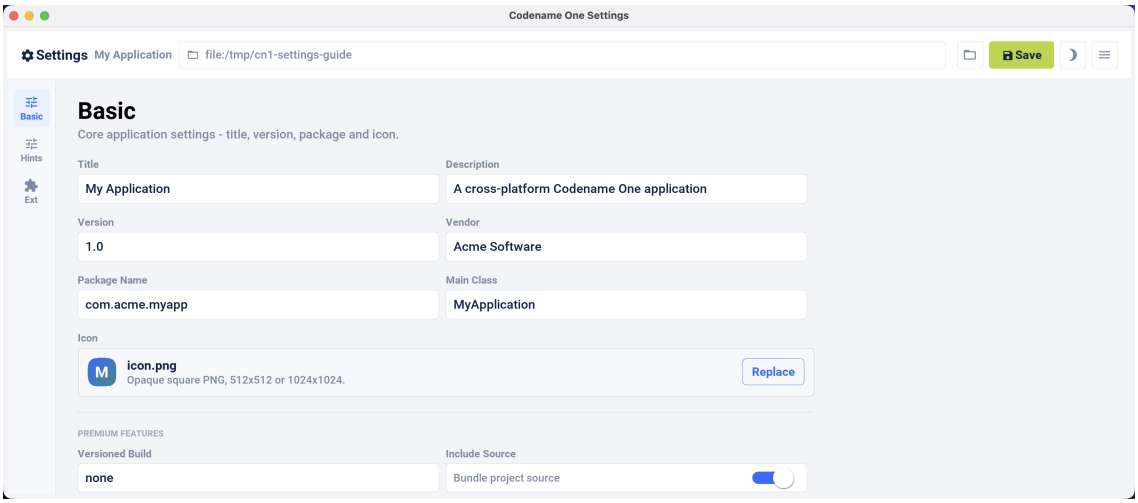
Codename One supports its own library format (cn1lib) which sort of "certifies" that it's compatible with Codename One. Run `mvn cn1:settings` and open **Extensions** to browse the growing catalog of available cn1libs. See Codename One Settings.

For more information about cn1libs, see the cn1libs section of the developer guide.

Appendix D: Codename One Settings

Codename One Settings is a standalone editor for the current Maven project. Use it to edit the application's basic properties, manage build hints, and browse, install, update, or uninstall extensions. Signing assets are managed by the separate Certificate Wizard, and cloud builds are monitored on the Codename One website.

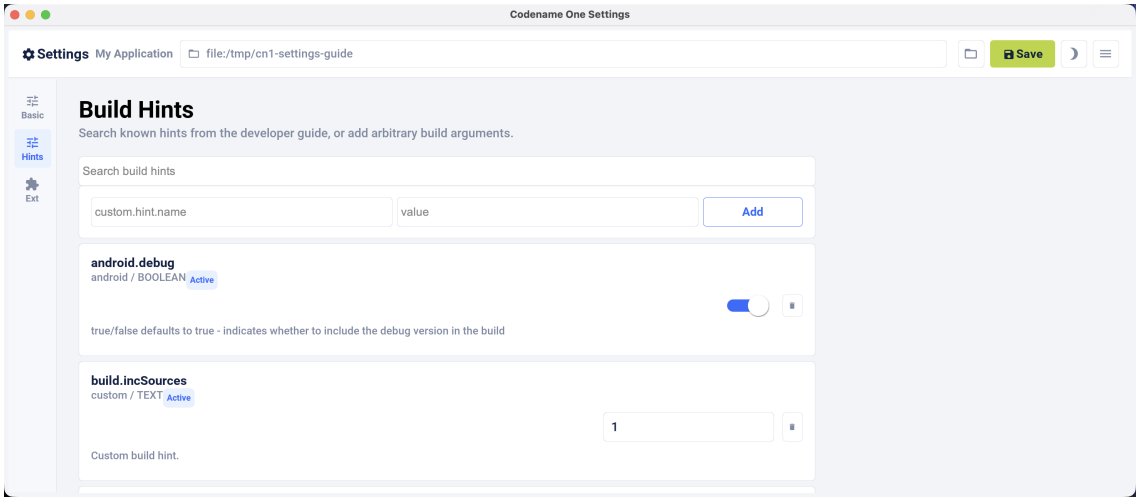
D.1. Opening Codename One Settings



Run the following command from the root directory of a Codename One Maven project:

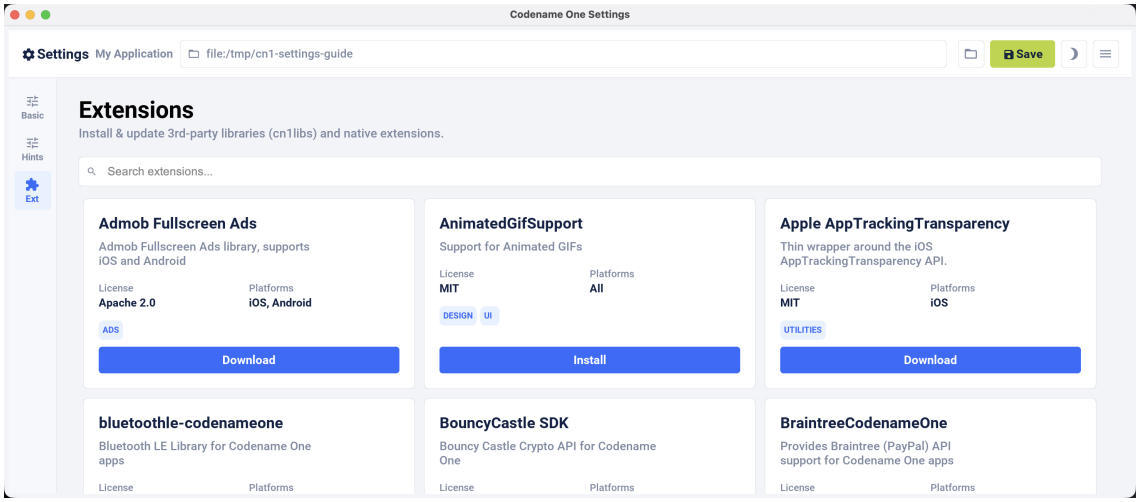
```
mvn cn1:settings
```

Maven downloads the Settings artifact that matches the Codename One Maven plugin version and opens it as a desktop application bound to the current project. The same command works in a terminal or an IDE's Maven runner.



D.2. Basic settings

The **Basic** view edits the application title, description, version, vendor, package name, main class, icon, versioned-build selection, and include-source option. Changes are written to `common/codenameone_settings.properties` when you click **Save**.



D.3. Build hints

The **Build Hints** view searches the build-hint catalog from this guide. It provides a control appropriate to each known hint and also accepts arbitrary key/value hints. The editor adds and removes the `codename1.arg.` prefix when reading and writing `codenameone_settings.properties`.

D.4. Extensions

The **Extensions** view searches the Codename One library catalog. Depending on how an extension is distributed, installation either adds a Maven dependency to `common/pom.xml` or installs a legacy cn1lib. Click the action for an installed extension to uninstall it. Settings displays a compatibility warning before installing a catalog entry known to target an older Codename One release.

Appendix E: Rich properties file (rpf) format

The rich properties file (rpf) format is used to store configuration for the `generate-app-project` goal. The format is the same as a regular properties file except that it can accommodate properties whose values are "rich" and lengthy.

"Rich" properties use the following syntax:

```
[keyname] ①
=== ②
Key value ③
=== ④
```

① The property key appears on a new line wrapped in square brackets.

② A separator consisting of 3 or more equals signs on the next line.

③ The property value, which can be one or more lines of content.

④ The separator with the same number of equals signs on a line of its own.

E.1. Example rich properties file

```
firstName=Bob
lastName=Smith
[bio]
====
Bob is a hard worker.
He attended Harvard and is looking for opportunities in the fast food industry.
====
age=23

# A comment that it is ignored
[xmldata]
========
<person>
    <name>Bob Smith</name>
    <age>23</age>
</person>
========

favoriteColor=Brown
```

Many of the properties of this file are regular properties. Two rich properties exist: `bio` and `xmldata`.

Appendix F: Gaming consoles

Codename One apps and games run on phones, desktops, the browser and TVs. Gaming consoles are a longer-term goal, and this appendix tracks where that work stands. Everything here is **experimental**: build hints, behaviour and packaging can change without notice, and nothing here is supported for production use.

F.1. Why consoles are different

A console doesn't run arbitrary binaries. Each platform holder controls which packages install, which SDK they're built with, and which APIs they may call. A retail console title also needs a publishing agreement with that platform holder, which gives access to its SDK, development hardware and certification process. None of that can be shipped as open source, so a console port has two parts:

- The **portable** part, which belongs in Codename One itself: rendering through the platform's graphics stack, controller input mapped to Codename One's game actions, TV overscan reported as the display safe area, and an app model without a desktop window.
- The **platform** part, which depends on each platform holder's SDK and terms and can't be published.

F.2. Xbox in Developer Mode

The first step is the one console that can be reached without a publishing agreement. Any retail Xbox can switch to Developer Mode and sideload UWP apps, and `windows.xbox=true` builds the native Windows port as such an app. See Section 122.7, "Xbox in Developer Mode" for how to build and install it.

What this target exercises:

- The port running inside the Windows app container on a `CoreWindow`, with Direct2D rendering into a Direct3D swap chain instead of a desktop window.
- Linking against `WindowsApp.lib` alone, which proves at build time that every system call the port makes exists inside the container.
- The controller arriving as key events: the D-pad and left stick map to the four directions, **A** to fire and **B** to back, through `Display.getGameAction()`.
- The visible bounds the console reports, exposed through `Display.getDisplaySafeArea()`.

Continuous integration cross-compiles this target on Linux, then installs and launches the package on a Windows machine and checks that it reaches its first frame. Controller input and TV overscan can only be observed on a console, and haven't been verified on one.

F.3. Beyond Developer Mode

Developer Mode is a sandbox for testing, not a distribution channel: a game sold on Xbox is built with Microsoft's Game Development Kit under a publishing agreement, and PlayStation and

Nintendo consoles likewise require their platform holder's SDK. The portable parts above (the windowless host, controller mapping, safe area, and game code from Unity projects or `com.codename1.gaming`) are what such a port would reuse.

F.4. Steam

The Steam Deck and Steam Machine aren't closed consoles: they run Linux, and Steam accepts the native Linux build. See Chapter 126, *Publishing to Steam*.

Historical reference

Chapter 138. Working with UWP

The Codename One UWP (Universal Windows Platform) target was discontinued in release 7.0.229. This chapter is retained to document historical context for legacy projects and older blog posts. New projects should target the supported Codename One platforms instead.

If you’re maintaining an older codebase or reading archived material that mentions UWP, treat those instructions as historical. The current Maven build templates, initializr output, and IDE shortcuts no longer include a UWP target.
